mould fungi; a maltose splitting enzyme is present in the intestine (Brown and Heron, Proc. Roy. Soc. 1880, 30, 393) and in numerous other animal tissues (Tebb, J. Physiol. 1894, 15, 421). Maltase is more difficult to extract than invertase; active extracts can only be obtained from yeast after the cells have been destroyed, or, better, after a preliminary drying in a thin layer at a low temperature. The enzyme is not liberated on shaking yeast with toluene water. Yeast juice made by Buchner's method of compression contains maltase. Brown and Heron found aqueous extract of pig's intestine to have no action on maltose, but after drying at 35° fine shreds of the intestine were active. Using similar methods Tebb found most maltase in the mucous membrane of the small intestine; it was also present in the spleen, lymphatic gland, liver, kidney, and in the pancreatic and salivary glands, and least of all in muscle. When the tissue is finely minced and sufficient time (several days) is allowed for adequate extraction, active maltase may be obtained from fresh tissues. Malt does not contain maltase.

Maltase is destroyed by precipitation of the aqueous extract with alcohol, so that it has not been possible to purify it.

Maltase also hydrolyses α-methylglucoside and other synthetical α-glucosides, although it is without action on the isomeric β-glucosides. Amygdalin is hydrolysed by an enzyme akin to maltase, present in some yeasts, to dextrose and amygdonitrileglucoside (Fischer, Ber. 1895, 28, 1508). This action is due, however, not to maltase, but to amygdalase (Caldwell and Courtauld, Proc. Roy. Soc. 1907, B, 79, 350). Maltase is able to cause synthetic as well as analytic changes (Croft Hill, Chem. Soc. Trans. 1898, 73, 634; 1903, 83, 578; *see* also Bayliss, The Nature of Enzyme Action, Longmans, 1911).

The optimum temperature of maltase is 35°–40° (*v.* FERMENTATION). E. F. A.

MALTHA. A variety of 'mineral tallow' or wax, sp.gr. 0·77, soluble in alcohol, naphtha, and oil of turpentine, said to be originally found on the coast of Finland. It is white, brittle, and stains paper like oil, melts at a moderate heat, and burns with a smoky flame. A similar hydrocarbon is met with in the oil-fields of California.

MALTODEXTRIN *v.* DEXTRIN.

MALTOSE *v.* CARBOHYDRATES.

MAMMIN *v.* SYNTHETIC DRUGS.

MANACCANITE. A variety of titaniferous magnetic oxide of iron found in grains and small angular fragments at Manaccan near Helstone, and other places in Cornwall, *v.* ILMENITE; TITANIUM.

MANCHESTER YELLOW. *Dinitronaphthol v.* NAPHTHALENE. Dinitronaphthol-yellow has been used to artificially colour natural saffron. To detect the adulteration, an infusion of the matter is prepared, to which some tartaric acid is added. A hank of wool is then dipped in the boiling solution. The wool thus dyed is washed in very dilute sulphuric acid, and the acid afterwards neutralised with ammonia. If saffron contained any dinitronaphthol, the wool or the solution will be coloured yellow, whereas wool dyed with a decoction of genuine saffron and treated in the same manner becomes colourless (Cazeneuve and G. Ginnossier, J. Soc. Chem. Ind. 5, 437).

MANDELIC ACID (*Phenylglycollic acid; α-phenylhydroxyacetic acid*) $C_6H_5\cdot CH(OH)CO_2H$. Discovered by Winkler in 1852 in the emulsion of bitter almonds. It may be obtained by warming ω-dibromoacetophenone with dilute alkali (Engler and Wöhrle, Ber. 1887, 2202); by oxidising ω-hydroxyacetophenone with copper sulphate (Breuer and Zincke, *ibid.* 1880, 635); by boiling phenylchloracetic acid with alkali (Spiegel, *ibid.* 1881, 239); and by warming benzoylformaldehyde with alkali (Pechmann, *ibid.* 1887, 2905; Müller and Pechmann, *ibid.* 1889, 2558). It is best prepared by shaking commercial benzaldehyde with a concentrated solution of sodium disulphite, filtering off and drying the disulphite compound. This is then made into a paste with water, and the calculated quantity of potassium cyanide solution added with stirring. The oily mandelonitrile soon separates, and is hydrolysed by boiling with three times the theoretical quantity of hydrochloric acid (Pape, Chem. Zeit. 1896, 20, 90; Chem. Fab. vor. Hofmann and Schoetensack, Eng. Pat. 14886; J. Soc. Chem. Ind. 1896, 614; *cf.* Müller, Arch. Pharm. [iii.] 2, 385, 389; Ber. 1872, 980; Wallach, Annalen, 193, 38; Luginin, *ibid.*, 139, 299; Winckler, *ibid.* 18, 310).

Forms colourless rhombic prisms; m.p. 118° (Claisen, Ber. 1877, 847); sp.gr. 1·361 at 4°/4° (Schröder, *ibid.* 1889, 1612); readily soluble in alcohol and ether. On heating the acid at 200°, benzaldehyde and an amorphous mass is obtained; benzaldehyde, water and diphenylmaleic anhydride are formed when it is heated in a current of air under reduced pressure (Bischoff and Walden, Annalen, 279, 118; Liebig, *ibid.* 18, 312). Fuming nitric acid yields *o-* and *p*-nitrophenylglycollic acids (Pratesi, Gazz. chim. ital. 21, ii. 402). Electrolysis of an aqueous solution of the potassium salt results in the production of hydrobenzoin and a small quantity of *iso*hydrobenzoin (Walker, Chem. Soc. Trans. 1896, 1279); but according to Miller and Hofer (Ber. 1894, 469) benzaldehyde, carbon dioxide, and carbon monoxide are the products. By passing carbonyl chloride into an ice-cold solution of the acid in pyridine the bimolecular anhydride, m.p. 240°, is formed (Einhorn and Pfeiffer, Ber. 1901, 2951). Hydrogen iodide and phosphorus convert mandelic acid into phenylacetic acid, and fuming hydrochloric acid at 140° yields phenylchloracetic acid. Mandelic acid condenses with phenols in the presence of 73 p.c. sulphuric acid to *o*-hydroxydiarylacetic acid lactones and *p*-dihydroxydiarylacetic acids (Bistrzycki and Flatau, Ber. 1895, 989; 1897, 124); *v.* also Simonis (Ber. 1898, 2821) for condensation with β-naphthol, resorcinol, and orcinol. The nitrile prepared as above, is a yellow oil, solidifying at −10°. The amide has m.p. 190°, the anilide 151°–152°, and the phenylhydrazide 182° (Tiemann and Friedländer, Ber. 1881, 635; Reissert and Kayser, Ber. 1890, 3701; Biedermann, *ibid.* 1891, 4083; Bischoff and Walden, Annalen, 279, 118). The methyl ester has m.p. 52° (Zincke and Brewer, Ber. 1880, 636; Ruhe, *ibid.* 1895, 259), and the ethyl ester has m.p. 34°, b.p. 253°–255° (Michael and Jeanprêtre, Ber. 1892, 1684;

Beyer, J. pr. Chem. [ii.] 31, 389); m.p. 37° (McKenzie, Chem. Soc. Trans. 1899, 755).

Mandelic acid contains an asymmetric carbon atom, and hence can be split into two optically active isomerides. Lewkowitsch (Ber. 1882, 1505; 1883, 1565, 2722) obtained *l*-mandelic acid by treating the inactive acid with *Saccharomyces ellipsoideus* (Rees) and *d*-mandelic acid by using various microzoa, such as *Pencillium glaucum*, &c. Partial resolution of the inactive acid has also been effected by means of the fractional crystallisation of salts with alkaloids, such as quinine and morphine, and with active amines such as methylhydrindamine; and by esterification with active alcohols, such as menthol and borneol (McKenzie, Chem. Soc. Trans. 1899, 968; 1904, 378; McKenzie and Thompson, *ibid.* 1905, 1004; Marckwald and Paul, Ber. 1906, 3654; Kipping, Chem. Soc. Trans. 1909, 416; Findlay and Hickman, *ibid.* 1909, 1386). Racemisation is found to take place on boiling the active acid with alkali (Holleman, Rec. trav. chim. 1898, 17, 323; McKenzie and Müller, Chem. Soc. Trans. 1907, 1814). Asymmetric syntheses have been conducted by McKenzie and Humphries (*ibid.* 1909, 1106) from *l*-menthylbenzoylformate, and by Rosenthaler (Biochem. Zeitsch. 1908, 14, 238) from *d*-benzaldehydecyanhydrin. *d*- and *l*-Mandelic acids can also be prepared by the hydrolysis of amygdalinic acid (Dakin, Chem. Soc. Trans. 1904, 1512; *cf.* Wöhler, Annalen, 66, 238; Tutin, Chem. Soc. Trans. 1909, 663; Feist, Arch. Pharm. 248, 101; Rosenthaler, *ibid.* 105). Incomplete hydrolysis of the ethyl ester by *lipase* yields the *d*-acid, whilst the ester remaining is lævorotatory (Dakin, Chem. Soc. Proc. 1903, 161; J. Physiol. 1903, 30, 253).

l-Mandelic acid has m.p. 132·8°, and $[\alpha]_D$ $-153{\cdot}1°$ in water (Walden, Zeitsch. physikal. Chem. 1895, 17, 705; *cf.* Lewkowitsch, *l.c.*; Rimbach, Zeitsch. physikal. Chem. 1899, 28, 251; Ber. 1899, 2385). *d*-Mandelic acid has m.p. 132·8°, and $[\alpha]_D+156°$ (Kipping, Chem. Soc. Trans. 1909, 416). For experiments on the *Walden Inversion* with mandelic and phenylchloracetic acids, *v.* McKenzie and Clough, Chem. Soc. Trans. 1909, 777.

MANDRAGORA ROOT. In 1889 Ahrens (Annalen, 251, 312) extracted from *Mandragora* root an alkaloid possessing similar physiological properties to atropine, and which he named *mandragorin.* Thoms and Wentzel (Ber. 1898, 31, 2031) showed that the *mandragorin* of Ahrens was a mixture of bases, the chief of which was *hyoscyamine,* and subsequently isolated another base, which they named *scopolamine* (Ber. 1901, 31, 2031). Hesse (J. pr. Chem. 1901, 64, 274) further investigated the subject and found that *madragora* root contains 0·36 p.c. *hyoscyamine,* 0·04 p.c. *hyoscine* (*scopolamine* of Thoms and Wentzel), 0·01 p.c. *ψ-hyoscyamine,* and a still smaller quantity of a new base *mandragorine.* To obtain these alkaloids, the roots are powdered, moistened with a solution of caustic soda, and extracted with ether under a reflux apparatus. The ethereal solution is repeatedly extracted with dilute sulphuric acid, the acid solution being made alkaline with sodium bicarbonate and extracted with chloroform. This operation is then repeated, whereby the hyoscyamine remains in the aqueous solution. The bases from the chloroform extract are neutralised with hydrobromic acid, and the filtered solution allowed to crystallise. The hydrobromides of the bases are then extracted with acetone, which leaves the pure hydrobromide (m.p. 194°) of hyoscine, $C_{17}H_{21}NO_4$. The free base is decomposed by baryta into tropic acid and oscine, $C_8H_{13}NO_2$. The mother liquors of the hyoscinehydrobromide yield *ψ*-hyoscyamine on addition of sodium bicarbonate and extraction with chloroform. On adding sodium carbonate to the residual solution, a new alkaloid *mandragorine,* forming a gold double salt $C_{15}H_{19}NO_2HAuCl_4$ is obtained. The free base is decomposed by baryta into atropic acid, and a base resembling tropine.

MANGANATES *v.* Manganese.

MANGANESE. Sym. Mn. At.wt. 54·93. (Fr. *Manganèse*; Ger. *Mangan.*) Manganese is not found in the metallic state. In combination, especially as oxide, it is widely distributed. The most important ores are those corresponding with the dioxide MnO_2, *pyrolusite.* It is also found as the oxides *braunite* Mn_2O_3, *hausmannite* Mn_3O_4, as hydrated oxide Mn_2O_3,H_2O in *manganite,* and associated with barium oxide in *psilomelane.* As sulphide it occurs as *alabandite* MnS and *hauerite* MnS_2; as carbonate in *rhodocrosite* or *dialogite* $MnCO_3$; as silicate in *rhodonite* $MnSiO_3$. The latter is of a beautiful red colour, found largely in the Ural Mountains, and used as an ornamental stone. It is often present to a small extent in other silicates, and confers on them its colour. The chief sources of the manganese ores are Russia, the Caucasus, Brazil, and India. Manganese is present in soils, and frequently in mineral, particularly chalybeate, waters. It occurs in many plants, especially in tea and tobacco.

Preparation.—Metallic manganese is not used in the arts except when alloyed with other metals. It may be prepared by reduction of the oxide with carbon, but the temperature necessary for the reduction is so high (1105°C., Greenwood, Chem. Soc. Trans. 1908, 1491) that it is only obtained with difficulty in ordinary furnaces. The original method of preparation described by John (Gehlen's Jour. für. Chem. Phys. 3, 452) consisted in making an intimate mixture of finely divided manganous oxide and carbon by mixing with oil and heating, and exposing it to as high a temperature as possible in a crucible lined with charcoal. The impure manganese so obtained was purified by fusing under salt and nitre.

Brunner (Annalen, 102, 330) prepared the metal by heating a mixture of sodium and manganese chloride or fluoride in a blast furnace for 15 minutes. It may also be obtained by the reduction of the chloride by magnesium.

Deville obtained the metal by the reduction of the pure red oxide Mn_3O_4 by means of sugar charcoal present in insufficient quantity to reduce the whole (Ann. Chim. Phys. 1856, 46, 182).

Valenciennes (Compt. rend. 70, 907) produced it by reduction of the pure oxide with carbon in a magnesia-lined crucible as a hard and brittle mass, quickly oxidised by exposure to air.

Dr. MARTHA A. WHITELEY, A.R.C.S., *Demonstrator in Chemistry, Imperial College of Science and Technology, South Kensington.* [GUANIDINE; GUANINE; HETEROXANTHINE; HISTIDINE; HYDANTOIN; HYDURILIC ACID; HYPOXANTHINE OR SARCINE; LEUCINE; LYSINE; MALONIC ACID; MUREXIDE; MUREXOIN.]

Geheimrat Professor Dr. OTTO N. WITT, *Polytechnic, Charlottenburg, Berlin.* [INDAMINES AND INDOPHENOLS; INDIGO, ARTIFICIAL, AND INDIGOID DYESTUFFS.]

Dr. W. P. WYNNE, F.R.S., F.I.C., A.R.C.S., *Firth Professor of Chemistry, University of Sheffield.* [NAPHTHALENE.]

A
DICTIONARY
OF
APPLIED CHEMISTRY.

GRAIN LAC *v. Lac resins,* art. Resins.

GRAIN OIL *v.* Fusel oil.

GRAIN TIN *v.* Tin.

GRAINS OF PARADISE *v.* Cocculus indicus.

GRANITE. A holocrystalline acid rock of plutonic origin; *i.e.* it is a rock consisting wholly of crystalline minerals, and containing from about 60 to 80 p.c. of silica, partly free and partly combined, whilst its texture suggests that it has slowly consolidated from a molten condition, under great pressure, at considerable depth beneath the surface. Granite is essentially an aggregate of felspar, quartz, and mica. The usual felspathic constituent is orthoclase, or common potash-felspar, generally associated with more or less plagioclase; and the mica is either muscovite (white mica) or biotite (dark mica), whilst in many granites both micas are present. Biotite-granite is now frequently known by G. Rose's name of *granitite.* Granitic rocks may contain various accessory minerals, such as hornblende, augite, and tourmaline, thus giving rise to varieties often distinguished by special names; whilst, on the other hand, it sometimes happens that one of the minerals of typical granite may disappear, thus producing a binary granite. *Aplite* is a name occasionally applied to a rock consisting only of felspar and quartz; but sometimes extended to all muscovite-granites. If the quartz and felspar are so intergrown as to suggest they have crystallised simultaneously, the rock is termed *graphic granite* or *pegmatite.* Under the name of *greisen,* German miners recognise a rock composed of quartz and mica, usually carrying topaz, and associated with tin-stone. An aggregate of orthoclase and black mica is known as *mica-syenite*; the typical *syenite,* sometimes distinguished as *hornblende-syenite,* being composed essentially of orthoclase and hornblende. Hornblende-granites are often called, by English writers, 'syenitic.' Schorl, or black tourmaline, is not unfrequently present in granite, especially near the margin of intruded masses. Garnet is an occasional constituent, but not so commonly in true granite as in *granulite,* a rock consisting mainly of quartz and felspar in small grains, so that microscopic sections present between crossed nicols a characteristic mosaic structure. When a granitic rock becomes foliated, or its constituent minerals exhibit more or less elongation in definite directions, it is said to acquire a 'gneissoid' structure, and may pass into a true *gneiss.*

Granite occurs frequently in the form of intrusive masses, which, while coarsely crystalline in the centre, may present a fine texture towards their margin. From the main mass, veins or apophyses are thrown off into the neighbouring rocks; and these veins, having cooled less slowly, are often fine-grained, and may pass into micro-granites and quartz-porphyries. It has been asserted that certain granites may have resulted from the extreme alteration of stratified rocks; and hence geologists who hold this view recognise two types of granite, one igneous, and the other metamorphic.

It is not uncommon to find in granite nodular masses which appear as dark patches on the fractured or polished surface of the rock. Whilst some of these inclusions seem to be fragments of foreign rock which have been caught up in the granitic magma and altered, others may be regarded as parts of the original magma differentiated during consolidation; and it is notable that the inclusions are usually more basic than the matrix. (For comparative analyses of the granite and its inclusions, *v.* J. A. Phillips in Quart. Journ. Geol. Soc. 1880, 36, 1.)

Granite is extensively employed for constructive purposes where massive work is required, as in the foundations of buildings, in docks, sea walls, the piers of bridges, and lighthouses. The specific gravity of granite is about 2·6; a cubic foot weighing about 166 lbs., and a cubic yard 2 tons.

Granite rocks are always divided by joints, which usually run in three directions, thus splitting the rock into masses of roughly cuboidal form. The stone is blasted in the quarry, and the blocks split up by 'plug and feather' wedges. When the surface is required to be dressed smooth, it is 'fine-axed' by continued tapping, at right angles to the face, with a special form of axe. Solid cylinders are turned on a lathe, and columns measuring as much as 8 feet in diameter may be thus wrought. The polishing of granite is effected by means of cast-iron planes worked over the smooth surface, first with sand and water, and then with emery, the final polish being given with putty powder applied on thick felt. In this way even elaborate mouldings may be readily polished. (For granite working, *v.* G. W. Muir, Journ. Soc. Arts. 1866, 14, 471; and G. F. Harris, Granite and our Granite Industries, London, 1888.)

Granite rocks are extensively developed and quarried in Cornwall and Devon, where they occur as a series of bosses protruding through the killas or clay-slate. The largest of these intrusions are, proceeding westwards, those of Dartmoor, Brown Willy or St. Breward district, Hensbarrow or St. Austell, Carn Menelez or Penryn, and the Land's End or Penzance district. In addition to these principal exposures there are numerous smaller masses. The granite of Devon and Cornwall is usually grey and coarse-grained, but red granite also occurs, as at Trowlesworthy in the western part of Dartmoor. A local variety, termed by R. N. Worth *Trowlesworthite*, and described by Prof. Bonney, is composed of red felspar, with a tourmaline, purple fluorspar, and a little quartz. A handsome red granitic rock occurring near Luxullian, in Cornwall, and hence called by Bonney *Luxullianite*, consists of red orthoclase, in large crystals, with schorl, or black tourmaline, and quartz. This is the rock of which the Duke of Wellington's sarcophagus, in St. Paul's, is formed.

The nearest exposure of granite to London is at Mount Sorrel, in Leicestershire, where pink and grey biotite-granite, rather hornblendic, is worked for kerb-stones, paving setts, and road metal. The hornblende granites of the Channel Islands are quarried for similar purposes. Shap Fell, in Westmoreland, yields a beautiful biotite-granite, with large crystals of salmon-coloured orthoclase, which is now largely used as an ornamental material, and has been employed, for example, in the posts around St. Paul's. The granites of Scotland are of much industrial importance. Aberdeen granite was brought to London for paving in the 18th century, but the great development of the trade dates from about 1850. The Aberdeen stone, which is of grey or blue tint, is valued for monumental work; the Peterhead granite is usually of a fine pink colour. The Ross of Mull, in Argyllshire, furnishes a handsome red granite, yielding blocks of exceptional size. Granite is also worked in Kirkcudbrightshire, where it occurs in bosses surrounded by slates; the grey granite of Dalbeattie being well known in commerce.

In Ireland, granite is very extensively developed, the chief districts being in counties Wicklow, Galway, Mayo, Donegal, and Down. The largest quarries are those near Dalkey, which yielded the stone for Kingstown Harbour. The quarry near Castlewellan, Co. Down, which was opened to supply granite for the Albert Memorial, in Hyde Park, has since been closed. Granite is also found in the Isle of Man, Arran, Anglesea, Lundy I., and the Scilly Isles.

It is needless to specify the numerous European localities in which granite is worked. Of late years a green 'granite' (gabbro) from Warburg, in Sweden, has been imported as a monumental stone. In the United States, workings are established in a large number of localities, the granite-producing States being, in order of relative importance, Massachusetts, Maine, Rhode Island, Connecticut, Virginia, and New Hampshire.

For a large collection of analyses of granites, *v.* J. Roth's Beiträge z. Petrographie d. plutonische Gesteine (Berlin, 1873–84); H. S. Washington, U. S. Geol. Survey, Prof. Paper, No. 14, 1903; No. 28, 1904. F. W. R.

GRANITE BLACK *v.* AZO- COLOURING MATTERS.

GRAPE. The berry of *Vitis vinifera* (Linn.). There are many varieties differing in size, shape, colour and composition.

König gives as the average percentage composition—

Water	Nitrogenous substances	Free acid	Invert sugar	Other carbohydrates	Fibre	Ash
79·1	0·7	0·7	15·0	1·9	2·1	0·5

The sugar (glucose) in particular is liable to considerable variation, ranging from 9 to 18 or 19 p.c.

This variation, as well as that in the acidity—due to tartaric acid or acid potassium tartrate—is influenced not only by the variety, but also by the climate and soil; a wet winter and a hot, dry summer being generally favourable to the production of sweet grapes, suitable for wine making, whilst much rain during the ripening period dilutes the juice and leads to the bursting and consequent injury of the berries.

The proportion of skin and seeds shows considerable variation in different varieties, averaging about 2·2 p.c. of the whole fruit, and of this the seeds usually constitute about one-fourth. The skin contains tannin, and, according to Malvezin (Compt. rend. 1908, 147, 384), a yellow colouring matter, which, on oxidation either by exposure to air in aqueous solution, or by the action of an enzyme, present in red, but absent in white grapes, changes to a red substance.

Sostegni (Gazz. chim. ital. 1902, 32, ii. 17) states that the red colouring matter is a tannin derived from protocatechuic acid and has the formula $C_6H_3(OH)_2CO{\cdot}C_6H_3(OH)O{\cdot}C_6H_3(OH)_2$.

The skin and seeds of grapes, in a moist condition, were analysed by Balland (Rev. intern. falsif, 1900, 13, 92), who found them to have the following percentage composition:—

	Water	Nitrogenous substances	Fat	Soluble carbohydrates	Crude fibre	Ash
Skin .	76·5	1·5	0·9	18·4	2·1	0·6
Seeds .	38·7	5·5	8·6	18·9	27·6	0·7

Wittmann found about 0·4 p.c. pentosans in grapes.

The ash, according to König, contains—

	Per cent. of ash in dry substance	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
Whole fruit	3·95	53·0	3·7	6·9	3-3	1·2	21·3	5·0	3·6	1·8
Skin .	4·03	44·2	1·9	21·0	5·7	1·5	17·6	3·7	3·0	0·6
Seeds .	2·81	28·7	—	33·9	8·6	0·6	24·0	2·5	1·1	0 3

About 0·2 p.c. of manganese oxide is also usually present.

Boric acid has been found in grapes (Crampton, Amer. Chem. J. 11, 227; Baumert, Ber. 21, 3290). Salicylic acid also occurs especially in the stalks (Mastbaum, Chem. Zeit. 1903, 27, 829).

Dried grapes constitute raisins and currants and are extensively used. Their average composition, as given by König, is respectively—

	Raisins	Currants
Water	24·5	25·4
Nitrogenous substances .	2·4	1·2
Fat	0·6	—
Free acid . . .	1·2	1·5
Invert sugar . . .	59·3	61·8
Cane sugar . . .	2·0	—
Other carbohydrates .	1·3	5·9
Crude fibre and seeds .	7·0	2·4
Ash	1·7	1·8

American analyses give considerably less water and more ash than these figures.

H. I.

GRAPE SEED OIL is obtained from grape seeds (*Vitis vinifera* [Linn.]) by expression or by extraction. The oil is only of local importance, and is expressed only for local consumption. Thus, in Italy and in the south of France (and even in south Germany) it is said to be used as an edible oil. The cold expressed oil has a golden-yellow colour, and is free from odour. If the seeds have been stored for some time the expressed oil is dark, and acquires a slightly bitter flavour. The chemistry of this oil is not fully known, as the *data* obtained by the several observers who examined grape seed oil are very conflicting. At first this oil was credited with a very high acetyl value, and was compared in this respect with castor oil, so that its use for the manufacture of Turkey red oil had been proposed. More recent examinations have shown that grape-seed oil has a very high iodine value, so that accordingly the oil would seem to belong to the semi-drying or drying oils. A fresh examination of this oil is desirable in order to remove the doubts existing as to its composition. J. L.

GRAPHIC TELLURIUM *v.* TELLURIUM.

GRAPHITE, a crystallised form of carbon, known also as *plumbago,* and popularly as *black lead.* It occurs usually in compact and crystalline masses, but occasionally in six-sided tabular crystals which cleave into flexible laminæ parallel to the basal plane. The crystals were referred to the hexagonal system until A. E. von Nordenskiöld, in 1855, after studying the crystals from Pargas, in Finland, declared them to be monoclinic. Kenngott, however, afterwards showed that they were truly rhombohedral (Pogg. Ann. 96, 110).

Graphite is a mineral of iron-black or steel-grey colour, with metallic lustre, having a sp.gr. of 2·2. In consequence of its softness (H.=1) and the ease with which it produces a metallic streak when rubbed on paper, it is largely used in the manufacture of pencils, whence the name 'graphite' given to it by Werner, from γράφω (I write). It was formerly called *molybdæna,* and confused with molybdenite (MoS_2), a mineral which also gives a metallic mark on paper. (On the history of these names, and of plumbago, *v.* J. W. Evans, Trans. Philological Soc. 1908, 133.) Graphite seems to have been first recognised as a distinct mineral by Gesner, who figured a lead pencil in 1565 (Roscoe). Scheele in 1779 showed that graphite was a kind of mineral carbon, since it could be converted into carbon dioxide by the action of nitric acid. As the carbon is usually associated with more or less iron, the older mineralogists described the mineral as a 'carburet of iron,' but Vanuxem demonstrated that the iron is present as ferric oxide and not as a carbide. The ash left on the combustion of graphite usually contains, in addition to the ferric oxide, silica, alumina, and lime.

Exposed on platinum foil to the flame of the blowpipe, graphite burns, but often with more difficulty than diamond. When heated with a mixture of potassium dichromate and sulphuric acid, it disappears. In order to obtain perfectly pure graphite, the mineral is first ground and washed to remove earthy matter, and then treated, according to Brodie's method, with potassium chlorate and sulphuric acid; on subjecting the resulting product to a red heat, pure carbon is obtained in a remarkably fine state of division.

The following analyses are selected from a large number by C. Mène (Compt. rend. 64, 1091):—

—	I	II	III	IV
Carbon . .	91·55	81·08	79·40	78·48
Volatile matters	1·10	7·30	5·10	1·82
Ash . .	7·35	11·62	15·50	19·70
	100·00	100·00	100·00	100·00

I. Very fine Cumberland graphite, sp.gr. 2·345. II. Graphite from Passau, Bavaria, sp.gr. 2·303. III. Crystallised graphite, from Ceylon, sp.gr. 2·350. IV. Graphite, from Buckingham, Canada, sp.gr. 2·286.

Graphite when used for pencils is frequently mixed, in a powdered state, with pure clay, and the mixture consolidated by hydraulic pressure. It is also sometimes mixed with sulphur or with antimony sulphide. Brockedon first suggested the use of the hydraulic press as a means of obtaining from powdered graphite a homogeneous and coherent mass, which could be readily sawn into pieces of convenient size. The finest pencil lead was yielded by the ancient mine at Borrowdale in Cumberland, where it occurred in pipes, strings, and irregular masses, or 'sops,' associated with a dyke of diorite and with intrusive masses of diabase, in the Cambro-Silurian volcanic series known as 'the green slates and porphyries.' The Cumberland graphite was formerly termed 'wad,' a name sometimes applied also to native oxide of manganese. (For description of the old Borrowdale workings *v.* J. C. Ward in Geol. Survey Mem. on Lake District, 1876.) A small amount of graphite, about 100 tons per annum, is obtained from the Craigman mine, near Cumnock in Ayrshire; here the mineral usually exhibits a columnar structure, and it has been produced by the baking action of dykes of igneous rock on seams of coal.

Excellent graphite is found in Siberia, especially at the Mariinoskoi mine, in the Tunkinsk Mountains, Government of Irkutsk. This deposit, discovered in 1838, occurs in gneiss, associated with diorite; it has been largely worked by M. Alibert to supply Faber's pencil factory. In 1860 graphite was discovered in granite near the river Nischne Tungusska, and workings were undertaken by M. Siderov. (For Russian graphite *v.* N. Koksharov, Materialien z. Mineralogie Russlands, 1862, 4, 153, where analyses are given.)

The best quality of graphite found in large quantities is that from Ceylon. The mineral is widely distributed through the western and north-western provinces of the island, and is obtained from a large number of small pits, there being but few mines of any size. The output amounts to about 30,000 tons per annum, with a value of rather over half a million pounds sterling. (On the graphite deposits of Ceylon *v.* A. K. Coomaraswamy, Mineralogical Survey of Ceylon, 1903, etc.; Quart. J. Geol. Soc. 1900, 56, 590.) In India, graphite is found at several localities, chiefly in the Madras Presidency, the best coming from Travancore, but even this is far inferior to that from Ceylon.

In the United States, graphite is widely diffused, but rarely in sufficient quantity to be worked. The principal locality is Ticonderoga, in Essex Co., New York, where the Dixon Crucible Co. have worked a schist containing about 10 p.c. of graphite. It has also been worked to a limited extent near Raleigh, North Carolina; at Stourbridge, Mass.; at Cumberland Hill in Rhode I.; and at Sonora in California. The graphite 'ores' are crushed or stamped, and then washed, whereby the flakes of graphite are readily separated from the denser matrix. In the Laurentian gneiss of Canada, graphite is of frequent occurrence, and has occasionally been worked, as at the Buckingham Mines. The mineral is usually found in veins and nodular masses, or finely disseminated through bands of limestone.

In Europe, extensive deposits of graphitic schists occur in the Eastern Alps and in the mountainous region between Bohemia and Bavaria (Böhmerwald). These are extensively mined in Austria (in Moravia, Styria, and particularly in the east of Bohemia), where the annual output reaches 50,000 tons; but the material is of inferior quality, containing often 50 p.c. of ash. Considerable amounts are also obtained in the north of Italy, but the well-known locality at Passau in Bavaria is now little worked. (On Alpine Occurrences of Graphite *v.* E. Weinschenk, Abh. bayer. Akad. Wiss. 1898, 19, 509, 521; 1901, 21, 279.)

Daubrée has obtained graphite artificially by decomposing carbon disulphide in contact with metallic iron at a high temperature; while H. Sainte-Claire Deville prepared it by passing vapour of carbon tetrachloride over fused cast iron. Crystalline graphite is often formed in blast furnace slag during iron smelting, and is known to workmen as *kish*; and it is present in grey pig iron. Considerable quantities of graphite are now produced commercially, together with carborundum, in the electric furnace. The artificial production of graphite (as well as various properties of the natural mineral) is dealt with by H. Moissan (The Electric Furnace, London, 1904). Graphite also occurs in certain meteoric irons, such as that of Toluca in Mexico. A cubic form of graphitic carbon, discovered in a meteoric iron from Youndegin, Western Australia, has been described by Fletcher under the name of *Cliftonite* (Min. Mag. 1887, 7, 121).

In consequence of its refractory character, graphite is largely used in the manufacture of crucibles, retorts, twyers, and other objects required to withstand high temperatures. For crucibles, the powdered mineral is mixed with Stourbridge fire-clay, and made into a paste with water; the kneaded mass is allowed to lie for many weeks before the crucible is moulded; the vessel when moulded is slowly dried, and carefully fired in a seggar.

As a lubricating agent graphite is highly valued, since it diminishes friction and tends to keep the moving surfaces cool. To obtain the best results the powdered mineral should be carefully selected and sized. For steam cylinders it is used dry; for heavy bearings it is mixed with grease; and for light bearings with oil. Made into a paint with linseed oil, it has been advantageously employed as a coating for metal work. Graphite is also used dry for polishing stoves and other objects of cast iron, the thin flakes forming a lustrous coating which protects the metal. Blasting powder and heavy ordnance powders are likewise glazed with graphite, for though it slightly diminishes the explosive force of the powder it protects it from damp. Being a good conductor of electricity, graphite is used in electrotyping, as originally suggested by Murray; the moulds upon which the metal is to be deposited receiving a conducting surface by being coated with finely divided graphite.

Cirkel, Graphite, its Properties, Occurrence, Refining, and Uses, Dept. of Mines, Ottawa, 1907; A. Haenig, Der Graphit, eine technische Monographie, Wien and Leipzig, 1910.

L. J. S.

GRASSES. The term 'grass' is used by the agriculturist to denote, not only plants which belong to the *gramineæ*, but also other pasture or meadow plants, or even certain weeds common on cultivated land.

The true grasses are characterised by a somewhat low content of nitrogenous substances and by the richness of the ash in silica and its poverty in lime and magnesia, whilst clovers and other leguminous crops possess the exactly opposite features.

H. I.

GREASES. The term 'grease' was applied originally to all kinds of fats having a buttery consistence. At present, however, the term 'grease' is restricted to low-class material, chiefly obtained from waste products, such as kitchen grease, ship's grease, tripe tallow, slaughter-house grease ('tankage' grease), bone grease, skin grease, greases from carcase-rendering establishments, and garbage fats. All these greases must be looked upon as varieties and (or) mixtures of lard, tallow, bone fat, horse fat, fish stearines, &c.

Greases are characterised by a dark colour, by a high percentage of free fatty acids, and a correspondingly high proportion of unsaponifiable matter. They are also characterised by an objectionable odour.

Black grease is the dark, almost black, fatty matter which is recovered from cotton seed mucilage, on decomposing the latter with mineral acids (*see* Cotton Seed Oil). This black grease is used in the manufacture of low-class candle materials, after a purification by distillation with superheated steam, and further treating the distillate in the same manner as the fatty acids of the candle industry are worked up (*see* Saponification). J. L.

GREEN EBONY. Green ebony is a yellow dyewood formerly employed to some extent in this country, but now almost entirely replaced by other colouring matters. It is a native of Jamaica or West India, and is obtained from the *Excœcaria glandulosa* (Siv.) or *Jacaranda ovalifolia* (R. Br.). The trunk of the tree is about 6 inches in diameter; the wood is very hard, and of an orange-brown colour when freshly cut and stains the hands yellow. References to this dyestuff are meagre, and it does not appear to have been ever largely employed. Bancroft (Philosophy of Permanent Colours, 1813, ii. 106) states that green ebony contains a species of colouring matter very similar to that of *Chlorophora tinctoria* (Gaudich) (old fustic), and is sometimes employed in its stead; and O. Neill (Dictionary of Calico Printing and Dyeing, 1862) mentions that it is used in dyeing greens and other compound shades. Until recently it had a limited sale in Yorkshire as a dye for leather, but appears to have entirely passed out of use as a woollen dyestuff. It is little used in silk dyeing, but was formerly employed for greening blacks.

Green ebony contains two crystalline colouring matters, which are distinguished by the fact that whereas one, excœcarin, is not precipitated by lead acetate solution, the second, jacarandin, is completely deposited by this reagent (Perkin and Briggs, Chem. Soc. Trans. 1902, 81, 210).

Excœcarin $C_{13}H_{12}O_5$ crystallises in lemon-yellow needles, sparingly soluble in cold alcohol, and melting with effervescence at 219°–221°. It is soluble in aqueous and alcoholic alkaline solutions with a violet-red colouration, and these liquids, on exposure to air, are rapidly oxidised, and assume a brown tint.

Excœcarin does not dye mordanted fabrics, but is a substantive dyestuff in that it has a weak but decided affinity for the animal fibres with which it gives, preferably in the presence of tartaric or oxalic acid, yellow shades. *Benzoyl excœcarin* $C_{13}H_9O_5(C_7H_5O)_3$, colourless needles, m.p. 168°–171°; and *excœcarindimethyl ether* $C_{13}H_{10}O_5(CH_3)_2$ yellow needles, m.p. 117°–119°. On fusion with alkali excœcarin gives *hydroquinonecarboxylic acid* ($CO_2H : OH : OH = 1 : 2 : 5$) and a substance melting at 124°, which is probably *hydrotoluquinone*

$$(CH_3 : OH : OH = 1 : 2 : 5).$$

By the action of bromine upon a solution of excœcarin in alcoholic potassium acetate *excœcarone* $C_{13}H_{10}O_5$, flat copper coloured needles or leaflets, melting at about 250°, is produced, and this by the action of sulphurous acid is readily converted into excœcarin. With alcoholic quinone solution excœcarin gives the compound $C_6H_4O_2 \cdot C_{13}H_{12}O_5$, minute green-coloured leaflets, melting with decomposition at 190°, and from this sulphurous acid also regenerates excœcarin. From these results it appears evident that excœcarin contains free hydroquinone hydroxyls.

Jacarandin $C_{14}H_{12}O_5$, yellow plates or leaflets, m.p. 243°–245°, dissolves sparingly in alcohol and the usual solvents to form pale yellow liquids having a green fluorescence. With caustic alkali solutions it gives orange-red liquids; with alcoholic lead acetate a bright orange coloured precipitate; and with alcoholic ferric chloride a dark greenish-black solution. It dyes mordanted woollen fabrics the following shades :—

Chromium	*Aluminium*	*Tin*	*Iron*
Dull yellow-brown	Orange-brown	Bright golden yellow	Deep olive

Acetyl jacarandin $C_{14}H_{10}O_5(C_2H_3O)_2$, pale-yellow needles, melts at 192°–194°, and when digested with boiling alcoholic potassium acetate gives the salt $(C_{14}H_{12}O_5 \cdot C_{14}H_{11}O_5)K$, yellow needles. *Benzoyljacarandin* $C_{14}H_{10}O_5(C_7H_5O)_2$ forms yellow prismatic needles, m.p. 167°–169°.

As indicated by Bancroft (*l.c.*) the colours given by green ebony are similar in character to those yielded by old fustic. Employing mordanted woollen cloth the following shades are produced :—

Chromium	*Aluminium*	*Tin*	*Copper*	*Iron*
Dull yellow-brown	Dull brown-yellow	Golden yellow	Pale brown	Olive green

With 40 p.c. of the dyewood the iron mordant gives greener and brighter shades than with larger amounts, in which case a browner colour is produced. Possibly from this green shade, and the extremely hard and compact nature of the wood, the name 'green ebony' has originated. A. G. P.

GREEN ALIZARIN *v.* Madder.

GREEN CINNABAR. A mixture of chrome yellow and Prussian blue.

GREEN EARTH, *Terre verte, v.* Pigments.

GREEN, EMERALD, *v.* Chromium.

GREEN, GUIGNET'S, *v.* Chromium.

GREEN SMALT, *Cobalt green, v.* Pigments.

GREEN ULTRAMARINE, *Chromium sesquioxide, v.* Chromium.

GREEN VITRIOL, *Ferrous sulphate, v.* Iron.

GREENLAND SPAR *v.* Cryolite.

GREENOCKITE, *Cadmium sulphide, v.* Cadmium.

GRENAT BROWN *v. iso*-Purpuric acid.

GREY ANTIMONY ORE, *Antimony sulphide, v.* Antimony.

GRI-SHI-BU-ICHI. Japanese name for an alloy of copper and silver of a rich grey colour.

GRISOUTINE. An explosive consisting of a mixture of nitroglycerin, nitrocellulose, ammonium nitrate, and kieselguhr.

GROSSULARITE *v.* Garnet.

GUACAMPHOL, GUAIACETIN, GUAIAFORM, GUAIAKINOL, GUAIAMAR, GUAIASANOL, GUATANNIN *v.* Synthetic drugs.

GUAIACENE *v. Guaiacum,* art. Resins.

GUAIACIC ACID *v. Guaiacum,* art. Resins.

GUAIACOL (*Monomethoxycatechol*)

$$OH \cdot C_6H_4 \cdot OMe$$

is a constituent of guaiacum resin (Herzig and Schiff, Monatsh. 1898, 19, 95), and occurs in beechwood tar from which it can be separated by treating the fraction of the tar that comes over at 200°–205° with ammonia to remove acids; it is then again fractionated, and the lower boiling fraction is dissolved in ether and treated with potassium hydroxide. The potassium salt of guaiacol is filtered, washed with ether, and recrystallised from alcohol, after which it is decomposed with sulphuric acid, and the guaiacol redistilled. (For other methods of separation, *cf.* D. R. PP. 87971, 56003, 100418, Chem. Zentr. 1899, i. 764.) Guaiacol is prepared from *o*-anisidine. 500 grams *o*-anisidine are diazotised, and the solution of the diazo salt is then poured into a boiling solution of 600 grams of copper sulphate in 600 c.c. of water. The guaiacol is then separated by distillation in steam (D. R. P. 167211; Frdl. 1905–7, 128; *cf.* also D. R. P. 95339; J. Soc. Chem. Ind. 1898, 269, 314).

Pure guaiacol can be obtained by dissolving catechol (55 parts) in ethyl alcohol (2000 parts) and adding nitrosomonomethyl urea. The mixture is cooled to 0° and 20 parts of sodium hydroxide dissolved in a small quantity of water is added, drop by drop, with constant stirring. The solution is filtered, the alcohol distilled off, and the residue is fractionated *in vacuô* (D. R. P. 189843; Frdl. 1905–7, 1151).

Guaiacol is also prepared by heating an equimolecular mixture of catechol, potash and potassium methyl sulphate in tightly closed vessels at 170°–180°, or by heating catechol and methyl iodide in methyl alcohol. Thompson (Eng. Pat. 5284, 1893) suggests the purification of guaiacol by treatment with a freezing mixture.

Guaiacol has a characteristic odour and crystallises in long vitreous transparent prisms, which appear rose-red in sunlight; m.p. 28·5°, b.p. 202·4°/738 mm. (Freyss, Chem. Zeit. 1894, 18, 565); sp.gr. 1·140 at 25°. When quite pure it is non-caustic and non-poisonous (Béhal and Choay, Compt. rend. 1893, 116, 197; Kuprianow, J. Soc. Chem. Ind. 1895, 57).

It is soluble in most organic solvents, and to a less extent in water. With a trace of ferric chloride its alcoholic solution gives a blue colour, which becomes emerald-green on the addition of more ferric chloride. Guaiacol also gives a blue colour with traces of hydrogen peroxide (Denigès, J. Pharm. 1909, 31).

Guaiacol is employed in pharmacy as an expectorant and intestinal antiseptic; also in pulmonary tuberculosis in cases of typhoid and other fevers, and for the relief of superficial neuralgia.

Kuprianow (Centralbl. f. Bakteriol. 1894, 15, 933, 981) has suggested the use of pure guaiacol in the internal treatment of cholera, since he found that a solution of 1 in 500 of this reagent completely prevents the development of the cholera bacillus.

Guaiacol should be preserved in amber-coloured bottles protected from the light, and should only be used in pharmacy when quite pure.

Tests.—(1) 2 c.c. of guaiacol mixed with 4 c.c. of light petroleum, should separate at once into 2 layers. (2) 1 c.c. of guaiacol should dissolve in 2 c.c. of N. sodium hydroxide when heated; on cooling the mixture should congeal to a white saline mass, which gives a clear solution with 20 c.c. of water. (3) 1 c.c. of guaiacol treated with 10 c.c. of N. sulphuric acid should give a pure yellow colour. For other tests, *v.* Marfori, J. Soc. Chem. Ind. 1891, 487; Fonzes Diacon, Bull. Soc. chim. 1898, 19, 191; Guérin, J. Pharm. Chim. 1903, [vii.] 17, 173.

Guaiacol can be estimated approximately by conversion into catechol, by heating with water in a current of hydrobromic acid; or 0·5 gram of the guaiacol is dissolved in a little water, 10 c.c. of alcohol added, and the solution made up to 1000 c.c., and 20 c.c. of this solution are mixed in a test-tube with 1 c.c. of sodium nitrite solution (1 : 100), and 1 c.c. dilute nitric acid (1 : 200). A characteristic red-brown colour is produced, which is compared within about 10 minutes with the colourations given by suitable standard solutions (Adrian, Zeitsch. anal. Chem. 1901, 40, 624).

Guaiacol, when treated with hydrogen cyanide, in the presence of sodium or zinc chloride, yields vanillin (Roesler, D. R. P. 189037; Frdl. 1905–7, 1280; Guyot and Gry, Compt. rend. 1909, 149, 928; Bull. Soc. chim. 1910 [iv.] 7, 902).

Guaiacol monosulphonic acids can be obtained by treating guaiacol with sulphuric acid at 30°–60°, the ortho- and para- acids formed being separated by converting them into the basic salts of the alkaline earths, or of the heavy metals, the ortho- salts being readily soluble in water, whereas the para- salts are insoluble or sparingly soluble. By the action of sulphuretted hydrogen, or some suitable acid, the salts are then converted into their respective acids (D. R. P. 188506; Frdl. 1905–7, 936; D. R. P. 132607; Frdl. 1900–02, 1113; Hähle, J. pr. Chem. 1902, [ii.] 65, 95; Lamière and Perrin, Bull. Soc. chim. 1903 [iii.] 29, 1228; Rising, Ber. 1906, 39, 3685; Paul, *ibid.* 2773, 4093; Ginhorn, Fr. Pat. 391601, 1908; J. Soc. Chem. Ind. 1908, 1176; Andrè, J. Pharm. Chim. 1898, 7, 324).

The most striking difference between the ortho- and the para- acids is their action with calcium or barium chloride, with which the para-acid yields a white precipitate, whereas the ortho- remains unchanged. With nitric acid the para- acid forms yellow dinitroguaiacol (m.p. 122°), whilst the ortho- acid merely gives a dark-red colouration. It is important that when the ortho- acid is used therapeutically, it should be free from the para- compound, as the latter gives rise to secondary reactions (Ellis, J. Soc. Chem. Ind. 1906, 335).

The alkali guaiacol sulphonates are employed as drugs (Alpers, U.S. Pat. 692588; J. Soc. Chem. Ind. 1902, 364). Tagliavini has prepared salts of the sulphonates with antipyretic and analgesic bases (Boll. Chim. farm. 1909, 48, 6).

Carbonyl chloride condenses with the alkali guaiacol sulphonates in alkaline solutions, giving derivatives such as *potassium carbonatodiguaiacol disulphonate* $CO[OC_6H_3(OMe)SO_3K]_2$, and *potassium carbonatodiguaiacol sulphonate*

$$C_6H_4(OMe)O{\cdot}CO_2C_6H_3(OMe)SO_3K$$

(Einhorn, D. R. P. 203754, 1909).

Guaiacol 5-sulphonic acid is obtained by sulphonating an acetyl derivative of guaiacol with or without the addition of dehydrating agents, the resulting acetyl guaiacol sulphonic acid is hydrolysed, neutralised, and the resulting acid is isolated as such, or in the form of its salts D. R. P. 212389; J. Soc. Chem. Ind. 1909, 1005). The corresponding *carbonate*

$$(MeO{\cdot}C_6H_3SO_3H)_2CO_3$$

is formed by treating guaiacol carbonate with sulphuric acid in the cold until the product is soluble in water. It melts at 115°–117°, with evolution of carbon dioxide (D. R. P. 215050; J. Soc. Chem. Ind. 1909, 1223).

Triphenyl guanidine guaiacol sulphonate is obtained by the action of triphenyl guanidine sulphate on barium guaiacol sulphonate. It crystallises in leaflets, m.p. 50°, and can be used as a local anæsthetic (Goldschmidt, Chem. Zeit. 1901, 25, 628).

A number of important compounds of *o*-guaiacol sulphonic acids with alkaloids are described by Schaefer (J. Soc. Chem. Ind. 1910, 928). They are used in medicine and are also of scientific interest. The alkaloid salts are prepared by neutralising the guaiacol sulphonic acid with the required alkaloid, and purifying the product by filtration and recrystallisation, or the amorphous salt is obtained by evaporation at low temperature or *in vacuô*. The salts may also be obtained by double decomposition between a soluble alkaloid, and a readily soluble salt of the acid in molecular proportions, using alcohol, water, &c., as a solvent. Most of the alkaloid salts are non-crystalline or crystallise with difficulty. The most important of the salts described by Schaefer are:

Quinine guaiacol bisulphonate (guaiaquin) $[C_6H_3(OH)(OMe)SO_3H]_2,C_{20}H_{24}N_2O_2$ is a yellowish crystalline powder, soluble in water, alcohol, and dilute acids. The solution is coloured blue by a drop of ferric chloride solution. It softens at about 80°, and becomes liquid at 130°.

Codeine-o-guaiacol sulphonate

$$C_6H_3(OH)(OMe)SO_3H,C_{18}H_{21}NO_3,$$

m.p. 164°–165°, is a well-crystallised neutral salt. It is readily soluble in hot water and in alcohol, but almost insoluble in ether and chloroform. It gives the characteristic blue colouration of *o*-guaiacol sulphonic acid with ferric chloride, and when its aqueous solution is treated with an alkali, codeine is precipitated. Other opium and cinchona compounds, as well as compounds with strychnine, brucine, atropine, hyoscine, hyoscyamine, and cocaine, are described.

Guaiacol iron and lithium sulphonates have been prepared (Schaefer, Eng. Pat. 21747, 1899).

Guaiakinol, quinine derivative of bromo-guaiacol, $C_{20}H_{24}N_2O_2,2HBr,C_6H_4(OH)(OMe)$, forms fine crystalline yellow scales, readily soluble in water. It is said to be practically non-toxic, and its aqueous or alcoholic solution is readily absorbed by the skin (Pharm. J. 1901, 66, 132; Schaefer, Eng. Pat. 8227, 1897).

Guacamphol, the camphoric acid ester of guaiacol $C_8H_{14}(CO{\cdot}OC_6H_4{\cdot}OMe)_2$, obtained by the action of camphoric acid chloride on sodium derivative of guaiacol. Forms white, odourless, tasteless needles, and has been recommended for the relief of night sweats in phthisis.

Guaiacol benzoate (benzosol, benzoyl guaiacol) $C_6H_5{\cdot}CO{\cdot}OC_6H_4{\cdot}OMe$ is prepared by heating an alcoholic solution of potassium derivative of guaiacol with the requisite amount of benzoyl chloride, and purifying the substance by crystallisation from alcohol. It is a colourless, odourless, tasteless powder, almost insoluble in water, readily soluble in organic solvents. It has m.p. 56°, and is used in the treatment of pulmonary tuberculosis (Eng. Pat. 5366, 1890; J. Soc. Chem. Ind. 1891, 383; Walzer, Chem. Zeit. Rep. 1891, 15, 165).

Guaiacol cinnamate (styracol, cinnamyl guaiacol) $C_8H_7{\cdot}CO{\cdot}OC_6H_4{\cdot}OMe$ is formed by the interaction of molecular weights of guaiacol and cinnamyl chloride. It forms colourless needle-shaped crystals, m.p. 130°, which are employed in catarrhal affections of the digestive tracts, and in the treatment of phthisis.

Guaiacol combines with tannin and cinnamic acid to form a compound which is said to be of use in medicine. It melts above 300°, is insoluble in most organic solvents, and dissolves in alkalis and also in pyridine, from which the pyridine derivative crystallises in well-shaped rhombic needles (D. R. P. 133299; Frdl. Nissel. 1900-02, 1111).

Guaiacol valerate $C_4H_9{\cdot}CO{\cdot}OC_6H_4{\cdot}OMe$, a yellowish oily liquid, b.p. 245°–265°, is used in medicine under the name of *geosote* (Rieck, J. Soc. Chem. Ind. 1897, 632). It is prepared by the action of valeryl chloride on sodium derivative of guaiacol.

Guaiacol salicylate (guaiacol salol)

$$C_6H_4(OH)CO{\cdot}OC_6H_4{\cdot}OMe$$

is a white crystalline, odourless, tasteless powder; m.p. 65°. It is formed by the action of phosphorus oxychloride on a mixture of sodium guaiacol salicylate, and is used as an intestinal antiseptic.

Guaiacol succinate $C_2H_4(CO{\cdot}OC_6H_4{\cdot}OMe)_2$ is formed by the action of phosphorus oxychloride on a mixture of guaiacol and succinic acid in molecular proportions. It forms fine silken crystalline needles; m.p. 136°.

Guaiamar, the *glyceryl ether of guaiacol* $C_6H_4(OMe)OC_3H_7O_2$, is formed by the action of anhydrous glycerol on guaicol. It is a white crystalline body, m.p. 75°, soluble in water and in most organic solvents. It has a bitter aromatic taste, and is employed in medicine as an antiseptic for internal and external application (J. Soc. Chem. Ind. 1900, 371; 1902, 1346).

Guaiasanol (diethylglycocollguaiacol hydrochloride) $MeO,C_6H_4O{\cdot}CO{\cdot}CH_2NEt_2,HCl$, m.p. 184°, is non-poisonous, and said to possess slight anæsthetic, antiseptic, and deodorising properties (Einhorn, Chem. Zeit. Rep. 1900, 24, 33; J. Soc. Chem. Ind. 1900, 464). By the action of the monochloracetic esters of phenols with secondary amines of the fatty series, many compounds, similar to the above, have been prepared (Einhorn and Heinz, Arch. Pharm. 240 [8] 631; D. R. P. 105346). They are non-poisonous, odourless, and strongly antiseptic substances.

Guaiaperol (piperidine derivative of guaiacol) is prepared by dissolving 85 parts of piperidine and 248 parts of guaiacol in benzene or light petroleum, and allowing the solution to evaporate (Tunnicliffe, Chem. Soc. Trans. 1898, 145).

Valuable albuminous products said to be applicable in medicine for tuberculous and other cases are obtained by the interaction of guaiacol with egg or other albumin in aqueous or alcoholic solution (D. R. P. 162656; Frdl. 1905-7, 931).

Guaiacol, when treated with ethoxyacetyl chloride, bromide, or iodide, reacts thus:

$$MeO{\cdot}C_6H_4{\cdot}O\boxed{H+Cl}COCH_2OEt \\ \rightarrow MeO{\cdot}C_6H_4CO{\cdot}OCH_2OEt.$$

The product is a colourless, odourless oil; b.p. 150°/10 mm. The corresponding methoxy derivative boils at 170°–171°/10 mm., and has very similar properties to the ethoxy derivative. Both substances are non-poisonous, and can be used therapeutically as external remedies (D. R. P. 171790; Frdl. 1905–7, 933).

Guaiaform (geoform) is produced by the condensation of guaiacol (2 mols.) with formaldehyde (1 mol.). It is a tasteless, yellow, non-irritant and non-toxic powder, but on keeping it acquires the vanilla flavour. It is insoluble in water, but readily soluble in ether, benzene, or alcohol (Ehlert, Pharm. J. 1902, 68, 61).

Guaiacol carbonate  $\begin{matrix}OMeC_6H_4O\\OMeC_6H_4O\end{matrix}\!\!>CO$ is prepared by passing phosgene into a solution of guaiacol in sodium hydroxide. The substance is filtered off, washed with sodium hydroxide solution, and recrystallised from alcohol. It is a white crystalline powder, m.p. 84°–87°, of neutral reaction, and almost odourless and tasteless, soluble in most organic solvents, but insoluble in water. Its alcoholic solution yields no characteristic colour with ferric chloride. When taken internally its action is very similar to that of guaiacol, but it is less liable to derange the stomach. It is employed as an expectorant in the treatment of tuberculosis and bronchitis, and also as an intestinal antiseptic in the treatment of typhoid fever and intestinal indigestion (D. R. PP. 99057, 58129, 117346, of 1901; D. R. P. 224160; Einhorn, Chem. Zentr. 1910, ii. 518).

Guaiacol chlorocarbonate is a colourless oil; b.p. 112°/25 mm. It is prepared by the interaction of antipyrine, carbonyl chloride and guaiacol (D. R. P. 117624 of 1901; Einhorn, D. R. P. 224108, 1910; Chem. Zentr. 1910, ii. 517).

Guaiacol carboxylic acid $C_6H_3(OH)(OMe)CO_2H$ is formed by the action of carbon dioxide on sodium derivative of guaiacol, previously heated; the product is heated for some time, and is then acidified with hydrochloric acid, the free acid being recrystallised from water or dilute alcohol. It is a white, odourless crystalline powder; m.p. 148°–150°. It has a bitter taste, is readily soluble in hot water, and its aqueous solution is coloured blue by ferric chloride. The acid and its salts have been recommended as antiseptics and antirheumatics (Pharm. J. 1890, 977).

Guaiacol, when oxidised with laccase, yields *tetraguaiacoquinone*  $\begin{matrix}O(C_6H_3{\cdot}OMe)_2O\\|\qquad\qquad|\\O(C_6H_3{\cdot}OMe)_2O\end{matrix}$, a fine crystalline powder, m.p. 135°–140°, having a purplish-red colour with a faint green metallic lustre. It is insoluble in water, but gives mahogany-red solutions with chloroform and with acetic acid. It also forms coloured solutions in alkalis (Bertrand, Compt. rend. 1903, 137, 1269).

Dimethylamino ε-guaiacylamyl ether, the corresponding piperido derivative and the piperido-γ-guaiacyl-propyl ether are formed by the interaction of a halogen hydrocarbon alkyl ether of guaiacol with a secondary amine, thus:

$$x(CH_2)_nO{\cdot}R+NHMe_2=Me_2N(CH_2)_nOR;\text{ or}$$
$$x(CH_2)_nO{\cdot}R+NHC_5H_{10}=C_5H_{10}N(CH_2)_nO{\cdot}R$$

(where x=halogen). They are employed in medicine as anæsthetics (D. R. P. 184986; Frdl. 1905–7, 1050).

Hexamethylenetetraminetriguaiacol crystallises in brilliant needles, which become soft at 80°, and melt to a turbid liquid at about 95°. When distilled in steam it yields guaiacol (Eng. Pat. 24072, 1908; J. Soc. Chem. Ind. 1909, 490).

Chloroacetyl guaiacol $OMeC_6H_4O{\cdot}CO{\cdot}CH_2Cl$ is prepared by treating a mixture of guaiacol monochloroacetic acid and pyridine with phosphorus oxychloride. It forms white needles, m.p. 58°–60° (Einhorn and Hentz, *l.c.*).

Guaiacol chloroformic ester is a colourless oil; b.p. 112°/25 mm. (D. R. P. 117624; Frdl. 1900-02, 1165).

Benzyl guaiacol is a yellow, beautifully fluorescent oil; b.p. 269°–270°/430 mm. (Boscogrande, Chem. Zentr. 1898, i. 207).

Guaiacol picrate forms orange-red needles; m.p. 80°. Many other guaiacol derivatives have been prepared, some of which have been recommended for use in medicine (Eng. Pat. 5856, 1894; Ruhemann, Chem. Soc. Trans. 1902, 421; D. R. P. 120558; Frdl. 1900–02, 1112; D. R. P. 157355; Frdl. 1902–04, 616; Knapp and Suter, Chem. Zentr. 1904, i. 391; Moureu and Lazennec, Compt. rend. 1906, 142, 894; Bischoff, Ber. 1906, 39, 3846; Gattermann, Annalen, 1907, 357, 313; Fourneau, J. Pharm. Chim. 1910, [vii.] 1, 55, 97; Manchot, Ber. 1910, 43, 949; Wohl and Berthold, *ibid.* 2175; Hoffmann, D. R. P. 255924; Chem. Zentr. 1910, ii. 1105).

A number of azo derivatives of guaiacol are described by Leonardi (Atti R. Accad. Lincei. 1907 [v.] 16, ii. 639); some nitro and amino derivatives by Reverdin and Crepieux, Ber. 1903, 36, 2257; 1906, 39, 4232; Paul, *ibid.* 2773; Kühling, *ibid.* 1905, 38, 3007; Fichter and Schwab, *ibid.* 1906, 39, 3339).

Thioguaiacol and *thioguaiacol xanthate* have been prepared by Mauthner (Ber. 1906, 39, 1347).

Guaiacol forms mono-, di-, tri-, and tetrahalogen derivatives (Cousin, Compt. rend. 1898, 127, 759; Tassily and Lerride, *ibid.* 1907, 144, 757; Bull. Soc. chim. 1908, [iv.] 3, 124; Mameli, Gazz. chim. ital. 1907, 37, ii. 366; Robertson, Chem. Soc. Trans. 1908, 791). The iodo derivatives are said to be applicable to medicine (Mameli and Pinna, Chem. Zentr. 1907, ii. 2044).

Guaiacol phosphite, m.p. 75·5°, is a white crystalline powder, with a piquant non-caustic taste and slight odour, soluble in most organic solvents, but only sparingly in water (Bollard, D. R. P. 95578; J. Soc. Chem. Ind. 1897, 632; Ellis, Eng. Pat. 27527, 1896). Its medicinal properties are similar to those of guaiacol.

Another *guaiacol phosphite*, m.p. 59°, is described by Dupuis (Compt. rend. 1910, 150, 622).

Guaiacol phosphate $(C_6H_4OMe)_3PO_4$ is prepared by the interaction of phosphorus oxychloride and sodium derivative of guaiacol. It forms colourless crystals; m.p. 98°, insoluble in water and alcohol, but soluble in ether, chloroform, and acetone. It is used as an intestinal antiseptic and in hectic fever.

A number of other phosphorus compounds of guaiacol are described by Auger and Dupuis (Compt. rend. 1908, 146, 1151), and by Dupuis (*ibid.* 1910, 150, 622).

Guaiacol-cacodylate $AsMe_2O_2{\cdot}C_6H_4OMe$ is a white hygroscopic, crystalline, very unstable salt (Astruc and Murco, J. Pharm. Chim. 12, 553).

GUAIACONE *v. Guaiacum*, art. Resins.

GUAIACONIC ACID *v. Guaiacum*, art. RESINS.

GUAIACUM *v.* RESINS.

GUAIENE *v. Guaiacum*, art. RESINS.

GUAIOL *v. Guaiacum*, art. RESINS.

GUANIDINE $HN:C(NH_2)_2$ occurs in small quantities in etiolated vetch seedlings, 3 kilos. of dried material yielding 1 gram of the nitrate (Schulze, Ber. 1892, 25, 658); and in beet juice (Lippmann, *ibid.* 1896, 29, 2651).

Guanidine was first prepared by Strecker (Annalen, 1861, 118, 159) by oxidising guanine with potassium chlorate and hydrochloric acid; and it is obtained in small quantity by oxidising egg albumen with potassium permanganate, or gelatin with barium or calcium permanganate (Lossen, J. Pharm. Chim. [iii.] 31, 32; Kutscher and Kickgraf, Sitzungsber. K. Akad. Wiss. Berlin, 1903, 28, 624); it is formed synthetically (1) by heating biuret and hydrogen chloride at 160°–170° (Finckh, Annalen, 1862, 124, 332); (2) from chloropicrin and alcoholic ammonia at 100° (Hofmann, Ber. 1868, 1, 145); (3) from ethyl orthocarbonate and aqueous ammonia at 150° (Hofmann, Annalen, 1866, 139, 111); (4) from carbonyl chloride and ammonia (Bouchardt, Zeitsch. Chem. 1870, 58); (5) from ammonium chloride and alcoholic cyanamide at 100° (Erlenmeyer, Annalen, 1868, 146, 259); (6) from cyanogen iodide and alcoholic ammonia at 100° (Bannow, Ber. 1871, 4, 161); (7) by the action of *aqua regia* on dicyanodiamide, when a quantitative yield of the nitrate is obtained (Ulpiani, D. R. P. 209431).

Guanidine is usually prepared by heating ammonium thiocyanate for 20 hours at 180°–190°, treating the fused mass with water and allowing the guanidine thiocyanate to crystallise from the solution; it is then purified by animal charcoal and recrystallised from alcohol and water. The thiocyanate is converted into the carbonate by treating the concentrated aqueous solution with one equivalent of potassium carbonate, the solution is evaporated and the residue extracted with hot alcohol in which the guanidine carbonate is insoluble, and this is afterwards recrystallised from water (Delitsch, J. pr. Chem. 1871, [ii.] 9, 2; Volhard, *ibid.* 15). According to Goldberg, Siepermann, and Flemming (D. R. P. 1898, 97820), a better yield of guanidine salts is obtained when the ammonium thiocyanate is mixed with wood charcoal and the oxide or salt of a heavy metal, and the mixture heated in a current of ammonia,

$$(1)\ 2NH_4CNS+ZnO =CH_5N_3,HCNS+ZnS+H_2O\ ;$$

$$(2)\ 2NH_4CNS+ZnO+PbCl_2 =2NH_3+2CH_5N_3,HCl+ZnS+PbS+H_2O\ ;$$

or guanidine thiocyanate can be prepared by heating the thiocyanate of a heavy metal under pressure in an atmosphere of ammonia at 180°

$$Pb(CNS)_2+2NH_3=PbS+CH_5N_3,HCNS.$$

Guanidine is a deliquescent crystalline solid, readily soluble in alcohol or water; it is volatile and strongly alkaline, absorbs carbon dioxide from the air and forms crystalline salts. The thermal value of the basic function of guanidine is +32·1 Cal., intermediate between that of barium hydroxide +31·7 Cal. and sodium hydroxide +36·4 Cal. (Matignon, Compt. rend. 1892, 114, 1432). Guanidine is decomposed into ammonia and urea on boiling with baryta water or dilute sulphuric acid (Ossikowsky, Bull. Soc. chim. 1872, [ii.] 18, 161; Baumann, Ber. 1873, 6, 1376); and is completely decomposed into carbon dioxide and ammonia by heating with concentrated acids or alkalis. Guanidine is decomposed, evolving two-thirds of its nitrogen, when mixed with sodium hypochlorite or hypobromite (Fenton, Chem. Soc. Trans. 1879, 14).

When the hydrochloride is heated at 180°, ammonia is evolved and *biguanide* is formed, the reaction being similar to the formation of biuret from urea:

$$2HN:C(NH_2) =NH_3+HN:C(NH_2)NH{\cdot}C(NH_2)NH.$$

In its physiological action, guanidine is highly toxic; doses smaller than poisonous ones are in rabbits excreted unchanged in the urine (Pommerrenig, Beitr. Chem. Physiol. Path. 1902, i. 561); it acts on frog's muscles, producing spontaneous twitching and affecting their contractility, and it is supposed that the guanidine acts by combining with two different substances in the muscle, one of which is responsible for the twitching, and the other for the changes in contractility (Camis, J. physiol. 1909, 39, 73). Although guanidine does not appear to be a normal oxidation product of arginine in the body (Pommerrenig, *l.c.*), it is found among the products of pancreatic autodigestion (Kutscher and Otori, Zeitsch. physiol. Chem. 1904, 43, 93). Small quantities of guanidine, 0·1 per thousand, are injurious to chlorophyllous plants, whilst fungi utilise it as a source of nitrogen but not of carbon (Kawakita, Bull. Coll. Agr. Tōkyō, 1904, 6, 181).

Many salts of guanidine give a yellowish-white flocculent precipitate with Nessler's reagent, which can thus be used as a test for small quantities of the salts of the base, a 0·05 p.c. aqueous solution of guanidine nitrate gives a bulky precipitate and a 0·01 p.c. solution is rendered turbid (Schulze, Ber. 1892, 25, 661). Another test for guanidine is the development of a deep yellow to orange red colouration with alkali hypochlorites (de Coninck, Compt. rend. 1898, 126, 142). Guanidine is usually estimated as the picrate, the salt being collected on a Gooch asbestos filter, dried at 110° and weighed (Vozarik, Zeitsch. angew. Chem. 1902, 15, 670); or it can be converted into the strongly alkaline carbonate and titrated with standard acid (Grossmann and Schück, Chem. Zeit. 1906, 30, 1205).

Guanidine forms crystalline salts with mineral and with organic acids; it also forms characteristic double salts. The *hydrochloride*

$$CH_5N_3,HCl$$

forms double salts with *mercuric chloride*

$$CH_5N_3,HCl,2HgCl_2$$

(Byk, J. pr. Chem. [ii.] 20, 233); with *gold chloride* $CH_5N_3,HCl,AuCl_3$, deep yellow, sparingly soluble needles (Hofmann, Ber. 1868, 1, 146); with *platinic chloride* $(CH_5N_3,HCl)_2,PtCl_4$, yellow needles, soluble in water, sparingly so in alcohol (Strecker, Annalen, 1861, 118, 160). The *nitrate*, CH_5N_3,HNO_3, crystallises in large plates, m.p. 214°, 10·75 parts dissolve in 100 parts of water at 15·9°. The *compound* with silver nitrate $CH_5N_3,AgNO_3$ crystallises in needles. The *nitrite* CH_5N_3,HNO_2 forms glittering prisms, m.p. 76°–78·5° (Lossen, Annalen, 1891, 265, 129). The *sulphate* $(CH_5N_3)_2,H_2SO_4$ crystallises in the regular system and is soluble in water (Bodewig, J. 1876, 763); it forms a double salt with *aluminium sulphate*

$$(CH_5N_3)_2,H_2SO_4,Al_2(SO_4)_3,12H_2O$$

crystallising in large, well-developed hexagonal prisms belonging to the scalenohedral class of the rhombohedral system, and having sp.gr. 1·806 at 13·5° (Ferraboschi, Proc. Camb. Phil. Soc. 1908, 14, 471). The *carbonate* $(CH_5N_3)_2,H_2CO_3$ forms octahedral or tetragonal prisms; sp.gr. 1·238–1·251 (Schröder, Ber. 1880, 13, 1072). The *metaphosphate* CH_5N_3,HPO_3 forms a fine crystalline precipitate (Pohl, Zeitsch. physiol. Chem. 1889, 13, 296). The *perchromate*

$$(CH_5N_3)_3CrO_8,H_2O$$

forms small brownish-yellow, double-refracting prisms, and yields the usual blue solution with ether and dilute sulphuric acid (Hofmann and Buchner, Ber. 1909, 42, 2773). The *thiocyanate* $CH_5N_3,HCNS$ has m.p. 118°, and 100 parts of water dissolve 73 parts at 0°, or 134·9 parts at 15° (Engel, Bull. Soc. chim. 1885, 44, 424). The *platinothiocyanate* $(CH_5N_3)_2,H_2Pt(CNS)_6$ forms beautiful red crystals that blacken at 170°–175° (Guareschi, Chem. Zentr. 1891, ii. 620). The *cyanurate* $(CH_5N_3)_3,(CNHO)_3$ forms silky needles (Bamberger, Ber. 1887, 20, 71). The *dioxalate* $CH_5N_3,C_2H_2O_4,H_2O$ is sparingly soluble (Strecker, *l.c.*). The *picrate* $CH_5N_3,C_6H_2(NO_2)_3OH$ is a sparingly soluble, yellow, crystalline salt, 1 part dissolves in 2630 parts of water at 9°, and it does not melt at 280° (Emich, Monatsh. 1891, 12, 24). According to von Cordier (Chem. Zentr. 1906, i. 340), guanidine picrate exhibits stereoisomerism. The salt, as usually prepared, forms dark yellow plates that, owing to repeated twinning, have a hook-like structure, but when guanidine prepared by decomposing methylguanidine sulphate with barium hydroxide is used, the picrate crystallises in rosettes of bright yellow needles. The two forms are identical in composition, sp.gr., temperature of decomposition and electric conductivity, but differ in colour, crystalline form and solubility, 100 parts of water dissolve 0·037 parts of the plates at 0°, 0·061 at 20°, and 0·574 at 80°. The solubility of the needles is 0·043, 0·060, 0·800 at these temperatures respectively. One form cannot be converted into the other by crystallisation, and the author suggests that they are stereoisomerides, the plates being the stable modification,

$\underset{\ddot{N}H}{NH_2\cdot C}\cdot NH_2\cdot C_6H_3O_7N_3$, and the needles the labile

$\underset{H\ddot{N}}{NH_2\cdot C}\cdot NH_2\cdot C_6H_3O_7N_3$. The *benzenesulphonate* has m.p. 200°, the *p-toluene-sulphonate*, m.p. 206°, and the α- and *β-naphthalenesulphonates*, m.p. 257° (Remsen and Garner, Amer. Chem. J. 1901, 25, 173). The 4-*nitroacetylanthranilate* has m.p. 247° (corr.) (Bogert and Klaber, J. Amer. Chem. Soc. 1908, 30, 807). The *acetate* $CH_5N_3\cdot C_2H_4O_2$ forms shining needles, m.p. 229°–230° (Ostrogovich, Gazz. chim. ital. 1897, 27, i. 223). The *picrolonate* $CH_5N_3\cdot C_{10}H_8O_5N_4$ is soluble in alcohol (Schenck, Zeitsch. physiol. Chem. 1905, 44, 427).

Guanamines. When the guanidine salts of the first seven of the fatty acid series are heated at 220°–230°, water and ammonia are eliminated and heterocyclic bases called *guanamines* are formed: these are well characterised crystalline compounds. *Formoguanamine*

$$HC\left\langle\begin{matrix}N{:}C(NH_2)\\ N\cdot C(NH_2)\end{matrix}\right\rangle N$$

melts and decomposes at a high temperature; *acetguanamine*

$CH_3\cdot C\left\langle\begin{matrix}N{:}C(NH_2)\\ N\cdot C(NH_2)\end{matrix}\right\rangle N$ melts at 265°; *propionoguanamine* blackens at 300°; *œnanthoguanamine* melts at 130° (Nencki, Ber. 1874, 7, 1584; Haaf, J. pr. Chem. 1891, [ii.] 43, 75).

Chloroguanidine CH_4ClN_3, obtained by the action of bleaching powder solution on guanidine carbonate in ice water, forms a pale yellow crystalline powder that decomposes at 150° (Kamenski, Ber. 1878, 11, 1602).

Bromoguanidine CH_4BrN_3, formed from equimolecular proportions of bromine and guanidine carbonate, crystallises in yellow needles. By the action of 3 mols. bromine on 1 mol. guanidine carbonate, the *compound*

$$CH_5N_3\cdot HBr\cdot Br_2$$

is formed, crystallising in dark red prisms. The corresponding *iodine compound* $CH_5N_3\cdot HI\cdot I_2$ crystallises in prisms the colour of iodine (Kamenski, *l.c.*).

Nitroguanidine $NH:C(NH_2)NH\cdot NO_2$ was first prepared by Jousselin (Compt. rend. 1877, 85, 548; 1879, 88, 814, 1086) by the action of fuming nitric acid and nitric oxide on guanidine nitrate, and called by him nitrosoguanidine. Pellizzari (Gazz. chim. ital. 1891, 21, ii. 405) showed that it was the *nitro* compound, and his results were confirmed by Thiele (Annalen, 1892, 270, 1), who also prepared it by the action of fuming nitric acid and sulphuric acid on guanidine thiocyanate. It crystallises from water in colourless needles, melts and decomposes at 230° with evolution of ammonia; it dissolves in 372–375 parts of water at 19·3°, or in 11 parts of boiling water. The heat of combustion at constant pressure is +210·3 Cal. and the heat of formation from its elements is +22 Cal. (Matignon, Compt. rend. 1892, 114, 1432). The *silver* derivative $CH_3N_4O_2Ag$ is colourless and almost insoluble in water; the *nitrate* $CH_4O_2N_4\cdot HNO_3$ is crystalline and melts at 147°; the *hydrochloride* $CH_4O_2N_4.HCl$ crystallises in plates or prisms.

Nitrosoguanidine $NH:C(NH_2)NH\cdot NO$ is obtained by the partial reduction of nitroguanidine with zinc dust and sulphuric acid. It forms yellow needles, explodes violently at 160°–165°, is soluble in alkalis and reprecipitated by carbon dioxide; it also gives the Liebermann reaction. The alkali solutions give a beautiful purple colouration with ferrous salts. The *silver salt* CH_3ON_4Ag is a colourless explosive precipitate; the *copper salt* $(CH_3ON_4)_2Cu$ is reddish brown, and the *nickel salt* $(CH_3ON_4)_2Ni$ is vermilion red (Thiele, Annalen, 1893, 273, 133). According to Hantzsch, Schümann, Engler (Ber. 1899, 32, 575, 1703), nitrosoguanidine is a true nitrosamine and its constitution is represented by the formula $NH:C(NH_2)NH\cdot NO$, since it has a neutral reaction, yields mainly nitrous acid and not nitrogen when decomposed by acids, and does not interact with phosphorus pentachloride or acetyl chloride. On the other hand, Whiteley (Chem. Soc. Trans. 1903, 31) and Tschugaeff

(Ber. 1906, 39, 3383) consider that the coloured metallic derivatives are salts of the tautomeric diazo-hydrate form HN : C(NH_2)N : N·OH.

Aminoguanidine HN : C(NH_2)NH·NH_2, is obtained by reducing nitroguanidine with zinc dust and acetic acid at 40° until a test portion develops no colouration with ferrous sulphate and an alkali (Thiele, Annalen, 1892, 270, 23). The mixture is filtered, the filtrate evaporated till it is only feebly acid, and the aminoguanidine bicarbonate precipitated in the cold by adding a concentrated solution of alkali bicarbonate (D. R. P. 59241). Also prepared by heating an alcoholic solution of hydrazinehydrochloride, and cyanamide in a reflux apparatus (Pellizzari and Cuneo, Gazz. chim. ital. 1894, 24, i. 450). A yield of 81 p.c. of the theoretical is obtained by the electrolytic reduction of the nitro compound, suspended in water slightly acidified with sulphuric acid, using a tin cathode and a current density of 250 amperes per square metre and a temperature of 10° (Boehringer and Söhne, D. R. P. 167637).

Aminoguanidine is crystalline, soluble in water or alcohol, decomposes on boiling with dilute acids or alkalis, yielding first semicarbazide and finally ammonia, carbon dioxide, and hydrazine (Curtius, Ber. 1896, 29, 759). Aminoguanidine forms crystalline salts with mineral acids: the *hydrochloride* CH_6N_4,HCl forms large prisms, m.p. 163°; the *double salt* with platinic chloride $(CH_6N_4,HCl)_2,PtCl_4$ is a yellow precipitate, m.p. 145°–146°; the *nitrate* CH_6N_4,HNO_3 forms large shining plates, m.p. 144°; 100 parts of water dissolve 12·01 parts at 15·9°; the *sulphate* $(CH_6N_4)_2,H_2SO_4,H_2O$ crystallises in needles, m.p. 207°–208°; the *bisulphate*

$$CH_6N_4,H_2SO_4$$

crystallises in large plates, m.p. 161°; the *picrate* $CH_6N_4,C_6H_3O_7N_3$ is precipitated as yellow needles from hot water. The *copper compounds* $Cu(CH_5N_4)_2,2HNO_3$ and

$$Cu(CH_5N_4)_2,H_2SO_4$$

are violet crystalline precipitates; the *bicarbonate* CH_6N_4,H_2CO_3 (Thiele, Annalen, 1898, 302, 332) melts at 172° and is almost insoluble in cold water.

Acetaminoguanidine $CH_5N_4(C_2H_3O)$ forms a crystalline *nitrate*, m.p. 85°–90° and *picrate*; *formylaminoguanidine nitrate*

$$HNO_3,H_2N{\cdot}C(NH)NH{\cdot}NH{\cdot}CHO$$

melts at 143°, the *picrate* melts at 193°; *oxalylaminoguanidine* HN : C(NH_2)NH·NH·CO·CO_2H melts at 231°–232° (Thiele and Manchot, Annalen, 1898, 303, 37).

Aminoguanidine and its alkyl and aryl derivatives contain the grouping —NH·NH_2, present in hydrazines, and semicarbazide, and like them readily form condensation products with aldehydes, ketones, sugars, and ketonic acids; these are usually well characterised crystalline compounds, forming crystalline salts with mineral and organic acids. For the condensation products with aldehyde, chloraldehyde, chloral, *v.* Thiele and Dralle (Annalen, 1898, 302, 278); with benzaldehyde, *v.* Thiele (*ibid.* 1892, 270, 1), Wedekind (Ber. 1897, 30, 444); with diacetyl, acetylacetone, acetonylacetone, *v.* Thiele and Dralle (*l.c.*); with galactose, glucose, and lactose, *v.* Wolff (Ber. 1895, 28, 2613); with glyoxylic acid, *v.* Thiele and Dralle (*l.c.*), Doebner and Gärtner (Annalen, 1901, 315, 1); with pyruvic acid, *v.* Wedekind and Bronstein (*ibid.* 1899, 307, 297). For the preparation and properties of *alkyl* and *aryl* substituted derivatives of aminoguanidine, *v.* Pellizzari and Cuneo (Gazz. chim. ital. 1894, 24, i. 450), Pellizzari and Rickards (*ibid.* 1901, 31, i. 526).

Diaminoguanidine HN : C(NH·NH_2)$_2$ does not exist in the free state; its *hydrobromide* CH_7N_5,HBr is formed by the action of cyanogen bromide (1 mol.) on hydrazine (2 mols.); it crystallises in plates, m.p. 167°; the *picrate*, $CH_7N_5,C_6H_3O_7N_3$, melts at 191°; the *hydrochloride* at 185°; the *platinochloride* at 172°–173°; all the salts reduce Fehling solution and ammoniacal silver nitrate solution. *Dibenzylidenediaminoguanidine* HN : C(NH·N : CHPh)$_2$ yellow crystals, m.p. 180°; the *hydrobromide* melts at 243°, and the *hydrochloride* at 230° (Pellizzari and Cantoni, Gazz. chim. ital. 1905, 35, i. 291).

Dihydroxyguanidine hydrobromide

$$HN : C(NH{\cdot}OH)_2,HBr$$

is formed by the interaction of cyanogen bromide and hydroxylamine in methyl alcohol and ether at −20°; it forms colourless, flat, hygroscopic needles that decompose at 95° (Wieland, Ber. 1905, 38, 1445).

Methylguanidine HN : C(NH_2)NHMe has been isolated from extract of muscle (Gulewitsch, Zeitsch. physiol. Chem. 1906, 47, 471), and is prepared by boiling creatine with mercuric or lead oxide and dilute sulphuric acid (Dessaignes, Annalen, 1854, 92, 407; 1856, 97, 340). It can be synthesised from methylamine hydrochloride and cyanamide (Erlenmeyer, Ber. 1870, 3, 896). It is a strongly alkaline, volatile, crystalline substance, and liberates ammonia and methylamine on heating with potassium hydroxide. The *aurichloride* $C_2H_7N_3,HCl,AuCl_3$ melts at 198°–200°; the *platinichloride* $(C_2H_7N_3,HCl)_2,PtCl_4$ melts at 194°–195° (Schenck, Arch. Pharm. 1909, 247, 466). The *oxalate* $(C_2H_7N_4)_2,C_2H_2O_4,2H_2O$ is crystalline and soluble in water. The *picrate* crystallises from water in two distinct modifications (Gulewitsch, *l.c.*). The *picrolonate*

$$C_2H_7N_3,C_{10}H_8O_5N_4$$

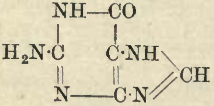
melts at 291° (Wheeler and Jamieson, J. Biol. Chem. 1908, 4, 111).

For other *alkyl* and *aryl* substituted derivatives of guanidine, some of which have therapeutic properties, *v.* Strakosch (Ber. 1872, 5, 692); Tatarinow (J. 1879, 401); Noah (Ber. 1890, 23, 2196); Hofmann (*ibid.* 1869, 2, 601); Fischer (*ibid.* 1897, 30, 2414); Alway and Vail (Amer. Chem. J. 1902, 28, 158); Kämpf (Ber. 1904, 37, 1681); Reidel (D. R. PP. 1892, 66550; 1898, 104361).

Guanidine forms condensation products with *dicarboxylic acids* (Traube, Ber. 1893, 26, 2551; Ruheman and Stapleton, Chem. Soc. Trans. 1900, 805; Kaess and Gruszkiewicz, Ber. 1902, 35, 3600); with *β-ketonic acids* (Jaeger, Annalen, 1891, 262, 365); with *β diketones* (Evans, J. pr. Chem. 1892, 45, 489; Wense, Ber. 1886, 19, 761); with *malononitrile* (Merck, D. R. PP. 165692, 165693); with *ethyl cyanacetate* (Traube, D. R. P. 1900, 115253).

Guanidine forms *compounds* with sugars containing 3 mols. of sugar and 1 mol. of guanidine; these exhibit mutarotation and have a lower optical activity than the sugars from which they are derived (Morrell and Bellars, Chem. Soc. Trans. 1907, 1010). M. A. W.

GUANINE, 2-*amino*-6-*oxypurine*,



was discovered by Unger in guano in 1844 (Annalen, 51, 395; 58, 18; 59, 58), and though Hoppe-Seyler failed to find it in the excrement of fowls and geese, Haeter obtained it from the excrement of a heron (*Ardea cinerea*) fed on fish and flesh (Med. Chem. Untersuch. 1871, 582); Will and Gorup Besanez found it in the excrement of a spider, in the organ of Bojanus of the mussel, and in the green gland of the crayfish (*cp.* Weinland, Zeit. Biol. 25, 390); and Pecile found 0·0068 gram of guanine per litre in the urine of a pig fed on bran, and in an unhealthy condition (Annalen, 1876, 183, 141). In addition to its occurrence among the excretory products of the animal, guanine is fairly widely distributed throughout the tissues; thus it occurs, together with hypoxanthine, in the protamine from salmon roe, forming 6–8 p.c. of the ripe organ (Piccard, Ber. 1874, 7, 1714); it occurs in the pancreas, spleen, liver, and muscle of the ox, in quantities varying from 0·020 to 0·746 p.c. (Braginsky, Zeitsch. physiol. Chem. 1883, 8, 395; Kossel, *ibid.* 404; Schindler, *ibid.* 1889, 13, 432); and it is found in the skin of fishes (Ewald and Kruckenberg, Chem. Zentr. 1883, 705). Guanine is widely spread throughout the vegetable kingdom, Schützenberger found it, together with other purine bases, in yeast extract (Compt. rend. 1874, 78; Chem. Zentr. 1877, 73); Schulze and Bosshard isolated it, together with hypoxanthine and xanthine, from young potato tubers, sugar beet, leaf buds of plane and maple, bark of plane, from lupins, red clover, vetch, young grass, and oats (Zeitsch. physiol. Chem. 1884, 9, 420); and v. Lippmann obtained it from beet juice (Ber. 1896, 29, 2645). According to Levene and Mandel (Biochem. Zeitsch. 1908, 10, 215) guanine is one of the cleavage products of nucleic acid, when the hydrolysis is effected by acetic acid in the presence of lead acetate at 150°.

Guanine exists in guano partly as the calcium compound, partly in substances like nuclein, from these it is liberated by boiling for 4 hours with dilute sulphuric acid, the liquid is cooled and filtered, and the filtrate made alkaline with sodium hydroxide and again filtered. The guanine and uric acid are precipitated in the filtrate by the addition of ammoniacal silver solution, the precipitate washed with cold and hot water, and then decomposed by hot dilute hydrochloric acid, the silver chloride filtered off, the filtrate decolorised with animal charcoal, and the guanine precipitated by ammonia, a small quantity of urea in hot nitric acid is added, and the mixture set aside to crystallise. The guanine nitrate now free from uric acid is dissolved in dilute sodium hydroxide and the guanine precipitated by the addition of ammonium chloride, this last operation removing the xanthine (Wulff, Zeitsch. physiol. Chem. 1893, 17, 468).

Fischer (Ber. 1897, 30, 559) has shown that guanine is 2-amino-6-oxypurine from the fact that *imino-ψ-uric acid*

$$HN:C\left<\begin{matrix}NH\cdot CO\\ NH\cdot CO\end{matrix}\right>CH\cdot NH\cdot CO\cdot NH_2$$

obtained synthetically by Traube (Ber. 1893, 26, 2551) from guanidine and ethylmalonate, yields, on treatment with hydrochloric acid (sp.gr. 1·19), at 120°, the same 2-*amino*-6 : 8-*dioxypurine*  as is obtained from *bromoguanine* $C_5H_4BrON_5$ (Fischer and Reese, Annalen, 1883, 221, 342) by the action of hydrochloric acid at 130°. Further, a synthetic guanine, identical in every way with the natural product, is obtained when 6-*oxy*-2 : 8-*dichloropurine* is heated with alcoholic ammonia, and the resulting *chloroguanine* reduced by means of hydriodic acid (Fischer, Ber. 1897, 30, 2226). The synthetical production of guanine has also been effected by Traube (Ber. 1900, 33, 1371) from 2 : 4-*diamino*-6-*hydroxy*·*pyrimidine*  $H_2N\cdot C\left<\begin{matrix}CH\cdot C(OH)\\ N:C(NH_2)\end{matrix}\right>N$, obtained by the condensation of guanidine and ethyl cyanoacetate in the presence of sodium ethoxide. The nitroso derivative of this compound yields, on reduction with ammonium sulphide, 2 : 4 : 5-*triamino*-6-*hydroxypyrimidine*, which, when heated with an equivalent amount of sodium formate and 8–10 times its weight of anhydrous formic acid, is converted into guanine. A similar synthetic production of guanine from 2-*cyanamino*-4-*amino*-6-*hydroxypyrimidine*

$$CN\cdot NH\cdot C\left<\begin{matrix}N.C(OH)\\ N:C(NH_2)\end{matrix}\right>CH,$$

obtained by the condensation of dicyanodiamide and ethyl cyanoacetate in the presence of sodium ethoxide, forms the subject of certain patents of Merck (D. R. PP. 1905, 158591, 162336).

Guanine is an amorphous powder, insoluble in water, alcohol, or ether, but soluble in acids or alkalis, forming salts of a di-acid base, or dibasic acid respectively. It can be obtained in the form of small rhombic crystals when the freshly precipitated compound is dissolved in a large excess of ammonia at 30°–35°, and the filtered solution allowed to evaporate slowly (Drechsel, J. pr. Chem. 1881, 24, 44); or in crystals resembling those of creatinine zinc chloride, when a warm dilute alkaline solution (1 : 2000) is mixed with about one-third its volume of alcohol, acidified with acetic acid and allowed to cool (Horbaczewski, Zeitsch. physiol. Chem. 1897, 23, 226).

The administration of guanine as food to rabbits produces neither increase in purine excretion nor pathological changes in the kidney; but subcutaneous or intravenous injections of guanine dissolved in caustic soda, cause a great increase of purine substances, especially uric acid, in the urine (Schittenhelm, Chem. Zentr. 1902, i. 1306; Schittenhelm and Bendix, Zeitsch. physiol. Chem. 1905, 43, 365).

Guanine is converted to the extent of 60–70 p.c. into xanthine when heated with excess of 25 p.c. hydrochloric acid for 32 hours (Fischer, Ber. 1910, 43, 805); and undergoes profound decomposition, yielding ammonia, carbon dioxide, formic acid, and glycocoll on prolonged treatment with concentrated hydrochloric acid at 180°–200° (Wulff, Zeitsch. physiol. Chem. 1893, 17, 468). A micro-organism belonging to the class of coccus bacteria and found in the excrement of pigeons, flourishes in a culture containing guanine, which is decomposed into urea, guanidine, and carbon dioxide (Ulpiani and Cingolani, Atti. R. Accad. Lincei, 1905, [v.] 14, ii. 596).

The following derivatives of guanine have been described :—

Salts. (1) *With bases*, the *sodium*

$$Na_2O{\cdot}C_5H_5N_5O,6H_2O\,;$$

barium $C_5H_3N_5OBa$; and *copper*

$$C_5H_5N_5O{\cdot}Cu_2O \text{ and } C_5H_5N_5CuO$$

derivatives. (2) *With acids*, the *hydrochloride* $C_5H_5N_5O,HCl,H_2O$, forms double salts with zinc, cadmium, mercury, or platinic chloride ; *hydrobromide* $C_5H_5N_5O,HBr,2\frac{1}{3}H2O$; *hydriodide*

$$C_5H_5N_5O,HI,2\tfrac{1}{3}H_2O$$

forms a double salt with bismuth iodide ; *nitrates* $C_5H_5N_5O,HNO_3,1\frac{1}{2}H_2O$;

$$C_5H_5N_5O,2HNO_3,2H_2O\,;$$

$$3C_5H_5N_5O,4HNO_3,4H_2O\,;$$

and $3C_5H_5N_5O,5HNO_3,5\frac{1}{2}H_2O$;

sulphate $(C_5H_5N_5O)_2H_2SO_4,2H_2O$; *oxalate* $3C_5H_5N_5O,2C_2H_2O_4$; *tartrate*,

$$3C_5H_5N_5O,2C_4H_6O_6\,;$$

dichromate $C_5H_5N_5O,H_2Cr_2O_7$; *picrate*

$$C_5H_5N_5O,C_6H_3N_3O_7,H_2O\,;$$

picrolonate $C_5H_5ON_5,2C_{10}H_8O_5N_4$; *ferricyanide* $(C_5H_5N_5O)_4,H_3Fe(CN)_6,8H_2O$; *nitroferricyanide* $(C_5H_5N_5O)2H_2(CN)_5NOFe,1\frac{1}{2}H_2O$; *metaphosphate* $C_5H_5N_5O,HPO_3,xH_2O$. (3) *With salts*, *mercuric chloride* $C_5H_5N_5O,HgCl_2,2\frac{1}{2}H_2O$; *silver nitrate* $C_5H_5N_5O,AgNO_3$, the *silver picrate compound* $C_5H_4AgN_5O,C_6H_3N_3O_7 1\frac{1}{2}H_2O$ is insoluble in cold water. (*Cp*. Unger, *l.c.* ; Strecker, Annalen, 118, 152 ; Balke, J. pr. Chem. [ii.] 47, 539 ; Neubauer and Kerner, Annalen, 103, 268 ; Wulff, Zeitsch. physiol. Chem. 1893, 17, 468 ; Levene, Biochem. Zeitsch. 1907, 4, 320).

Acyl derivatives. *Acetylguanine*

$$C_5H_4N_5O(C_2H_3O)$$

is crystalline, sparingly soluble in water, alcohol, or ether, and may be heated at 260° without change. *Propionylguanine* $C_5H_4ON_5(C_3H_5O)$ is crystalline, and remains unchanged when heated at 260°. *Benzoylguanine*

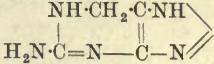
$$C_5H_4ON_5(C_7H_5O)$$

is also crystalline (*cp*. also Bayer & Co., D. R. P. 213711).

Azo derivatives. Guanine and other purine bases that are not substituted in position 7 react with diazobenzenesulphonic acid to form coloured *azo* compounds, in which the ·N : NR group is attached to carbon atom 8. Guanine and *p*-dichlorodiazobenzene chloride yield a dark-red dye, which forms 8-aminoguanine when reduced. The amino compound does not itself couple with diazo compounds, but can be diazotised at 40°, and then yields a violet dye with an alkaline solution of R salt (Burian, Ber. 1904, 37, 696, 708 ; Hans Fischer, Zeitsch. physiol. Chem. 1909, 60, 69). This reaction has been applied by Amatore de Giacomo (Zeitsch. wiss. Mikroscop. 1910, 27, 257) to a microchemical method for demonstrating the presence of guanine in the renal system of birds.

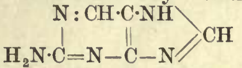
Bromoguanine $C_5H_4N_5OBr$ is a white crystalline powder, almost insoluble in water, alcohol, or ether. It forms crystalline salts with acids, *e.g.* $C_5H_4N_5OBr,HCl$, and also unites with lead or silver to form crystalline compounds, which, when heated with methyl iodide at 100°, yield bromocaffeine. Nitrous acid converts bromoguanine into bromoxanthine (Fischer and Reese, Annalen, 1883, 221, 336).

Deoxyguanine



$$\begin{array}{l} NH{\cdot}CH_2{\cdot}C{\cdot}NH \\ \;\;| \qquad\qquad\;\; \| \\ H_2N{\cdot}C{=}N{-}C{-}N \end{array}\!\!{>}CH$$

is obtained when guanine is electrolytically reduced in 60 p.c. sulphuric acid solution, it crystallises in microscopic needles, melts and decomposes at 204°, and has strongly basic properties combining with atmospheric carbon dioxide. It is oxidised by bromine to 2-*aminopurine*



$$\begin{array}{l} N{:}CH{\cdot}C{\cdot}NH \\ \;\;| \qquad\quad \| \\ H_2N{\cdot}C{=}N{-}C{-}N \end{array}\!\!{>}CH$$

a crystalline base more readily soluble than its isomeride, *adenine*.

Tests. Warm dilute solutions of guanine hydrochloride give with a saturated solution of picric acid, an orange-red crystalline insoluble precipitate ; xanthine and hypoxanthine give a similar reaction in very concentrated solutions only (St. Capranica, Zeitsch. physiol. Chem. 1880, 4, 233).

When guanine nitrate solution is evaporated it leaves a yellow residue, soluble in potassium hydroxide with a yellow colouration. On evaporating the yellow solution to dryness, it affords first a purple, then a violet colouration, and on exposure to air the original colour returns (Brücke, Montash. 1886, 7, 617).

Estimation. The formation of the insoluble picrate has been recommended by Wulff (Zeitsch. physiol. Chem. 17, 468) for the estimation of guanine. M. A. W.

GUANO *v.* FERTILISERS.

GUANOSINE, identical with *Vernin*

$$C_{10}H_{13}O_5N_5,2H_2O,$$

a compound of guanine and *d*-ribose, occurs in certain plants, and forms one of the products of hydrolysis of nucleic acid; it decomposes at 237°, and has $[\alpha]^{20}_{D}-60{\cdot}52°$ (Levene and Jacobs, Ber. 1909, 42, 2469 ; Schulze, Zeitsch. physiol. Chem. 1910, 66, 128 ; Schulze and Trier, *ibid.* 1910, 70, 143).

GUANYLUREA, *Dicyandiamidine*, *v.* DICYANDIAMIDE.

GUARANA (*Uarana*). Guarana is a dried paste prepared from the seeds of the *Paullinia Cupana* (H. B. and K.), a climbing shrub inhabiting the northern and western provinces of Brazil. It is made for the most part by different sections of the Guaranis, a tribe of South American Indians, and probably by different methods. Generally, however, the ground or powdered seeds are moistened by exposure to dew, or by the addition of water, kneaded into a paste, made into cylindrical or globular masses and dried before fires, in chimneys, or by the heat of the sun. These cakes as they appear in commerce are hard, with a rough reddish-brown exterior, and somewhat lighter colour inside. They evolve a chocolate-like odour, and have a bitter astringent taste. In South America guarana is an article of food used much in the same manner as we employ cocoa, and in European medicine it is administered as a nervous stimulant for the relief of certain kinds of headache. For further details as to its source, preparation, and uses *v.* Cooke (Pharm. J. [iii.] 1, 221); Hallawell (*ibid.* [iii.] 3, 773); Squibb (*ibid.* [iii.] 15, 165); Rusby (*ibid.* [iii.] 18, 1050); and Marsden (Annals Trop. Med., 4, 105).

The physiological activity of guarana depends upon the presence of an alkaloid at first termed 'guaranine' but afterwards found to be identical with *caffeine* (*v.* CAFFEINE) (Martius, Kastn. Archiv. 7, 266; Annalen, 36, 93; Berthemot and Dechastelus, J. Pharm. Chim. 26, 518). Stenhouse obtained the alkaloid by extracting powdered guarana with about fifty times its weight of boiling water, and treating the solution when cold with basic lead acetate. A precipitate of alkaloid and salts of lead falls from which repeated extraction with hot water removes the caffeine. The aqueous solution is freed from lead by sulphuretted hydrogen, evaporated to dryness, and the residue treated with hot alcohol. From this solution, on concentration, crystals of the alkaloid are obtained, which may be purified by recrystallisation (Pharm. J. [i.] 16, 212). For other methods *v.* Greene (*ibid.* [iii.] 8, 87), who prefers to extract a mixture of guarana and three times its weight of litharge with boiling water; C. J. Williams (Chem. News, 26, 97), who exhausts a moistened and slowly dried mixture of guarana and lime with benzene; Squibb, (Pharm. J. [iii.] 15, 165) and Bochefontaine and Gusset (Ch. Tech. C. Anzeiger, 4, 322), who treat a mixture of guarana and magnesia with weak alcohol and chloroform respectively. Kremel (Ph. Post. 21, 101) determines the caffeine in guarana by placing 10 grams in a flask with 100 c.c. of 25 p.c. alcohol, noting the total weight, and digesting for 1 or 2 hours at 100°. The weight lost by evaporation is made up with similarly diluted alcohol, and 50 c.c. of the solution, corresponding to 5 grams of guarana, is separated by filtration, mixed with calcium hydroxide, and evaporated to dryness. The residue is extracted with chloroform, from which the alkaloid is obtained in crystals, dried at 100° and weighed. The following percentages of caffeine are selected from published analyses of guarana; 5·10, 5·04 (Stenhouse); 5·05 (Greene); 4·20-5·00 (5 samples, Feemster, Pharm. J. [iii.] 13, 363); 4·5 (B. and Gusset); 3·12, 3·80 (Kremel). Feemster found in the seeds 5·08 p.c. and Peckolt (J. 1866, 709), in the shelled seeds 4·81 p.c.; seed shells 2·44 p.c. and pulp 4·29 p.c. Thoms (Pharm. Centh. 1890, 533) however states that the proportion of caffeine in guarana has been overestimated, and this has been confirmed by Kirmsse (Arch. Pharm. 236, 122), who found in three samples 2·68, 2·97, and 3·10 p.c. respectively.

Besides caffeine, guarana contains gum, starch, an acrid *green fixed oil*, a *concrete volatile oil*, and *tannin* (Fournier, J. Pharm. Chim. 1861, 291). The tannin further examined by Greene (Pharm. J. [iii.] 8, 328) was found to behave towards reagents unlike previously known varieties, and the term *paullinitannic acid* was, therefore, applied to it. It forms a yellowish-white amorphous mass, having an astringent taste. It is easily soluble in water or alcohol. By extraction of the crude tannin with ether, crystals are obtained identical with those of the catechin of Pegu catechu (Kirmsse, *l.c.*). Kremel found 1·3-2·0 p.c. of *ash* consisting chiefly of phosphates.

A specimen of guarana examined by Nierenstein, probably derived from *Paullinia trigonia* (Vell.), was found to contain an alkaloid, *β-guaranine.* This was obtained in the form of small needles, m.p. 217°-219°; after drying, the substance had the composition $C_{40}H_{47}O_{21}N_4$. The guarana contained 4·3 p.c. of tannic acid, which, after purification, was obtained in small colourless needles; m.p. 199°-201°. The tannin, *guaranatannic acid*, appears to resemble the chlorogenic acid obtained from coffee (Gorter, Annalen, 358, 327; 359, 217) rather than catechin, but is not identical with either of these substances (Annals Trop. Med. 4, 115). A. S.

GUAVA. The fruit of *Psidium Guajava* (Linn.). Prinsen-Geerligs (Chem. Zeit. 1897, 21, 719), gives the following data:—

Average wt. in grammes	The fruit consists of			The flesh contains		
	Flesh	Skin	Seeds	Glucose p.c.	Levulose p.c	Sucrose p.c.
65·0	85·0	12·0	3·0	2·0	0·5	1·7

H. I.

GUERNSEY BLUE. A colouring matter belonging to the INDULINE group (*q.v.*).

GUIGNET'S GREEN *v.* CHROMIUM.

GUINEA GREEN B. The sodium salt of the disulphonic acid of diethyl- dibenzyl- diamino- triphenyl- carbinol. Is a dark-green powder resembling Light-green S or Acid Green, *v.* TRIPHENYLMETHANE COLOURING MATTERS.

GULAUCHA, GULOE, and **GILOE.** Indian names for *Tinospora cordifolia* (Miers.). This plant flourishes in India, the drug being sold extensively in the bazaars as a tonic and antiperiodic, in the form of cylindrical pieces 2–5 cm. long and 1–5 cm. in diameter. It is a perennial creeper, climbing to the summits of the highest trees, its branches putting forth roots which, reaching to the ground, initiate a fresh growth. Roots, stems, and leaves are equally in demand as a drug. The Indian pharmacopœia commends its use as a tincture (4–8 c.c. *in die*); as an extract (0·6–1 gram *per diem*) in the form of pills; and as an infusion (1 : 10), of which 60-90 c.c. are to be taken thrice a day. The stems contain *verberin*, an uncrystallisable bitter substance, changed by dilute sulphuric acid into a glucoside, and a bitter kind of starch meal known as 'palo' (J. Soc. Chem. Ind. 6, 49).

GUM RESINS. This article includes the more important members of that group of products which consist essentially of a mixture of gum and resin. They are generally the exudated milky juice of plants dried by spontaneous evaporation. When triturated with water they give more or less perfect emulsions. Compare introduction to article RESINS.

Ammoniacum; *Gummi-resina ammoniacum. Gomme-résine ammoniaque*, Fr.; *Ammoniak gummi-harz*, Ger.

Persian ammoniacum. The ammoniacum of the early Greek physicians came from Africa, and was probably that variety known as African ammoniacum. The drug, which has however since the tenth century been an article of European commerce, is obtained from Persia and neighbouring districts, reaching our markets according to Dymock (Pharm. J. [iii.] 6, 321) now generally by way of Bombay. It is the inspissated juice collected from the stems of the *Dorema Ammoniacum* (D. Don). For plates *v.* Bentl. a. Trim. 131. This plant attains a height of 6–8 feet, and the flow of juice from its stem is caused by punctures made by beetles.

The gum-resin occurs in commerce as brittle grains or tears or roundish lumps, pale yellow externally and waxy milky-white within. It softens readily when warmed. In taste it is bitter and acrid, and it possesses a characteristic odour. Triturated with water it forms an emulsion. A very complete account of the literature of ammoniacum, including the result of the examination of some twenty specimens, will be found in the memoir of Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 612, 710, and 770). The sp.gr. of ammoniacum is 1·207, and 3 parts of it dissolve in 4 of alcohol. Hypochlorites, as for example a solution of bleaching powder, impart to it a bright-orange colour, a character that serves to distinguish it from the African variety which is not affected by these reagents. The allied gum-resin galbanum also gives no colour reaction with hypochlorites.

Ammoniacum consists essentially of *resin*, *gum*, and a small proportion of *volatile oil.* The *resin* constitutes 70 p.c. of good specimens of the drug. A sample of ammoniacum examined by Luz (Arch. Pharm. 233, 540) contained 4·5 p.c. of water, 69 p.c. of resin, 22·7 p.c. of substances soluble in water, and 3·5 p.c. of substances, other than resin, insoluble in water. A considerable amount of salicylic acid was present, but no aldehydes or terpenes. Normal butyric and valeric acids were also present largely in combination with a resin alcohol *ammoresinotannol* $C_{18}H_{30}O_3$, a chocolate-brown, tasteless and odourless powder, soluble in alkalis and acids. The resin consists essentially of ammoresinotannol salicylate. It melts at from 35° to 50°, is soluble in alcohol, chloroform, glacial acetic acid, sulphuric acid, and alkalis, partly soluble in carbon disulphide, benzene, and solution of ammonia, and insoluble in light petroleum. Sommer (J. 1859, 573) was unable to obtain umbelliferone from the gum-resin, but resorcinol, $C_6H_4(OH)_2$, and protocatechuic acid, $C_6H_3(OH)_2COOH$, are formed when it is fused with potash (Hlasiwetz and Barth, Annalen, 130, 354). It yields styphnic acid, trinitroresorcinol, $C_6H(NO_2)_3(OH)_2$, when treated with nitric acid (Will and Böttger, Annalen, 58, 269; *cf.* Schwanert, *ibid.* 128, 123).

Ammoniacum gum is partly soluble and partly insoluble in water. The insoluble portion, which constitutes a fourth of the gummy constituents, appears to be identical with the similar bassorin-like gums which occur in asafœtida and galbanum. When treated with 20 p.c. hydrochloric acid, besides humus substances, it yields lævulic acid, and, on oxidising with nitric acid, 31·3 p.c. of mucic acid (equivalent to 41·75 p.c. of galactose), but no saccharic acid. When distilled with dilute hydrochloric acid, it yields 9·35 p.c. furfuraldehyde (equivalent to 16·67 p.c. of arabinose), and when boiled with dilute sulphuric acid reducing sugars are obtained, consisting chiefly of galactose (Frischmuth, Chem. Zentr. 1897, ii. 1078).

Volatile oil of ammoniacum exists only to the extent of ⅓ p.c. Hirschsohn obtained no volatile oil by distillation with water, but light petroleum gave him 1·4–6·7 p.c. of volatile oily residues. Flückiger and Hanbury describe the oil as unlike that of galbanum, possessing in a high degree the odour of the drug, and being free from sulphur.

To test ammoniacum for galbanum resin 5 grams is boiled with 15 grams of strong hydrochloric acid for 15 minutes, 15 c.c. of water is then added, and the liquid filtered through a wetted, double filter; ammonia is added to the clear filtrate when a blue fluorescence reveals the presence of galbanum (Dieterich. Chem. Zentr. 1896, ii. 1137). For method of examination and table giving analytical constants, *see* Dieterich, *l.c.*, and Pharm. Centh. 40, 467.

Ammoniacum is employed in medicine internally as an expectorant, and externally as a constituent of plasters.

African ammoniacum. This, according to Hanbury (Pharm. J. [iii.] 3, 741), is the ammoniacum of Dioscorides and the older writers. It is derived, according to Lindley (Pereira, Mat. Med. 1853, 1715), from the *Ferula tingitana* (Linn.), a plant inhabiting the African coast of the Mediterranean Sea.

African ammoniacum, which is scarcely known in European markets, is described by Pereira as consisting of dark-coloured masses which internally have much the appearance of the Persian variety. The odour is, however, quite distinct. It forms an emulsion with water. Moss examined a specimen in 1873 (Pharm. J. [iii.] 3, 742) which consisted of *resin* 67·76 p.c., *gum* 9·01 p.c., *water* and *volatile oil* 4·29 p.c., and *bassorin* and *insoluble matter* 18·85 p.c. It contained 13·47 p.c. of *ash.* It softened between the fingers more readily than Persian ammoniacum. Similar results were obtained by Hirschsohn By distilling it, however, the last observer isolated *umbelliferone*

$$C_6H_3(OH)\Big<\begin{matrix}CH=CH-CO\\ O\text{————————}\end{matrix}.$$

Goldschmiedt (Ber. 11, 850) announces that by fusion with potash African ammoniacum yields resorcinol, together with *an acid* $C_{10}H_{10}O_6$. This acid is not produced when the Persian drug is similarly treated.

Asafœtida; *Gummi-resina Asafœtida. Asafœtida*, Fr.; *Asant, Stinkasant, Teufelsdreck*, Ger.

Gum-resin asafœtida is the dried juice of the roots of two large herbaceous plants which inhabit Tibet, Afghanistan, Turkestan, and the country from the Sea of Aral to the Persian Gulf. These are the *Ferula Narthex* (Boissier) and the *Ferula fœtida* (Regel). For drawings *v.* Bentl. a. Trim. 126–127, and Holmes (Pharm. J. [3] 19, 21, 41, and 365). Details of the mode of preparing the roots and of collecting the dried exudation are given by Flückiger and Hanbury (Flück. and Hanb. 316) and by Pereira (Mat. Med. 1853, 2, 1704). It is certain that asafœtida was known to the Arabian writers of the tenth century, and there is reason to believe that a knowledge of the drug is far more ancient.

Supplies of asafœtida are now almost entirely derived by way of India from Afghanistan. It occurs as tears more or less agglutinated, and sometimes as a honey-like mass. It is often largely mixed with earthy matter. A characteristic property of the drug is that when broken the milky white surface changes gradually to a pink, which passes into a brown hue. Touched with nitric acid (sp.gr. 1·2) it gives a green colour. With water it forms an emulsion. The tears are brittle, and may be powdered when cold. Asafœtida has a powerful alliaceous odour and an acrid bitter alliaceous taste.

The chief constituents of asafœtida are *resin, gum,* and *volatile oil.* For results of early investigations *v.* Gm. 17, 398. The analysis of Pelletier (Bull. Pharm. 3, 556) shows that the resin amounts to 65·0 p.c., the soluble gum 19·44 p.c., the insoluble gum 11·66 p.c., and the volatile oil 3·6 p.c., or, according to Flückiger and Hanbury, 6–9 p.c. The resin is only partly soluble in ether and chloroform, but is entirely dissolved without alteration by concentrated nitric acid (*cf.* Johnston, Phil. Trans. 1840, 354). Hlasiwetz and Barth (Annalen, 138, 64) discovered in the resin *ferulic acid,* the methylphenolic ether of hydroxycinnamic or caffeic acid,

$$C_6H_3(CH{:}CH{\cdot}COOH)(OCH_3)(OH)1:3:4$$

An alcoholic solution of asafœtida is precipitated by an alcoholic solution of lead acetate, and from the insoluble lead salt the ferulic acid is regenerated. It consists of needles melting at 168°–169° (Tiemann, Ber. 9, 416). Vanillin was shown to be present in asafœtida by Schmidt (Arch. Pharm. [3] 24, 534).

Pure drops of *Asafœtida amygdaloides* examined by Polásek (Arch. Pharm. 235, 125), gave the following results: resin, soluble in ether, *asaresinotannol ferulate,* 61·40; resin, insoluble in ether, free *asaresinotannol,* 0·60; gum, 25·1; essential oil, 6·7; vanillin, 0·06; ferulic acid, 1·28; moisture, 2·36 p.c. On hydrolysis with potassium carbonate, the soluble resin yields asaresinotannol and ferulic acid; with sulphuric acid, however, it is hydrolysed into the same tannol and umbelliferone. Asaresinotannol is a brownish-yellow amorphous substance, and has the composition $C_{24}H_{34}O_5$.

When asafœtida resin is distilled alone, *variously tinted oils* are obtained, with $\frac{1}{4}$ p.c. of umbelliferone (Sommer J. 1859, 573). Fused with potash, resorcinol and protocatechuic acid are formed (Hlasiwetz and Barth), and treated with nitric acid it yields trinitroresorcinol or styphnic acid (Will and Boettger, Annalen, 58, 269).

The gum of asafœtida consists of two portions, the one soluble and the other insoluble in water. The volatile oil is described by Flückiger and Hanbury as of a light-yellow colour with the odour of asafœtida. The taste is at first mild and then irritating, but it does not stimulate when applied to the skin like mustard oil. The oil is neutral, but becomes acid by exposure to the air, at the same time evolving sulphuretted hydrogen. By fractional distillation of the oil under reduced pressure, Semmler (Ber. 23, 3530; 24, 78) finds that it contains two *terpenes* $C_{10}H_{16}$; a *substance* $(C_{10}H_{16}O)_x$, which gives a *sesquiterpene* $C_{15}H_{24}$ when acted upon by sodium; an *oil* $C_7H_{14}S_2$ boiling at 210°–212° with slight decomposition; and an *oil* $C_{11}H_{20}S_2$, which decomposes on distillation under the ordinary pressure with evolution of most repulsive smelling gases.

Asafœtida is used in medicine as a nervous stimulant and antispasmodic, and in the East as a condiment.

Other varieties of asafœtida. The *Hing* used by the natives of Bombay is a variety of asafœtida. It is derived from *Ferula alliacea* (Boissier). It is more repulsive, and contains a larger proportion of volatile oil than asafœtida (Flückiger, Pharm. J. [iii.] 6, 401; Flück. a. Hanb. 319).

Bdellium.

Indian Bdellium; False Myrrh; Bdellium. This is the bdellium of the Bible, and is now used chiefly as an adulterant of myrrh. It is the product of *Balsamodendron Mukul* (Hooker) and, according to Dymock, also of the *B. Roxburgii* (Arnott) (*cf.* Pharm. J. [iii.] 6, 661). Both are indigenous to India, but grow perhaps also in Southern Arabia. The gum-resin breaks with a flat conchoidal fracture, and though somewhat darker in colour, it resembles myrrh in appearance. It may be distinguished from myrrh by its not giving the violet colour reaction (*v. Myrrh*). (For analytical constants of bdellium *v.* Dieterich Pharm. Centr. 40, 467.)

African Bdellium. A more highly esteemed bdellium, the product of *Balsamodendron africanum* (Arnott), a shrub indigenous to West Africa. It is used in France as a constituent of plasters. In fracture and other respects it resembles myrrh, but it does not give the violet colour reaction (*v. Myrrh*). African bdellium was analysed by Pelletier (Ann. Chim. Phys. [ii.] 80, 38), who found *resin* 59 p.c., *soluble gum* 9·2 p.c., *insoluble gum* 30·6 p.c., *volatile oil* and loss 1·2 p.c. The resin was further examined by Johnston (Phil. Trans. 1840, 368). *Cf.* Bley and Diesel (Arch. Pharm. [ii.] 43, 304).

Euphorbium. *Gomme-résine d'Euphorbe,* Fr.; *Euphorbium,* Ger. This extremely acrid drug has been known since the time of Dioscorides, but it is now very seldom employed in medicine. It is the inspissated milky juice of the *Euphorbia resinifera* (Berg), a cactus-like plant inhabiting Morocco and neighbouring districts of Northern Africa. A drawing is given by Bentl. a. Trim. 240. Euphorbium consists of irregular masses of a waxy-yellow or brown appearance, often inclosing spines and other fragments of the plant. It has a slight aromatic odour and an extremely acrid taste, its dust causing violent and even dangerous irritation to the nose or throat.

Flückiger (Flück. and Hanb. 560) found a selected specimen to consist of *amorphous resin,* 38 p.c.; *euphorbon,* 22 p.c.; *mucilage,* 18 p.c.; *malate of calcium, sodium,* &c., 12 p.c.; *mineral compounds,* 10 p.c. It contains no volatile oil.

Examined by Tschirch and Paul (Arch. Pharm. 234, 249) 100 parts of the drug were found to contain euphorbic acid, 0·7; euphorbone, 40; amorphous resins, 21; malates, 25; carbohydrate, 2; impurities and loss, 11. *Euphorbic acid,* which is extracted from an ethereal solution of the resin by 1 p.c. aqueous ammonium carbonate, is amorphous, has the m.p. 107°–108° and the composition $C_{24}H_{30}O_6$. *Euphorbone* $C_{30}H_{48}O$ is best obtained from the drug by extraction with light petroleum and crystallisation first from alcohol and then repeatedly from acetone. It melts at 115°–116°.

Euphorboresene $C_{33}H_{48}O_4$ remains as an amorphous mass, m.p. 74°–76°, after steam distillation for some weeks of the resin freed from euphorbone and mixed with aqueous potassium hydroxide. The residual alkaline liquid, on being acidified, gives an amorphous precipitate of *a-euphorboresene* $C_{28}H_{48}O$, which melts at about 75°, and is now insoluble in dilute aqueous potassium hydroxide. From an aqueous extract of the drug calcium malate was isolated; also a dextrorotatory carbohydrate precipitated by alcohol, and another, possibly a pentosan, which remained dissolved.

When a filtered light petroleum extract of euphorbium resin is floated on a solution of one drop of concentrated sulphuric acid in 20 c.c. of water, a very stable blood-red layer is formed at the surface where the two liquids touch; on shaking, the whole of the acid liquid becomes red, and this colour only slowly changes to brown. This reaction may be used for purposes of identification; an extract of the most suitable concentration is obtained from 0·1 gram of euphorbium and 10 c.c. of light petroleum.

Euphorbium is now used only in veterinary medicine. Applied externally to the human subject it is irritant and vesicating, and internally administered it causes violent vomiting and purging. It is said to be an efficient preservative of iron and steel against corrosion (Year Book Pharm. 1880, 344).

Galbanum; *Gummi-resina Galbanum. Galbanum*, Fr.; *Mutterharz*, Ger. Galbanum has entered into the constitution of incense, and has been employed in medicine from the earliest times. It was used by the Israelites, and was well known to Hippocrates, Theophrastus, and Dioscorides, also to the Arabians, and still retains its place in the official pharmacopœias of Europe and the United States. But notwithstanding its antiquity, the precise plant from which galbanum is derived still remains uncertain. It is most probably obtained from the *Ferula galbaniflua* (Boissier and Buhse), and perhaps from other allied species of *Ferula*, natives of Persia. For figure *v.* Bentl. a. Trim. 128 (*cf.* Holmes, Pharm. J. [iii.] 19, 365).

The gum-resin occurs in commerce in drops or tears, usually adhering into solid masses. In colour it exhibits various shades of light yellowish-brown, sometimes tinted with green. The odour of galbanum is aromatic, and the taste unpleasant, bitter, and alliaceous. Flückiger and Hanbury (Flück. a. Hanb. 323) note that when galbanum is warmed with concentrated hydrochloric acid a red colour is developed, which on the careful addition of spirit of wine, turns violet or bluish. Asafœtida treated in the same manner assumes a dingy colour, whilst ammoniacum gives no colour change at all. Further details of the characters of galbanum and its behaviour towards reagents are given in an elaborate memoir by Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 369, 389, 429, 531, and 571). This observer divides galbanum of commerce, according to its physical character, into three varieties, one coming from Persia and two from the Levant, or, according to its behaviour towards reagents, into four sorts—one from Persia and three from the Levant.

Galbanum resin examined by Conrady (Arch. Pharm. 232, 98) was found to contain 9·5 p.c. of ethereal oil; 63·5 p.c. of a resin soluble in alcohol; and 27·0 p.c. of impurities and gum. The pure resin obtained from the commercial product by extraction with alcohol and subsequent treatment with sodium salicylate contains 20 p.c. of combined umbelliferone; 50 p.c. of galbaresinotannol; and 0·25 p.c. of free umbelliferone. The resin which most probably consists of a galbaresinotannylic salt of umbelliferone is best hydrolysed by sulphuric acid since umbelliferone is unattacked by this reagent. *Galbaresinotannol* on analysis gives numbers agreeing with the formula $C_{18}H_{30}O_3$; on distillation with phosphoric anhydride it yields a hydrocarbon $C_{15}H_{20}$ and, on oxidation with nitric acid, camphoric and camphoronic acids. The volatile oil is obtained by distillation with water or by extraction with light petroleum. According to Flückiger and Hanbury, the crude oil possesses an aromatic taste and is dextrorotatory. On the addition of bromine to the oil extracted from Persian galbanum a red to violet or blue colour appears. The oil consists partly of a *hydrocarbon* $C_{10}H_{16}$ which gives a crystalline hydrochloride $C_{10}H_{16},HCl$. The chief part, however, is a mixture of heavier hydrocarbons (*cf.* Moessmer, Annalen, 119, 237).

When galbanum resin is distilled a small quantity of umbelliferone is obtained (Sommer, J. 1859, 573). This compound is now known to be a product of the distillation of many other resins or gum-resins, especially those of the *Umbelliferæ*. Galbanum yields 0·83 p.c., sagapenum 0·32 p.c., asafœtida 0·28 p.c. Synthetically, umbelliferone may be produced, as pointed out by Pechmann (Ber. 17, 932), by acting upon a mixture of resorcinol and malic acid with dehydrating agents such as sulphuric acid, thus:

$$C_6H_4(OH)_2+C_2H_3(OH)(COOH)_2$$

$$=C_6H_3(OH)\begin{cases}CH=CH-CO\\O\end{cases}+HCOOH+2H_2O$$

Another product of the destructive distillation of galbanum resin is a thick *brilliant blue oil.* The oil deposits in the cold crystals of umbelliferone. It has a bitter acrid taste and aromatic odour. Kachler (Ber. 4, 36) separated it into a *colourless hydrocarbon* $C_{10}H_{16}$ boiling at 240°, and a *blue oil* $C_{10}H_{16}O$ which boiled at 289°. The flowers of the wild chamomile *Matricaria Chamomilla* (Linn.) yield a blue oil very similar to that obtained from galbanum. Both oils are converted by potassium into the hydrocarbon $C_{10}H_{16}$, which on the addition of bromine vapour gives the blue colour reaction. Hlasiwetz and Barth (Annalen, 130, 354) have shown that by fusing galbanum resin with potash as much as 6 p.c. of resorcinol is formed (*cf.* Goldschmied, Ber. 11, 850); and by treatment with nitric acid, Will and Boettger (Annalen, 58, 269) obtained styphnic acid (*cf.* Schwanert, Annalen, 128, 123).

Hirschsohn in his experiments, after removal of the volatile oil and resin and a little saccharine and astringent matter, by extraction of galbanum with light petroleum, ether, and 85 p.c. alcohol, successively, treats the residue with water to obtain the gum. The yield was 6–17 p.c. The sugar obtained from this gum by the action of dilute acids is optically distinct from that produced in the same way from gum arabic.

Galbanum is administered in medicine internally as an expectorant, and externally it is applied in the form of plasters.

A table of the acidity, ether, and saponification numbers of galbanum resin is given by Dieterich (Pharm. Centh. 40, 467).

Gamboge. *Cambogia, Cadie Gum, Gummi Gambogia, Gummi Gutti. Gomme Gutte*, Fr.; *Gutti, Gummigutt*, Ger. This beautiful orange-red gum-resin comes to us from Camboja, Siam, and Cochin China, where it is the product of a laurel-like tree, the *Garcinia Hanburyi* (Hook.); *v.* Bentl. a. Trim. 33. Gamboge was known to the Chinese in the thirteenth century, but it was not until the seventeenth century that it appeared in European markets. For the purpose of collecting it the trees are incised, and sections of bamboo are attached to collect the milky juice, which, hardening by evaporation, takes the cylindrical shape of the receiving vessel. Gamboge as it occurs in commerce is brittle, and may be powdered readily. In presence of water it forms at once a yellow emulsion. It has a disagreeable and acrid taste.

Among the earlier investigators who analysed gamboge are Braconnot (Ann. Chim. Phys. [i.] 68, 33), John (Chem. Schriften, 4, 193), Unverdorben (N. Jour. Trommsdorf. 8, 1, and 60), Christison (Annalen, 23, 185), Johnston (Phil. Trans. 1839, 281), and Büchner (Annalen, 45, 72). Costelo (Amer. J. Pharm. 1879, 174), finds the *resin* to vary from 68 to 79 p.c., and the *gum* from 19 to 27 p.c. (*cf.* Hurst, Pharm. J. [iii.] 19, 761). The gum is extracted by water. Its solution, like arabic, is not precipitated by neutral lead acetate, but its behaviour towards other reagents shows it to be a different gum. By the action of dilute acids it yields a *non-fermentable sugar*, and when oxidised by nitric acid, mucic acid $C_4H_4(OH)_4(COOH)_2$ is formed.

Alcohol dissolves the resin. It combines with bases, and is called by Johnston *gambodic acid.* By fusion with potash, Hlasiwetz and Barth (Annalen, 138, 68) obtained a number of interesting products. Besides several acids of the fatty series, these observers isolated phloroglucinol $C_6H_3(OH)_3(1:3:5)$; pyrotartaric acid $CH_3{\cdot}CH(COOH)CH_2{\cdot}COOH$; and *isomesidic, isouvitic*, or *isovitinic acid* $C_6H_4{\cdot}CH_2(COOH)COOH$. This last-mentioned acid has since been produced by the action of hot dilute alkali on benzylcyanide-*o*-carboxylic acid $CN{\cdot}CH_2{\cdot}C_6H_4{\cdot}COOH$, which converts the cyanogen into a carboxylic group (Wislicenus, Annalen, 233, 106).

For the detection of gamboge in mixtures, *v.* Hirschsohn (Pharm. Zeit. 24, 609). In medicine gamboge is employed as a drastic purgative, usually in combination with other substances. It is also an important colouring agent.

Ivy gum resin. *Gummi-resina Hederæ.* In Southern Europe and in the Levant a gum-resin is obtained from the old trunks of the common ivy, *Hedera Helix* (Linn.). It consists of irregular masses of a reddish or yellowish-brown colour externally, but showing a deep red by transmitted light. The taste is bitter and acrid, but when heated it evolves a balsamic odour. Pelletier (Bull. Pharm. 4, 504) found the gum-resin to consist of *resin* 23 p.c., *gum* 7 p.c., and 70 p.c. of woody fibre. Examined by Sommer (Arch. Pharm. [ii.] 98, 11) it gave no umbelliferone.

Besides the gum-resin the leaves, berries, and the wood itself of ivy have been used in medicine and they have been examined by chemists. Hartsen (J. 1875, 827) found ivy leaves to contain a glucoside allied to saponin, and this was afterwards studied by Davies and Hutchinson (Pharm. J [iii.] 7, 275), Davies (*ibid.* [iii.] 8, 205), Kingzett (*ibid.* [iii.] 8, 206), Vernet (J. 1881, 91), Vincent (Bull. Soc. chim. 35, 231), and Block (Arch. Pharm. [iii.] 26, 953). Most of these observers obtained the glucoside from ivy berries. Davies and Hutchinson regard it as identical with the *hederic acid* which, together with *hederotannic acid*, Posselt found in ivy berries (Annalen, 69, 62).

Hederic acid or *ivy glucoside* $C_{32}H_{54}O_{11}$ is deposited in needles from the alcoholic extract of ivy berries that have been previously exhausted with ether (D. and H.), or the berries may be exhausted with alcohol, and the residue, after the alcohol has been removed by distillation, washed in the cold with benzene and extracted with hot acetone. On concentrating the solution a crystalline mass is obtained which is purified by recrystallisation from alcohol (Vernet; Vincent). The glucoside forms silky needles which melt at 233°. It is insoluble in water, chloroform, or light petroleum, is slightly soluble in cold acetone, benzene, or ether, and very soluble in hot alcohol and alkalis. It is inodorous, but possesses the taste of the berries. By the action of dilute acids it breaks up into a crystalline *compound* $C_{20}H_{42}O_6$ (?), which melts at 278°–280° and a non-fermentable *sugar* which reduces Fehling's solution.

Houdas (Compt. rend. 128, 1463) has separated from ivy a glucoside *hederin* $C_{64}H_{104}O_{19}$, which crystallises from alcohol in thin needles, melting at 248°. When hydrolysed with dilute sulphuric acid hederin gives rise to an insoluble product hederidin, and to two sugars hederose and rhamnose. *Hederidin* $C_{26}H_{40}O_4$ crystallises from boiling alcohol in sparkling prisms, which melt at 324°, and sublime undecomposed. *Hederose* $C_6H_{12}O_6$ crystallises in shining needles, and is very soluble in water or boiling alcohol. It melts at 155°, and is dextrorotatory.

The physiological action of ivy and hederin has been studied by Joanin (Compt. rend. 128, 1476).

Myrrh. *Myrrha*; *Heerabol Myrrh*; *Gummi-resina Myrrha. Myrrhe*, Fr.; *Myrrhe*, Ger. Together with olibanum, myrrh has been used as a constituent of incense from the earliest times. It is mentioned in Genesis and in other places in the Bible. The Egyptians employed it not only in fumigations, but also in embalming and in medicine. It has retained its place down to the present day, and is included in all the pharmacopœias. Myrrh is the spontaneous gum-resinous exudate of the shrubs or small trees of the *Balsamodendron Myrrha* (Nees), an inhabitant of the Somali coast of the Gulf of Aden and of the Red Sea coast of Arabia (Trimen, Pharm. J. [iii.] 9, 893). A drawing of the tree is given by Bentl. a. Trim. 60. The exudate is allowed to harden on the tree before collection. It occurs in irregular-shaped masses of a red-brown colour and dusty appearance. When cold it is brittle, and breaks with an uneven, waxy, oily-looking fracture, often exhibiting lighter-coloured semicircular striations. With water it readily yields an emulsion. The odour of myrrh is fragrant and agreeable, and the taste bitter, aromatic, and acrid.

The chief constituents of myrrh are *gum*, *resin*, and *volatile oil.* The relative proportions, even in the case of true myrrh, vary greatly in different specimens. Generally the gum constitutes 40–65 p.c., the resin 25–40 p.c., and the volatile oil is said to reach 4·4 p.c. Flückiger and Hanbury (Flück. a. Hanb. 143) found 27 p.c. of resin in a good specimen, and Köhler (Arch. Pharm. 228, 291) found 7–8 p.c. of volatile oil. Brückner's analysis (Neues Rep. Pharm. 16, 76) gave: soluble in water, gum, 67·76 p.c.; resin soluble in carbon disulphide, 14·06 p.c.; resin soluble in ether, 12·57 p.c.; resin insoluble in ether, 4·81 p.c.; substances soluble in diluted alcohol, 0·43 p.c.; insoluble (sand, bark, &c.), 0·38 p.c.

Myrrh resin is soluble in alcohol or chloroform, but it is only partly soluble in ether, carbon disulphide, or alkalis. According to Köhler (*l.c.*) it is a mixture of several resins, the greater portion of which is a soft resin $C_{26}H_{34}O_5$ soluble in ether. There are also present two dibasic acids $C_{13}H_{16}O_{18}$ and $C_{26}H_{32}O_9$ respectively.

Tschirch and Bergmann (Arch. Pharm. 243, 641) have made an examination of *Myrrha electa*, which is the true or Heerabol myrrh obtained by sorting from the other resins mixed with which myrrh is imported into the United Kingdom. By extraction of the ethereal solution with 1 p.c. aqueous potassium hydroxide two amorphous greyish-yellow neutral substances were obtained: *α-heerabo-myrrhol* $C_{17}H_{24}O_5$, m.p. 158°–165°, which is precipitated from alcoholic solution by lead acetate, and *β-heerabo-myrrhol* $C_{19}H_{28}O_4$, m.p. 116°–124°, not precipitated in this way. From the residue insoluble in ether, alcohol extracted two brown amorphous substances, *α-heerabo-myrrholol* $C_{15}H_{22}O_7$ or $C_{30}H_{44}O_{14}$, m.p. 207°–220°, and *β-heerabo-myrrholol* $C_{29}H_{36}O_{10}$, m.p. 205°–213°. These differ in their behaviour towards lead acetate. The portion of the resin soluble in ether but insoluble in alkali consists of *heeraboresene* $C_{29}H_{40}O_4$, m.p. 98°–104°. From the portion of the resin of *Myrrha electa*, insoluble in light petroleum, but soluble in ether, von Friedrichs (Arch. Pharm. 245, 427) isolated the following compounds: *α-commiphoric acid* $C_{14}H_{18}O_4$, m.p. 201°–203°; *β-commiphoric acid* $C_{14}H_{18}O_4$, m.p. 205°; *γ-commiphoric acid* $C_{17}H_{22}O_5$, m.p. 169°–172°; *α-herrabo-myrrhol* $C_{18}H_{26}O_5$, m.p. 248°–250°; *β-heerabo-myrrhol* $C_{20}H_{26}O_6$, m.p. 168°; *commiphorinic acid* $C_{28}H_{36}O_8$, m.p. 135°; a yellow *alcohol* $C_{14}H_{22}O_2$, b.p. 264°; and *herraboresene* $C_{42}H_{56}O_8$, m.p. 100°–102°; and from the portion of the resin insoluble both in light petroleum or ether, *α-heerabo-myrrhololic acid* $C_{15}H_{22}O_7$, m.p. 220°–225°, and *β-heerabo-myrrhololic acid* $C_{25}H_{32}O_6$, m.p. 187°–190°.

Myrrh resin gives a violet colour when a fragment moistened with alcohol is treated with nitric acid, but the colour is not so marked as in the case of galbanum (*cf.* Ruickholdt, Arch. Pharm. [ii.] 41, 1; Held, Annalen, 63, 59; Hager, Pharm. Centh. 1865, 58). Distilled, it gives no umbelliferone, but by fusion with potash Hlasiwetz and Barth (Annalen, 139, 78) obtained small quantities of catechol and protocatechuic acid. The property of giving a violet colour when oxidised by nitric acid, or better, by bromine vapour, is confined to that resin which dissolves in carbon disulphide, and which, according to Brückner, contains 75·6 p.c. of carbon.

The gum of myrrh on analysis gives numbers agreeing with the formula $C_6H_{10}O_5$. On treatment with hydrochloric acid it yields levulic acid (Köhler). It contains an enzyme which has the properties of an oxydase (Tschirch and Bergman; von Friedrichs).

The quantity of volatile oil in myrrh varies very greatly. The oil, according to Ruickholdt, has the composition $C_{10}H_{14}O$. Gladstone (Chem. Soc. Trans. 17, 11) describes it as a viscid brownish-green oil that, boiling at 266°, gave an oxidised product. Its sp.gr. was 1·0189. The oil prepared by Flückiger (*cf.* Ber. 9, 471) was lighter than water, the sp.gr. at 13° being 0·988, and the boiling-point 270°–290°. Redistilled in a current of carbon dioxide it passed over between 262° and 263°. After redistillation the oil, on addition of a drop of nitric acid, gave after an hour or two a permanent violet hue, but this is better observed when bromine vapour is applied to a solution of the crude oil in carbon disulphide.

Samples of the oil examined by Lewinsohn (Arch. Pharm. 244, 412) contained cuminaldehyde up to 1 p.c. and small quantities of eugenol and *m*-cresol, and of acetic and palmitic acids. By distillation over sodium, pinene, dipentene, and limonene were isolated, and in one commercial sample, a fourth *terpene* $C_{10}H_{16}$, b.p. 78°–80° (20 mm.). Two other possibly new *sesquiterpenes* $C_{15}H_{24}$, b.p. 151°–154° (15 mm.) and b.p. 163°–168° (12 mm.) respectively, were obtained from two other samples of the oil. Von Friedrichs (*l.c.*) obtained from the essential oil, formic and acetic acids; a crystalline *acid*, m.p. 159°; *m*-cresol; cuminaldehyde and cinnamaldehyde; crystalline monobasic *myrrholic acid* $C_{17}H_{22}O_5$, m.p. 236°; and the sesquiterpene *heerabolene* $C_{15}H_{24}$, b.p. 130°–136° (16 mm.).

According to Flückiger, the *bitter constituent* of myrrh is a glucoside. v. Bolton (Zeitsch. Elektrochem. 14, 211), by extracting myrrh with alcohol, evaporating to dryness and then extracting with water, obtained a substance *burseracin*, which forms 1·5–2 p.c. of the original drug. It is a yellow hygroscopic powder, m.p. 78°, and has the composition $C_{20}H_{28}O_8$. It is not a glucoside. On treatment with hydrogen peroxide a compound is obtained, which appears to be radioactive.

Myrrh is a reputed stimulant and tonic, but its employment in medicine depends chiefly on its aromatic properties.

Other varieties of myrrh. Several gum-resins more or less resembling true myrrh are occasionally found in commerce. Two are described by Flückiger and Hanbury. One of these, often incorrectly called *East Indian myrrh*, but which is really an African drug, is known as *bisabol* or *hebbakhade.* In outward appearance it is very similar to true myrrh, but it is more acrid, and its resin, soluble in carbon disulphide, gives no violet colour with bromine vapour. An analysis of bisabol-myrrh from Somaliland gave the following results: gum soluble in water, 22·1; gum soluble in soda, 29·85; resin, 21·5; bitter principles, 1·5; volatile oil, 7·8; water, 3·17; and inorganic matter, &c., 13·4 p.c. (Tucholka, Arch. Pharm. 235, 289).

The other variety is *Arabian myrrh.* It is collected in Southern Arabia east of Aden, and is probably the product of a distinct species (Hanbury). It is very nearly related to true myrrh in appearance, and some specimens give the violet colour reaction.

Olibanum. *Frankincense*; *Gummi-resina Olibanum*; *Thus masculum. Encens*, Fr.; *Weirauch*, Ger. Olibanum or frankincense has been the favourite basis of incense from the earliest times. It is frequently referred to in the Bible, and the Egyptians employed it for fumigations and for embalming.

Duemichen, in his book on the Paintings of the Temple of Dayr el Báhri in Upper Egypt, which represent the traffic between Egypt and a land called Punt as early as the seventeenth century B.C., has shown that these paintings include, not only representations of olibanum in bags, but boxes or tubs containing living olibanum trees. Tribute offerings of frankincense were common throughout the ancient world. At the present day the incense of the Roman and Greek Chruches is largely composed of olibanum.

The gum-resin is the dried exudated juice of several species of *Boswellia.* These trees, the fragrance of which is noticeable even at a distance, inhabit Eastern Africa, near Cape Gardafui, and the southern coast of Arabia. They were studied by Birdwood (Trans. Linn. Soc. 27, 111, 148). One of them is figured by Bentl. and Trim. 58 (Flück. a. Hanb. 134). Olibanum is a solid which softens in the mouth, and has a slightly terebinthinous, not disagreeable, taste. It consists of tears of various shapes, generally detached. The odour, especially on heating, is pleasantly aromatic. It has a pale yellow or brown colour, and the larger fragments are more or less milky and translucent. Triturated with cold water it yields an emulsion.

The chief constituents of frankincense are *resin*, *gum*, and *volatile oil.* The oil is obtained by distillation; alcohol dissolves the resin and water the gum. Braconnot (Ann. Chim. Phys. [i.] 68, 60) found resin 56 p.c., soluble gum 30 p.c., insoluble gum 6 p.c., and volatile oil 8 p.c.; whilst the analysis of Kurbatow gave resin 72 p.c., gum 21 p.c., and volatile oil 7 p.c. (Zeitsch. Chem. [ii.] 7, 201). From the resin Tschirch and Halbey (Arch. Pharm. 236, 487) obtained *boswellic acid* $C_{32}H_{52}O_4$, a white powder, m.p. 150°, which shows little tendency to crystallise. The resin probably contains boswellic acid in the form of an ethereal salt, and also *olibano-resene* $(C_{14}H_{22}O)_n$, a powder insoluble in sodium hydroxide and melting at 62°. According to Kurbatow, an *oil* boiling at 360° is obtained when the resin is subjected to destructive distillation. No umbelliferone is obtained (Sommer, J. 1859, 573).

The gum of olibanum behaves towards reagents exactly as gum arabic (Heckmeijer, J. 1858, 482).

Volatile oil of olibanum, examined by Stenhouse (Annalen, 35, 306), boils at 179·4°, and has a sp.gr. of 0·866. This oil Kurbatow has succeeded in separating into a hydrocarbon $C_{10}H_{16}$ *olibene*, which boils at 156°–158°, has the odour of turpentine, and the sp.gr. at 12° of 0·863, and an *oxidised oil* boiling above 175°. Olibene is soluble in alcohol and ether, and gives a crystalline hydrochloride $C_{10}H_{16},HCl$, which melts at 127°. Wallach (Annalen, 252, 94) finds that olibene is identical with *lævopinene*, and that *dipentene* is contained in the higher boiling fractions. At the present day olibanum is seldom employed in medicine. It is used almost exclusively in the preparation of incense.

Opopanax. A bright orange-brown gum-resin occurring in hard nodular or earthy-looking lumps. It was used by Hippocrates, and several varieties were known to Theophrastus and Dioscorides. It is said to be derived from the *Opopanax Chironium* (Koch), a native of Southern Europe.

Opopanax consists essentially of *resin*, *gum*, and a little *volatile oil.* The most recent examination of opopanax is that by Tschirch and Knitl (Arch. Pharm. 237, 256) who found a specimen from the *Opopanax Chironium* (Koch) to contain: resin soluble in ether 51·8, resin insoluble in ether 1·90, gum 33·8, volatile oil 8·3, free ferulic acid 0·22, vanillin 0·0027, moisture 2·0, bassorin and plant remains 2·0 p.c. The resin soluble in ether is the ferulate of a resinotannol, and on hydrolysis ferulic acid and *oporesinotannol* are obtained. The latter is a light brown powder having the composition $C_{12}H_{13}O_2(OH)$. The resin of opopanax insoluble in ether consists of free oporesinotannol. The purified gum contained 3·53 p.c. of ash, and an arabic acid was prepared from it containing C 43·17, H 6·42 p.c. From the volatile oil a product was obtained in needles, which melted at 133°-134° and had the composition C 66·6, H 2·7 p.c. This substance is named *oponal.*

A sample of opopanax examined by Baur (Arch. Pharm. 233, 209) contained plant fragments which showed it to be derived from some member of the genus *Balsamodendron*, order *Burseraceæ*, probably from *B. Kafal* [*Commiphora abyssinica* (Engl.)]. It contained 19 parts p.c. of resin, 6·5 of ethereal oil, and 70 of gum, besides plant fragments.

The resin of opopanax gives no umbelliferone when distilled. When fused with potash, Hlasiwetz and Barth found the resin to yield catechol, together with protocatechuic acid (Annalen, 139, 78). The substance formerly known by the name of opopanax was altogether different in odour and appearance from the resin described above. It was probably derived from a Persian member of the *Umbelliferæ* (Powell, Economic Products of the Punjab, 1, 402; Flück. a. Hanb. 327). This resin differs from the usual variety by yielding umbelliferone on dry distillation, also the volatile oil obtained from it contains sulphur.

Opopanax was highly esteemed in ancient medicine, but it has now gone entirely out of use.

Sagapenum. This gum-resin, which, like galbanum and asafœtida, has been known from the earliest times, is now seldom met with. Its botanical origin is not known with certainty.

Flückiger and Hanbury (Flück. a. Hanb. 324) describe sagapenum as consisting of a tough, softish mass of closely agglutinated tears. The tears are brownish, not milkwhite like asafœtida, and when broken do not acquire a pink tint, and are without alliaceous odour. The specimen of sagapenum examined by these observers contained no sulphur, but yielded umbelliferone. Seven out of the eight specimens examined by Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 771), however, contained sulphur, and this character served to distinguish sagapenum from ammoniacum, galbanum, and opopanax. Umbelliferone was always obtained. Resorcinol is formed when sagapenum is fused with potash (Hlasiwetz and Barth, Annalen, 139, 78), and styphnic acid by treatment with nitric acid (Boettger and Will, *ibid.* 58, 269). When some specimens of sagapenum are immersed in hydrochloric acid (sp.gr. 1·13) they acquire a permanent blue colour, but others do not exhibit this behaviour.

A specimen of sagapenum investigated by Hohenadel (Arch. Pharm. 233, 259) was found on examination of the plant fragments contained in the drug to have been obtained from the stems and fruits of a Persian species of *Ferula*, order *Umbelliferæ*. It contained resin, 56·8; volatile oil, 5·8; water, 3·5; gum, 23·3; and impurities, 10·6 p.c. The purified resin is yellowish-brown, and melts at 74°–76°; when hydrolysed by boiling with sulphuric acid it is decomposed into umbelliferone and *sagaresinotannol*, a brown substance having the composition $C_{24}H_{28}O_5$. The 56·8 parts of purified resin contained 40 of sagaresinotannol, 15·7 of combined, and 0·11–0·15 of free umbelliferone. The ethereal oil contains 9·7 p.c. of sulphur.

Scammony. *Scammonée*, Fr.; *Scammonium*, Ger. A purgative gum-resin derived from the *Convolvulus Scammonia* (Linn.), a native of Greece, Asia Minor, Syria, and Southern Russia.

The gum resin obtained by incision from the living root, and known as scammony or 'virgin scammony,' has been used medicinally for many centuries. The value of this drug depends on its resinous constituent, which, however, is now usually prepared by extracting the dried scammony root with alcohol, and precipitating the resin from the solution with water; but the resin from both of these sources appears to have been displaced in the market, to a large extent, by the resin obtained from the root of *Ipomoea orizabensis* (Ledanois), commonly known as 'Mexican scammony root,' and until lately these two resins have usually been considered to be chemically identical.

An investigation of scammony root and scammony made by Power and Rogerson (Chem. Soc. Trans. 1912, 101, 398) shows that the resins obtained from the root by the methods of incision and extraction, although similar, are not identical, while both these resins differ very considerably from that obtained from the root of *Ipomoea orizabensis*, which has also been examined by Power and Rogerson (*ibid.* 101, 1). Both of these resins are exceedingly complex in character, but consist to a large extent of glucosides and methylpentosides of jalapinolic acid and its methyl ester, and, whilst the methylpentose obtained by the hydrolysis of the resin of scammony root appears to be identical with rhamnose, that from the resin of *Ipomoea orizabensis* yields a crystalline tetra-acetyl derivative not hitherto described. The resin from the last-mentioned source also contains small proportions of hentriacontane and cetyl alcohol, which are not present in the resin from scammony root; also, differences are observed in extracting with various solvents both the crude resins and the products of their alkaline hydrolysis.

Jalapinolic acid $C_{15}H_{30}(OH)CO_2H$ was first obtained by Mayer (Annalen, 95, 149) from 'jalapin,' the name given to that portion of the resin of *Ipomoea orizabensis*, which is soluble in ether. Jalapinolic acid, subsequently investigated by Kromer (J. pr. Chem. [ii.] 57, 448), has been studied by Power and Rogerson (*l.c.*). It forms silky needles, m.p. 67°–68°, and is slightly dextrorotatory. The *methyl ester* boils at 220° (20 mm.) and crystallises in laminæ, which melt at 47°–48°.

Earlier investigations of scammony resin were made by Johnston (Phil. Trans. 1840, ii. 341); Keller (Annalen, 104, 63; 109, 209); Spirgatis (*ibid.* 116, 289); Kromer (Chem. Zentr. 1893, i. 310), who have assigned formulæ to the resins obtained, but in view of their complexity, it is evident that they cannot be regarded as definite substances (*cf.* Power and Rogerson, J. Amer. Chem. Soc. 32, 112).

The sugars contained in scammony root and those obtained by hydrolysis of the resin and of 'jalapin' have been investigated by Votoček (Zeitsch. Zuckerind. Böhm. 27, 257; 30, 20, 117; Ber. 37, 3859, 4615): Requier (J. Pharm. Chim. [vi.] 20, 148, 213; [vi.] 22, 435, 492, 540). For assay of scammony resin, *v.* Guigues (J. Pharm. Chim. [vi.] 22, 241; Bull. Soc. chim. [iv.] 3, 872). A. S.

GUMS. Gums are amorphous substances, composed of carbon, hydrogen, and oxygen, which are characterised by the property of either dissolving in water, or of taking up enough of that solvent to become glutinous and form a mucilage. They are either derived from plants by spontaneous exudation, or are extracted by means of solvents. The gum usually contains some inorganic matter and occasionally a small proportion of nitrogen (*cf.* Stevens, Amer. J. Pharm. 77, 255). For a long time, the gums were considered to be carbohydrates. It is now known, however, from the researches of O'Sullivan on gum arabic (Chem. Soc. Trans. 45, 41; 57, 59), Gedda gum (*ibid.* 59, 1029), and gum tragacanth (*ibid.* 79, 1164), that the gums are acids of high molecular weight, composed of an acid nucleus to which is attached a number of residues of various hexoses, pentoses, and bioses by means of ethereal oxygen linkings.

The proportions of the sugars united to the nucleus acid to form the natural complex gum acid, and the proportions of the complex acids in the mixture that constitute the natural gum, appear to vary in different seasons, since investigations have shown that the properties of the gum of a given plant are not always the same.

The finer gums are used in pharmacy in the preparation of emulsions and pastilles, and as a constituent of emollient medicines, whilst the commoner qualities are used in the arts as adhesive agents, in the finishing of cloth, in the preparation of ink, of water colours, and in calico printing.

Many drugs, known as gums in commerce and not included in this article, will be found by reference to Balsams or Gum resins.

One of the most important factors in determining the quality of a gum is the viscosity of the solution it forms with water, and as no standard method is yet in use the results recorded by different investigators are usually not comparable. The simplest method of determining the viscosity is to allow a quantity of the solution to flow by its own weight out of a tube, provided with a capillary orifice, and to note the time of flow. The results obtained by this method are of little value, since the pressure under which the liquid flows varies continuously, but the method is still in use as affording a rough comparison of viscosities. For more accurate work, recourse may be had to the use of a viscometer, such as that described by Ostwald (Physico-Chemical Measurements, 162).

In addition to the viscosity determination, it is generally necessary to ascertain the percentage of moisture present in a sample of gum, the acidity, the amount of ash, the colour, taste, odour, and character of the solution it forms with water. The amount of moisture present should be merely enough to prevent the gum being excessively friable; as a rule it varies between 12 and 16 p.c. The ash should be merely that due to the bases combined with the natural gum acid and in good samples is generally about 3 p.c. The solution should be free from marked taste or odour and not very dark in colour.

In the early part of the 19th century, a good many gums were known, and the work then done resulted in the description of the properties of a few gum substances to which the names *bassorin*, *cerasin*, and *arabin* were given; and chemists, dominated by the idea that the number of organic compounds was only small, on investigating a gum, identified its constituents with one or more of these substances. It now appears that the number of gum compounds is very considerable, and it cannot be safely inferred that the arabin, or cerasin, &c., found in one gum, is the same substance as the compound, given the same name, found in another natural product. For further particulars, *see* Robinson (Brit. Assoc. Reports, 1906, 227; and the Imperial Institute Bulletin, 6, 29), from which much of the information embodied in this article has been obtained.

Acacia and Allied Gums.

Acacia gum. *Gum arabic*; *Acacia gummi. Gomme arabique*, Fr.; *Arabisches gummi*, Ger. Acacia gum is the exudation from the stems and branches of various species of acacia, notably the *A. Senegal* (Willd.), which inhabit Africa from Senegambia in the West to Kordofan, Southern Nubia, and the region of the Atbara in the East (Bentl. a. Trim. 94; Höhnel, Pharm. J. [iii.] 18, 1089; Flück. a. Hanb. 233). The drug has been known from the earliest times, having been an article of Egyptian commerce in the 17th century B.C.

The most esteemed variety is *Picked Turkey* or *white Senaar gum*. This gum, also known as *Sudan or Kordofan gum*, is collected from the grey barked acacia tree, *Acacia Senegal* (Willd.), known locally as 'hashab.' In Kordofan, the gum is obtained both from gardens of acacia trees which are private property and from wild trees. In the gardens, the gum is obtained by artificially incising the trees soon after the end of the rainy season, the bark is removed in strips from the principal branches of all trees which are three years old or upwards; the strips should be 1 to 3 inches wide, according to the size of the branch, and 2 to 3 feet in length. The incision should not penetrate into the wood, and a thin layer of the inner bark should be left. About 60 days afterwards, the first collection of gum is made, and after that the gum is collected every fourth day until the rains recommence and new leaves appear; at this stage the exudation ceases. The gum obtained from the wild or uncultivated trees is slightly darker in colour and of less value than that derived from trees under cultivation. It exudes naturally from the wild trees and usually dries into pear-shaped pieces which vary in size, according to the length of time between successive collections. Young hashab trees, 8 to 10 feet high and 6 to 8 inches in girth, will produce gum, and the limits of age for this purpose may be taken as 3 to 15 or 20 years; probably trees of from 8 to 12 years old are the most productive. The gum consists of lumps of various sizes, sometimes as large as a walnut, and of a white or nearly white colour. The unbroken masses are rounded in shape, and traversed by numerous minute fissures. They are brittle and break with a vitreous fracture, exposing a transparent and in the finer varieties quite colourless interior.

Suakin, Talca, or Talha gum is derived from the 'red' and the 'white' barked acacia trees, both of which are varieties of *Acacia Seyal* (Delile). It is collected chiefly in the forests of the Blue Nile. The red talha tree is more abundant than the white and consequently most of the talha gum is derived from that variety. The trees are said not to be barked or wounded by the collectors, who gather the gum they find exuding. Talha gum is so brittle that commercial specimens have usually, for the most part, fallen to powder. The particles exhibit a great variety of colour.

Senegal gum, collected in the French colony of Senegal, is obtained almost entirely from the same species of acacia which yields the Kordofan gum, but it is probable that the poorer qualities are procured from other species. The gum exudes naturally through fissures produced by the rapid and unequal desiccation of the barks of the trees by the hot winds experienced immediately after the wet season, but in recent years incisions have been made. Senegal gum is much darker in colour than the Sudan gum, and the surface of the lumps is unbroken by cracks or fissures. It is chiefly imported into France. A considerable quantity of this is, however, exported to other European countries.

Morocco, Mogador, or **Brown Barbary gum** is exported from Morocco. It is stated to be obtained from *Acacia arabica* (Willd.), and *Acacia gummifera* (Willd.), but according to some authorities, much of the gum now exported is merely Senegal or Sudanese gum, brought to Morocco by caravans from the interior. It consists of light dusky brown tears or vermiform pieces; they show numerous superficial fissures.

Cape gum is the product of the *Acacia horrida* (Willd.), a native of Cape Colony. Its colour is amber brown.

Aden and **East Indian gum** is produced in Abyssinia and Somaliland and is exported from the towns on the Somali coast principally to Aden and Bombay. From these two ports, it is reshipped to Europe as 'Aden gum' and 'East Indian gum' respectively. The source of the gum is not known with certainty but some of it is doubtless collected from *Acacia abyssinicia* (Hochst.) and *Acacia glaucophylla* (Steud.), which are known to occur in those regions. It consists of tear-shaped masses, often as large as an egg, and of a pale amber or pinkish hue. The best qualities approach the better classes of Kordofan gums in appearance, solubility, and other characters, but these gums are usually darker in colour.

Australian or **Wattle gum**, the product of several Australian species of Acacia known locally as 'Wattles,' occurs in large hard globular tear-like masses or lumps, varying in colour from deep yellow to deep reddish-brown (*v.* Maiden, Pharm. J. [iii.] 20, 86; *cf.* Flück. a. Hanb.).

Gum arabic is not much more soluble in hot than in cold water. In alcohol it is insoluble. The aqueous solution is precipitated by basic lead acetate, but not by neutral acetate. It is also thickened or rendered turbid by the addition of solutions of borates or ferric salts or alkaline silicates. Salts of mercury or silver have no action on the solution, neither is it coloured blue by iodine. Gum arabic yields about 3 p.c. of ash, consisting of calcium magnesium and potassium carbonates. For analytical distinctions between pure gum arabic and gums with which it may be associated, *v.* Hager (Zeitsch. anal. Chem. 11, 350; Pharm. Centh. 1885, 388); Schlosser (Chem. News, 20, 120); Roussin (J. Pharm. Chim. [iv.] 7, 251); Elwood (Pharm. J. [iii.] 19, 339); Hefelmann (Zeitsch. öffentl. Chem. 11, 195); Palladino (Bull. Soc. chim. [iii.] 9, 578); Vamvakus (Ann. Chim. anal. 12, 12). Methods of valuation of gum arabic are given by Fromm (Zeitsch. anal. Chem. 40, 143); Dieterich (*ibid.* 40, 408), and a method for detecting the presence of gelatin is given by Trillat (Compt. rend. 127, 724).

The chief constituent of gum arabic is *Arabin, Arabic acid*, or *Gummic acid*, combined with calcium and also perhaps with magnesium and potassium. The crude acid is precipitated when alcohol is added to an aqueous solution of gum arabic previously acidified with hydrochloric acid. By successively redissolving in water and reprecipitating, the product can be obtained pure. Arabic acid is amorphous, soluble in water and insoluble in alcohol. Heated to 100° it is converted into insoluble *meta-arabic acid* (Neubauer, J. 1854, 624; Annalen, 102, 105; Gelis, J. 1857, 496), or the same change may be effected by treatment with concentrated acid (Fremy, J. 1860, 503). Meta-arabic acid is readily changed back again to soluble arabic acid by the action of alkalis. Heat of combustion, *v.* Stohmann (J. pr. Chem. [ii.] 31, 298). Action of light, *v.* Eder (*ibid.* 19, 299).

The constitution of arabin has been investigated by O'Sullivan (*l.c.*) who showed that it contains the acid nucleus, $C_{23}H_{38}O_{22}$, to which he gave the name *λ-arabinosic acid*, but afterwards unfortunately called it *arabic acid*, the name already given to the naturally occurring gum acid, arabin, which is a compound of arabinosic acid with the sugar residues, arabinan and galactan, the termination 'an' indicating the anhydride of the corresponding sugar. On complete hydrolysis, arabin yields arabinose, galactose, and arabinosic (arabic) acid.

When oxidised with ordinary nitric acid, gum arabic yields oxalic, mucic, tartaric, and racemic acids (Guerin, Annalen, 4, 255; Liebig, *ibid.* 113, 4; Kiliani, Ber. 15, 35; Hornemann, J. 1863, 381; Maumene, Bull. Soc. chim. [iii.] 9, 138; Béchamp, *ibid.* [iii.] 7, 587). The so-called nitro derivatives of arabin are, like those of starch and cellulose, nitrates (Béchamp, J. 1860, 521; *l.c.*). Acetic anhydride also reacts forming acetyl derivatives (Schutzenberger and Naudin, Zeitsch. Chem. 1869, 265).

Gums from various species of *Acacia* grown in known localities have been examined by Meininger (Arch. Pharm. 248, 171).

Allied gums. The gum known in commerce as *Gedda gum*, in appearance very similar to the inferior kinds of gum arabic, has also been examined by O'Sullivan. He found that it is a mixture of several gum acids, which are constituted of the radicles of galactose and of arabinose or arabinan, attached in considerable numbers to a nucleus acid to which the name geddic acid is given. Geddic acid is an isomeride of arabic acid, $C_{23}H_{38}O_{22}$. *Chagual gum* is obtained from Chile, where it is produced by the *Puza lanuginosa* (Schult.). It is partly insoluble in water. Chagual gum has been investigated by Winterstein (Ber. 31, 1571). *Feronia* or *wood apple gum* is derived from the Indian tree *Feronia elephantum* (Correa) (*cf.* Flück. a. Hanb. 239). *Ghati gum* is the name given in India to gum produced in India itself, as distinguished from East Indian gum of exotic origin. In European commerce, however, the name 'Ghatti' or 'Gatty' is practically restricted to the partially soluble and viscous gum derived from *Anogeissus latifolia* (Wall.) and certain other species. It is derived from various trees and no attempt is made to keep the products of the different species separate. The result of this is that the gum may differ considerably in properties. *Hog* or *Doctor gum* consists of reddish tears. It is derived from the *Rhus Metopium* (Linn.), or perhaps the *Moronobea grandiflora* (Choisy), natives of South America. This gum is quite distinct from the Hogg or Kuteera gum of India (*cf. Tragacanth*). Plants containing gums similar to acacia (*v.* Gm. 15, 195). *Para* and other gums (Pharm. J. [iii.] 18, 623, 745, and 1009).

TRAGACANTH AND ALLIED GUMS.

Tragacanth. *Tragacantha. Gomme adragante*, Fr.; *Traganth*, Ger. A gummy exudate consisting in part of altered cells obtained either spontaneously or by means of incisions from the stems of various species of *Astragalus*, some of which occur in South Western Europe, while others are found in Greece and Turkey. The largest number, however, are indigenous in the mountainous regions of Asia Minor, Syria, Armenia, Kurdistan, and Persia. The tragacanth of commerce is produced in the last-named countries. In July and August, the shrubs are stripped of their leaves and short longitudinal incisions or slits are made in the trunks. The gum flows out, and, drying spontaneously, is ready for gathering in three or four days. If the weather is fine during the drying process, the 'white leaf' form of gum is obtained which is the most prized variety. If, however, rain falls or the wind rises, particles of dust collect on the surface of the gum which thereby loses its whiteness and becomes the 'yellow leaf' form, the second quality. The form of the pieces is determined by the shape of the incision; longitudinal incisions produce 'leaf' or flake tragacanth, punctures yield 'thread' tragacanth, while irregular shaped incisions give knob-like masses, generally coloured, and of relatively low value. Another form, known in Persia as 'Arrehbor,' exudes from branches which have been cut by a saw (Imp. Inst. Reports, 1909, No. 63).

When tragacanth is treated with water, one part dissolves and the other swells up, absorbing water, to the extent of even fifty times the weight of the gum used, the whole forming a thick mucilage. This may be diffused through more water when, on filtering, a soluble gum passes through, and there remains on the filter a slimy non-adhesive mucilage, *bassorin*, *tragacanthin*, or *adraganthin*. In presence of alkalis, the whole of the gum dissolves readily in water (Flück. a. Hanb. 178; Sandersleben, Phytochem. Untersuch. Leipzig, 1880, 90; Fremy, J. 1860, 504). On hydrolysis of three samples of white tragacanth, Widtsoe and Tollens (Ber. 33, 132) obtained fucose and arabinose, whilst fucose and xylose were obtained from two samples of brown tragacanth. Five different samples of tragacanth examined by Helger and Dreyfus (Ber. 33, 1178) were found to contain 9·4 to 15·4 p.c. of water; 3·1 to 2·7 of ash, also 15·1 to 22·4 p.c. of galactose (estimated as mucic acid) and 30 to 42 p.c. of arabinose (estimated as furfuraldehyde phenylhydrazone). A specimen of vermicelli tragacanth contained 4 p.c. of cellulose and 3 p.c. of starch. The samples obtained by artificial incision contain the larger proportions of water and ash.

Tragacanth gum, investigated by O'Sullivan, was found, like Gedda gum, to be a mixture of several gum acids. It can be separated into a group of acids which remain in solution in dilute alcohol, and an insoluble portion, for which the name *bassorin* is appropriated. The acids of the soluble group were found to be built up on a nucleus acid, very similar if not identical with geddic acid, by its union with galactose and arabinose residues. The constitution of the insoluble portion has not been completely worked out; but it yields a nucleus acid of the formula $C_{14}H_{20}O_{13}$, to which the name *bassoric acid* is given, and also intermediate acids formed of bassoric acid united to the residues of xylose, and of a new pentose sugar, *tragacanthose*.

Allied gums. *Bassora*, *Kuteera*, or *Caramania gum*, *Hogg gum tragacanth*, consists of yellow or brown waxy masses. It comes from Persia where it is said to be derived from almond and plum trees, and is employed in Smyrna in the adulteration of tragacanth (Flück a. Hanb.). The *Cochlospermum Gossypium* (D.C.), a small deciduous tree growing abundantly in India, furnishes a gum which occurs in irregular rounded translucent lumps of a pale buff colour. The gum is sold in the Indian bazaars as a substitute for tragacanth, which it closely resembles. This gum has the property of slowly giving off acetic acid when exposed to moist air, a property also possessed by the gum of *Sterculia urens* (Roxb.) (Gurbourt, Pharm. J. 15, 57). A stable acid, *gondic acid*, $C_{23}H_{36}O_{21}$, has been obtained from the gum of *Cochlospermum Gossypium* (D.C.) in the same manner as the arabic and geddic acids of O'Sullivan. On hydrolysis, the gum yields 18 p.c. of acetic acid, calculated on the dry and ash-free substance, and is thus an acetyl derivative. Xylose and a hexose are among the other products (Robinson, Chem. Soc. Trans. 89, 1496). *Cashew gum* is the exudation of the *Anacardium occidentale* (Linn.), a small tree indigenous to tropical America. *Cherry tree gum* behaves towards water in a similar manner to tragacanth. The insoluble portion consists of *cerasin*, combined with metals of the alkalis or alkaline earths (Fremy, J. 1860, 504). For hydrolysis of cherry tree gum, *v.* Hauers and Tollens (Ber. 36, 3306). *Linseed*, *marshmallow*, and *fleaseed gums* closely resemble tragacanth (Schmidt, Annalen, 51, 50; Frank, J. pr. Chem. [ii.] 95, 494; Kirchner and Tollens, Annalen, 175, 215; Hilger, Ber. 36, 3197). *Persian gum* (*v.* Pharm. J. [3] 20, 793) is of a hard glassy type and its solutions in water are intermediate in character between those of tragacanth and gum arabic. The trade in this gum is considerable, but the commercial value is lower than that of either tragacanth or fine gum arabic (Imp. Inst. Report). *Wood gum* has been extracted from various woods, straw, loofah, and similar materials. It resembles cherry tree gum. On hydrolysis it yields xylose, and in some cases arabinose (Th. Thomsen, J. pr. Chem. [ii.] 19, 146; Poumarède and Figuer, Annalen, 64, 338; J. Soc. Chem. Ind. 1890, 335; Wheeler and Tollens, Ber. 22, 1046; 23, 137; Annalen, 254, 320; Allen and Tollens, *ibid.* 260, 289; Bader, Chem. Zeit. 19, 55; Johnson, Amer. Chem. J. 18, 24; Browne and Tollens, Ber. 35, 1457; Salkowski, Zeitsch. physiol. Chem. 34, 162).

OTHER GUMS.

Agar agar gum, *Bengal isinglass gum*, the dried jelly of seaweed, which, under the name of agar agar, is obtained from China, forms with water, is largely composed of the gum *gelose* (Payen, J. 1859, 562) or *pararabin* the latter being contained also in the carrot and the sugar beet (*cf. sugar beet gum*). Gelose is insoluble in cold water, alcohol, dilute acids, and alkalis. 1 part in 500 of boiling water forms a jelly on cooling (Morin, J. 1880, 1010; Porumbara, J. 1880, 1011; Bauer, J. pr. Chem.

[ii.] 30, 375) (*v.* Agar Agar). *Galactin*, a very similar gum to gelose, is found in the seeds of the *Leguminosæ* (Müntz, Bull. Soc. chim. 37, 409).

Amyloid gums. These are distinguished from most gums by being coloured blue by iodine. The more important are: *Amyloid* (distinct from that derived from cellulose), the soluble gum of the cotyledons of the tamarind and other plants; *Quince gum*, which breaks up into cellulose, gum, and sugar when heated with dilute sulphuric acid; and *Salep gum*, derived from the bulbs of orchids (Frank, J. pr. Chem. [ii.] 95, 479; Hilger, Ber. 36, 3197).

Animal gum. A gummy substance having the composition $C_{12}H_{20}O_{10},2H_2O$ has been isolated from the secretions of the salivary glands, from the brain, pancreas, kidneys, and other parts of the body. It is unaffected by the digestive ferments but is converted into sugar by dilute acids. It reduces ammoniacal silver nitrate solution with formation of a mirror. With water, it gelatinises, forming a mucilage. It is insoluble in alcohol and ether (Landwehr, Zeitsch. physiol. Chem. 8, 122; 9, 367; 13, 122; Zeitsch. anal. Chem. 23, 601; 24, 640; Pouchet, Compt. rend. 20, 21; Folin, Zeitsch. physiol. Chem. 23, 347).

Fermentation gum. This gum, *Dextran* or *Viscose*, which occurs in the unripe sugar beet (Scheibler, Wag. J. 1875, 790), is formed in the lactic fermentation of cane sugar by the action of the bacterium *Streptococcus* (*Leuconostoc*) *mesenteroides* (van Teighem, Jahresb. Agrik. Chem. 1879, 544; Béchamp, J. Th. 1881, 85; Brüning, Annalen, 104, 197). Formed also in mucic fermentation (Nägeli, J. pr. Chem. [ii.] 17, 409). Dextran $C_6H_{10}O_5$ is amorphous, soluble in water and precipitated therefrom as an elastic thread-like mass by alcohol. By treatment with dilute sulphuric acid, sugar is obtained, and when oxidised with nitric acid, oxalic but no mucic acid.

Dextrin *v.* Dextrin.

Gum from German yeast (*v.* Salkowski, Ber. 27, 497, 925, 3325; Hessenland, Zeit. Vereins. Rübenzuch-Ind., 1892, 671).

Iceland moss gum. Two gums have been isolated from the jelly of Iceland moss, *Cetraria islandica* (Acharius). The one, *lichenin* $C_6H_{10}O_5$, is unaffected by iodine, while the other, *isolichenin*, is coloured blue by that reagent. Lichenin is a transparent brittle mass which dissolves in hot water, the solution gelatinising on cooling. It is soluble in solution of ammonio-copper sulphate; combines with bases; is converted by dilute acids into sugar; oxidised by nitric acid, it yields oxalic acid, and it reacts with glacial acetic acid, forming *triacetyl lichenin* $C_6H_7Ac_3O_5$ (Knop and Schnedermann, Annalen, 55, 165; J. 1847–8, 831; Errera, Inaug. Dis. Brussels, 1882, 18; Mulder, Annalen, 28, 279; Helger and Buchner, Ber. 23, 461). *iso*Lichenin is soluble in water, and unlike lichenin forms no acetyl derivative, nor is it soluble in ammonio-copper sulphate solution (Berg, J. 1873, 848; Errera; Hönig, Monatsh. 8, 452).

The lichen, *Evernia Prunastri* (Ach), contains a gum resembling lichenin, *everniin* $C_9H_{14}O_7$ (Stüde, Annalen, 131, 241).

Irish moss gum. The Irish moss, *Chrondus crispus* (Linn.), contains a gum which is soluble in water, insoluble in ammonio-copper sulphate, is not coloured blue by iodine and yields mucic acid when oxidised with nitric acid (Blondeau, J. 1865, 659; Flückiger and Obermeyer, J. 1868, 805; Painter, Pharm. J. [iii.] 18, 362).

Sterculia gum, derived from various species of *Sterculia* (*v.* Maiden, Pharm. J. [iii.] 20, 381).

Sugar beet gum. Several forms of gum have been separated from the juice of the sugar beet. *Arabic* or *meta-arabic acid* (*cf. gum acacia*), *dextran* (*cf. fermentation gum*), *pararabin* (Reichardt, Ber. 8, 808), and *lævulan* (v. Lippmann, *ibid.* 14, 1509). Pararabin is a powder which forms a jelly with water of quite a different appearance from that obtained with meta-arabin. It is soluble in dilute acid solutions from which alkalis or alcohol precipitate it. Lævulan is a by-product in the extraction of crystallisable sugar from beet sugar molasses. When anhydrous, it is insoluble in water, but in its hydrated form it dissolves readily. When oxidised by nitric acid it yields mucic acid, and heated with dilute sulphuric acid it is entirely converted into lævulose.

Wine gum (*v.* Béchamp, J. 1875, 987; Chancel, J. 1875, 987; Neubauer, Zeitsch. anal. Chem. 15, 194). A. S.

GUTTA PERCHA is the product obtained by coagulating the latex of certain species of *Palaquium* and *Payena*, belonging to the natural order *Sapotaceæ*, which are natives of the Malay Peninsula and Archipelago. The name is derived from two Malay words: *getah* and *percha* or *pertja*. The word *getah* is applied to any exudation from a tree, whilst *percha* or *pertja* refers either to the local name of the tree which was erroneously thought at first to furnish the product, or to the Malay name for Sumatra ‘Pulau Percha.’

The introduction of gutta percha into commerce dates from 1843, when specimens were forwarded to London independently by two doctors resident in Singapore, Dr. William Montgomerie and Dr. José D’Almeida, and the remarkable properties of the material at once attracted attention. In 1847 the principal tree yielding gutta percha was described and named by Sir W. J. Hooker, and in the same year Dr. Ernst Werner von Siemens employed the material for insulating underground telegraph wires.

The principal trees yielding gutta percha of the best quality are *Palaquium Gutta*, Burck, *P. oblongifolium*, Burck, and *P. borneënse*, Burck. *P. oblongifolium* is considered by some botanists to be only a variety of *P. Gutta*; the common name for both in the Malay peninsula is Taban. A number of other species of *Palaquium* furnish gutta percha of second quality, the chief of these being *P. obovatum*, King (Taban putih), *P. Maingayi*, King and Gamble (Taban simpor), and *P. oxleyanum*, Pierre (*Dichopsis pustulata*, Hemsley), which is variously known as Taban sutra, Taban putih, and Taban chaier in different parts of the Malay peninsula. *Payena Leerii* (Hook. and Benth.); and *P. Havilandi* (King & Gamble), furnish the white gutta percha known as Getah sundek or soondie.

There has been considerable confusion regarding the botanical identity of the trees yielding gutta percha, which has been increased by the fact that the same native name is frequently applied to distinct species in different districts.

Palaquium Gutta is a large forest tree which usually attains a height of about 60 feet and has a straight cylindrical trunk. Trees up to 150 feet or more in height and 4 to 5 feet in diameter have been recorded. The tree is easily recognised by its leaves which are a beautiful coppery gold colour on the under surface and dark glossy green on the upper. They vary considerably in size, the leaves of mature trees being about 2 inches long, whereas those of young trees are much longer.

The geographical distribution of the trees which furnish gutta percha is curiously restricted, as they only occur naturally in a small area comprising the southern portion of the Malay peninsula, Sumatra, Banca, Borneo, Celebes, the Susu Islands, and the Philippines. The trees are not indigenous in Java but have been introduced and are now being cultivated there.

The latex is contained in isolated sacs which occur chiefly in the inner layers of the bark and also in the leaves. On making incisions in the bark the latex exudes and quickly coagulates, so that only a small yield of gutta percha can be obtained at one tapping. In consequence of this fact the Malays have adopted the destructive method of felling the trees in order to collect the gutta percha. The tree is cut down and incisions extending right round the trunk are made at intervals of 9 to 12 inches or even less. In the case of the best kinds of gutta percha, the latex exudes into the incisions where it quickly coagulates and in about half an hour can be rolled off on a stick or scraped off with a knife. The latex of the inferior varieties does not coagulate so rapidly; it is collected in vessels placed underneath the incisions and is afterwards coagulated by gentle heating. The gutta percha is subsequently boiled in water and made into blocks of various shapes.

The amount of gutta percha obtained per tree by the native method has been very variously stated, but it seems probable that the average return from 15 to 20 year old trees is not above 14 ozs. Large forest trees have, however, been known to yield over 2 lbs. of gutta percha and a tree 160 feet high, in the Philippines, is stated to have furnished 8½ lbs.

In view of the serious destruction of the trees which is involved in the native method of obtaining the gutta percha, attempts are now being made in Perak and in Java to collect the product by tapping the standing trees. The average yield by this method is not yet definitely determined, but in Perak a tree 59½ inches in girth has yielded 1 lb. 3¾ ozs. of gutta percha in 21 tappings extending over 6 weeks. Gutta percha is also being extracted by mechanical processes from the leaves of the trees. The older methods, involving the use of solvents, which were first employed for this purpose, have been abandoned, as it was found that the chemical treatment adversely affected the durability of the gutta percha when exposed to air and light.

Gutta percha resembles rubber in consisting essentially of a hydrocarbon, having the formula $(C_{10}H_{16})_n$, associated with resinous substances. It differs widely, however, from rubber in its physical properties. At ordinary temperatures it is hard, very tenacious, and cannot be stretched like rubber. On immersion in hot water it becomes soft and plastic so that it can be readily moulded; on cooling, it retains the shape given to it when soft and becomes hard but not brittle. When heated in the air, gutta percha decomposes and then takes fire, burning with a luminous smoky flame and giving off a characteristic odour resembling that of burning rubber. When submitted to destructive distillation, it yields a mixture of liquid hydrocarbons, including isoprene, similar to those obtained by the distillation of caoutchouc.

Gutta percha is not affected by weak mineral acids, strong hydrochloric or acetic acids, or strong alkalis, but is readily attacked by strong nitric or sulphuric acid. It is partially soluble in ether, alcohol, acetone, and cold petroleum spirit, which dissolve the resin; and completely soluble in carbon disulphide, chloroform, carbon tetrachloride, and hot petroleum spirit.

The hydrocarbon present in gutta percha, known as *gutta*, is the essential constituent and exhibits in an enhanced degree the characteristic properties of the product. When dissolved in chloroform and treated with chlorine, bromine, or iodine, *gutta* forms addition products, with some evolution of the halogen acid; and by the action of nitrogen oxides, nitrosites resembling those obtained from caoutchouc are formed.

Gutta percha slowly absorbs oxygen when exposed to air and light, and in the process the *gutta* is converted into a brittle resin. Gutta percha is, however, not energetically attacked by ozone like caoutchouc. Harries has shown that if gutta is dissolved in chloroform and treated with ozone, an ozonide $C_{10}H_{16}O_6$ is formed which, when decomposed by steam, gives a mixture of lævulic aldehyde and acid and lævulic aldehyde peroxide like the corresponding ozonide prepared from caoutchouc, but in different proportions. Harries concludes that the hydrocarbons of rubber and gutta percha are identical, both being probably 1 : 5 dimethyl*cyclo*octadiene (Ber. 1905, 38, 3985).

The resinous bodies associated with the gutta are oxygenated substances. They were separated by Payen in 1852 into two portions: (1) a crystalline white resin, soluble in hot but insoluble in cold alcohol, which he named *albane*; and (2) an amorphous yellow resin, soluble in cold alcohol, which he named *fluavile.* It seems probable from recent investigations that these substances are mixtures and not single compounds. In 1892 Oesterle discovered in gutta percha a fourth constituent, which he named *guttane* and found to contain C 86·4 p.c. and H 12·0 p.c. For information on the composition and chemical properties of gutta percha see papers by Ramsay, Chick, and Collingridge, and by Caspari in J. Soc. Chem. Ind. 1902, 21, 1367; 1905, 24, 1274.

In the analysis of crude gutta percha, it is customary to determine the moisture, the resin, the gutta, and the insoluble matter (dirt). The moisture is usually determined by heating a weighed quantity in an air or water oven, or *in vacuô*, until no further loss in weight occurs; sometimes the water given off is collected and weighed. The resins are determined by extraction with hot acetone in a Soxhlet apparatus, or by ether or petroleum spirit in the cold; the solvent is distilled off and the resin weighed. The residue left after removal of the resin is treated with chloroform which dissolves the gutta leaving the insoluble matter; the latter is removed by filtration, washed with chloroform, dried, and weighed. The gutta may be weighed after distilling off the chloroform or it may be precipitated from the chloroform solution by the addition of alcohol and then dried and weighed.

The composition of several representative specimens of gutta percha, derived from trees belonging to a single species, which have been examined at the Imperial Institute and by Dr. Obach, is given in the following table:—

Variety of gutta percha	Botanical source	Gutta	Resin	Dirt	Moisture	Ash
Getah taban merah[1]	*Palaquium Gutta* . .	70·6	13·9	0·7	14·8	0·95
,, ,, ,,	,, ,,	68·3	13·4	8·1	10·2	0·89
Getah taban putih .	Uncertain . . .	35·6	49·5	7·4	7·5	0·72
Getah taban chaier .	,,	52·0	43·4	3·4	1·2	1·61
Getah simpor . .	*Palaquium Maingayi* .	44·9	45·5	8·4	1·2	2·13
Getah taban sutra[2] .	*Palaquium oblongifolium*	84·3	10·7	3·7	1·3	—
Getah sundek[2] .	*Payena Leerii* . .	43·9	37·6	5·1	13·4	—

The commercial brands of gutta percha vary very considerably in composition and quality. They are usually designated by the names of the countries in which they are produced or of the ports from which they are shipped. Obach has classified the 12 principal brands into four groups as follows:—

I. First quality—genuine from *P. Gutta* or *oblongifolium* and allied species: (1) Pahang from the Malay peninsula, (2) Bulongan red, and (3) Banjer red from Borneo;

II. Second quality—Soondie from *Payena* spp.: (4) Bagan goolie soondie, (5) Goolie red soondie, both from Borneo, and (6) Serapong goolie soondie from Sumatra;

III. Third quality—white, botanical source not definitely known: (7) Bulongan white, (8) Mixed white, (9) Banjer white, all from Borneo;

IV. Fourth quality—mixed and reboiled: (10) Sarawak mixed, (11) Padang reboiled, and (12) Banca reboiled.

Obach has given the average results of 751 analyses of these varieties, representing 2282 tons of raw gutta percha (*see* Cantor Lectures on Gutta Percha, published by the Society of Arts, Appendix v. 90–92). The figures for the genuine varieties may be given for comparison with those recorded above:—

—	Quantity represented by analyses		Percentage composition			
	Lots	Tons	Gutta	Resin	Dirt	Water
Pahang .	93	233	57·0	13·3	11·5	18·2
Bulongan red	37	60	51·8	18·2	10·8	19·2
Banjer red .	91	232	40·7	20·0	17·4	21·9

The treatment which crude gutta percha undergoes in the factory previous to its technical use may be briefly described. The lumps, after slicing if necessary, are softened by immersion in hot water and are then freed from impurities by treatment in a washing machine with hot water. The washed gutta percha while still soft is forced by pressure through wire gauze in order to remove any solid impurities which have not been eliminated in the washing process. The strained product is usually rewashed and is then transferred to the masticator or kneading machine, where the mechanically enclosed water and air are eliminated and the material rendered homogeneous. It is afterwards passed through a rolling mill and formed into sheets from ⅛ to ¼ inch thick, which are cut into convenient lengths and stored in cellars until required for use. If it is desired to mix various kinds of gutta percha in order to obtain a product of a required composition, or to incorporate pigments, &c., the operation is conducted by means of a mixing machine fitted with specially shaped rollers which can be heated by steam.

In certain cases the crude gutta percha is washed with a hot 5 p.c. solution of sodium hydroxide in order to improve the colour. After treatment in this way, the product must be thoroughly washed with water to remove all trace of alkali.

The loss which results on cleaning raw gutta percha (*i.e.* the quantity of dirt and water present) is considerable, usually amounting to from 30 to 40 p.c. and sometimes to as much as 50 p.c.

[1] Obtained by tapping standing trees.

[2] Analyses by Dr. Obach.

For some purposes a very hard gutta percha is required, and this can be obtained by removing the resin from the ordinary material by extraction with solvents.

The physical and mechanical properties of gutta percha depend very largely on the proportions of gutta and resin present. Thus the temperature at which it softens; the time required to harden on cooling; the tensile strength; and the degree of elongation before breaking are all related to the value of the ratio gutta : resin.

The electrical properties, *i.e.* the insulation resistance, the inductive capacity and the dielectric strength, depend principally on the nature of the gutta and on the amount of water present, and are affected very little by the removal of the resin. (For determinations of the electrical properties of gutta percha, *see* Obach, *l.c.* 62–65.)

Gutta percha is employed for a variety of purposes, the chief of which are the insulation of submarine cables, and the manufacture of the covers of golf balls.

The amount of gutta percha which has been used in the cable industry forms a very large percentage of the total consumption. It was stated by Obach that of the 71,933 tons of raw gutta percha used in the United Kingdom from 1845 to 1896, at least two-thirds, and probably more, had been utilised for electrical purposes. The gutta percha employed for cable manufacture has to be specially selected for the purpose, as the insulating power of the different commercial brands varies enormously.

The gutta percha used for the covers of golf balls is 'hardened' by removal of the resin in order to render it as tough and elastic as possible.

Gutta percha is also utilised for the manufacture of driving belts; rings, valves, &c., for pumps and hydraulic presses; boot soles; tubes, funnels, bottles, buckets, &c., for use with acid liquids; for cements (such as Chatterton's compound); for taking casts; and for surgical and many other minor purposes.

H. B.

GYNOCARDIN *v.* Glucosides.

GYNOVAL *v.* Synthetic drugs.

GYPSUM (Fr. *Gypse*; Ger. *Gyps*; Ital. *Gesso*). A common mineral composed of hydrated calcium sulphate $CaSO_4,2H_2O$, crystallising in the monoclinic system. The name *selenite* is sometimes applied to the clear crystallised variety, *satin-spar* to the finely fibrous variety, and *alabaster* (*q.v.*) to a compact, marble-like variety used for carving. The low degree of hardness (No. 2 on the scale) is a very characteristic feature; the mineral can be readily scratched with the finger-nail. Sp.gr. 2·32. The mineral is usually white, but sometimes greyish, yellowish, or reddish; and the glistening cleavage surfaces are usually conspicuous on a broken surface. The crystals possess a highly perfect cleavage in one direction parallel to the plane of symmetry; on the smooth, bright cleavage surfaces the lustre is pearly, and coloured bands (Newton's rings) are often to be seen. Cleavage flakes are flexible but not elastic (thus differing from mica), and when bent a fibrous cleavage is developed parallel to the faces of a pyramid: this fibrous cleavage is seen as silky striations on the principal cleavage, and is a very characteristic feature of gypsum.

Single crystals of gypsum, with a rhomb-shaped outline, are of common occurrence, embedded in clays. Fine groups of water-clear crystals are found in the sulphur mines of Sicily, the salt mines of Bex in Switzerland, and at many other localities. Enormous crystals, a yard in length, have been found in a cave in Wayne Co., Utah. Various types of twinned crystals are of common occurrence. The deposits of massive gypsum, such as are mined for economic purposes, occur as thick beds and nodular masses in sedimentary rocks of various geological periods. Those of the midlands of England are interbedded with the red marls and sandstones of Triassic age; those worked near Battle, in Sussex, belong to the later Purbeck beds; many of the deposits of the United States are of Palæozoic (Silurian, Devonian, and Carboniferous) age; whilst the important deposits in the Paris basin are of Tertiary (Eocene and Oligocene) age. These more extensive deposits of gypsum have been formed by the evaporation of water in inland lakes and seas; and they are often associated with beds of rock-salt. The mineral has, however, in many cases originated by the action of water containing sulphuric acid and soluble sulphates (produced by the weathering of iron-pyrites and other sulphides) on limestone and other calcareous rocks. It is also formed by the action of volcanic vapours on the surrounding rocks.

The output of gypsum in England amounts to about a quarter of a million tons per annum; about half of this amount is mined in Nottinghamshire, considerable quantities in Staffordshire, Sussex, and Cumberland, and less in Derbyshire, Yorkshire, Westmoreland, and Somersetshire. The value ranges from 6 to 10 shillings per ton. In France, the output reaches 1½ million tons per annum, and about the same amount is produced in the United States. Nova Scotia and New Brunswick are also large producers. The French gypsum is remarkable in containing some admixed calcium carbonate and soluble silica, and for this reason it makes a harder plaster.

The principal use of gypsum is for the manufacture of plaster of Paris, stucco, and various kinds of wall plaster. Hence the popular name '*plaster-stone.*' The employment of plaster of Paris for making the moulds in the potteries has given rise to the name '*potter's stone*' for gypsum. The coarser grades of material are used as fertilizers (land plaster). Alabaster is used for carvings for inside decorations; and satin-spar is cut as beads and other small personal ornaments. Under the names 'terra alba,' 'annaline,' and 'satinite,' ground gypsum is used for adulterating paints and as a mineral loading in the manufacture of paper (*v.* Calcium).

L. J. S.

GYROPHORIC ACID $C_{16}H_{14}O_7$ is found in *Umbilicaria pustulata* (Hoffm.), *Gyrophora vellea* [(Linn.) Ach.], *Gyrophora spodochroa* [(Ehrh.) Ach.] and other lichens. It crystallises in needles from ether or dilute alcohol, melting at 202° with decomposition. Very easily soluble in acetone and alcohol. The alcoholic solution has an acid reaction, and gives a violet colour with ferric chloride. Is soluble in alkali to a yellow solution; boiling acetic acid converts it into orsellinic acid and boiling alcohol into orsellinic acid and its ethyl ester (Stenhouse, Annalen, 70, 218; Hesse, J. pr. Chem. [ii.] 58, 475; 62, 462; 63, 522; 68, 1; Zopf, Annalen, 300, 330; 313, 322; 317, 110; 338, 35; 340, 276; 346, 82).

H

HAARLEM BLUE. *Antwerp blue v.* Pigments.

HÆMATEÏN *v.* Logwood.

HÆMATIN *v.* Blood.

HÆMATITE or **HEMATITE.** A mineral consisting of ferric oxide (Fe_2O_3), crystallising in the rhombohedral system, and an important ore of iron (Fe, 70 p.c.). According to whether it is crystallised, massive, or earthy, it varies considerably in external appearance. In all cases, however, the mineral gives a characteristic brownish-red streak or powder; and it is on account of this colour (resembling that of dried blood) that the mineral receives its name hæmatite, meaning, in Greek, blood-stone. The sp.gr. of the crystals is 5·2, but of the compact and earthy varieties it may be as low as 4·2; hardness 6 (except in the soft, earthy varieties).

The crystals are iron-black with a brilliant metallic lustre, and they vary from rhombohedral to tabular in habit. This variety is distinguished as *iron-glance*, or *specular iron*; or, when the crystals are thin and scaly, as *micaceous iron-ore*. The compact varieties are distinguished as *red iron-ore* or *red hæmatite*. These sometimes exhibit a fibrous or columnar structure and a nodular surface, being then known as *kidney-iron-ore*; or, when the fibrous structure is so marked that the mineral breaks into rods, as *pencil-ore*. In these cases the material is often dark-red with a dull surface, but sometimes it may be iron-black with a sub-metallic to metallic lustre. Earthy, ochreous varieties are brighter red in colour, and are often mixed with clay and other impurities; these are known as *reddle*, *ruddle*, and *red iron-froth*.

Hæmatite occurs under a variety of conditions. The best crystals are found in connection with metamorphic silicate rocks and in mineral-veins; whilst the extensive masses of red iron-ore occur as bedded deposits in sedimentary rocks, often in association with limestone. The deposits on the east coast of the island of Elba, which have been extensively worked since the time of the Romans, consist of specular iron; whilst those of west Cumberland and north Lancashire, filling large irregular cavities in limestone, consist of red iron-ore and kidney-iron-ore.

Besides being used as an ore of iron, hæmatite, in its harder, compact varieties, is used, to a limited extent, as a gem-stone, and it was the material employed for some of the ancient Babylonian cylinder-seals. The pencil-ore of Cumberland is cut and polished for mounting on scarf-pins, &c., and for the burnishing tools used by jewellers and bookbinders. Ochreous varieties are used as a polishing material, and for making red paint and red pencils.

L. J. S.

HÆMATOGEN. A soluble iron albuminate.

HÆMATOXYLIN *v.* Logwood.

HÆMOGLOBIN *v.* Blood.

HAIDINGERITE *v.* Calcium.

HALFA. *Alfa, alva.* Arabic name for *Stipa tenacissima* (Linn.); especially applied to the Esparto grass from Algeria.

HALITE *v.* Sodium chloride.

HALLYOSITE. An uncrystallised clay-mineral with approximately the composition of kaolinite (*q.v.*) but containing rather more water (about 19 p.c.). It forms compact masses wtih a slight greasy feel and lustre, and may be white, grey, or shades of various colours; sp.gr. 2·0–2·2; H. 1–2. It occurs as beds in sedimentary rocks and as masses in mineral-veins, and has sometimes been observed as a decomposition product of granite and other rocks containing felspar. Possibly the minute amorphous granules of china-clay and some other clays may be referable to this species. (*See* H. Ries, Clays, their Occurrence, Properties, and Uses, 2nd ed., 1908.)

L. J. S.

HALOGEN. A term originally applied by Berzelius to the group of non-oxygenated electro-negative radicles, simple and compound, which combine with metals to form salts known as *haloid salts*. Usually restricted to the four elements—Fluorine, Chlorine, Bromine, and Iodine.

HALOGEN ACETIC ACIDS. Derivatives of acetic acid in which the hydrogen of the methyl group is partly or wholly replaced by a halogen.

Chloroacetic Acids.

Monochloroacetic acid $CH_2Cl{\cdot}COOH$. Prepared by passing chlorine into acetic acid alone (Hoffmann, Annalen, 102, 1), or in the presence of iodine (Müller, *ibid.* 133, 156), sulphur (Auger and Béhal, Bull. Soc. chim. [iii.] 2, 145), or red phosphorus (Russanow, J. Russ. Phys. Chem. Soc. 23, 222); by the action of chlorine on acetyl chloride in the presence of iodine (Jazukowitsch, Zeitsch. Chem. 1868, 234); by the interaction of chlorine, glacial acetic acid, and acetic anhydride at 100° (Hentschel, Ber. 1884, 17, 1286); together with acetyl chloride by the action of chlorine on acetic anhydride at 100° (Gal, Annalen, 122, 374); by the interaction of ethylene and chlorine peroxide (Fürst, *ibid.* 206, 78).

Crystallises in two modifications, α- prisms, m.p. 61·8°; β- plates, m.p. 56·01°. By evaporating an aqueous solution or by melting the solid substance, the β- modification is produced; this changes to the α- form on the addition of a crystal of the latter (Pickering, Chem. Soc. Trans. 1895, 665, 670; *cf.* Tollens, Ber. 1884, 17, 665; Tanatar, J. Russ. Phys. Chem. Soc. 24, 694); b.p. 185°–187°, 104°–105°/20 mm. (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 476); sp.gr. 1·3978 at 64·5°; hydrates (Colles, *ibid.* 1906, 1252); heat of solution

(Pickering, *l.c.*; Luginin, Ann. Chim. Phys. [v.] 17, 251; Tanatar, *l.c.*); heat of combustion 171·0 Cals. (Berthelot, *ibid.* [vi.] 28, 567); electrical conductivity (Kortright, Amer. Chem. J. 18, 368); magnetic rotation (Perkin, Chem. Soc. Trans. 1896, 1236); esterification constant (Sudborough and Lloyd, *l.c.*; *cf.* Lichty, Amer. Chem. J. 1895, 17, 27; 1896, 18, 590). Readily soluble in cold water, but on heating the solution decomposes into hydrochloric and glycollic acids (Buchanan, Ber. 1871, 4, 340, 863; Thomson, Annalen, 200, 75; Bevan, Proc. Camb. Phil. Soc. 1906, 13, 269; Senter, Chem. Soc. Trans. 1907, 460). Metallic hydroxides of the type R′OH decompose it, yielding glycollic acid, whilst those of the type $R''(OH)_2$ yield diglycollic acid (Schreiber, J. pr. Chem. [ii.] 13, 346). By heating salts of chloroacetic acid with water in a sealed tube glycollic acid is produced (Kastle, Amer. Chem. J. 1892, 14, 586; Kastle and Keiser, *ibid.* 1893, 15, 471; *cf.* Euler, Ber. 1906, 39, 2726). On distilling the acid *in vacuô* with phosphorus pentoxide, the anhydride

$$(CH_2ClCOO)_2O$$

is produced, whilst by distilling the acid through a heated tube, carbon monoxide, hydrogen chloride, *sym*-dichloromethyl ether and trioxymethylene are the products (Grassi-Cristaldi, Gazz. chim. ital. 27, ii. 502). On heating with 4 parts of phosphorus pentachloride, it yields carbon tetrachloride and other products (Michael, J. pr. Chem. [ii.] 35, 96); with ammonia glycine is produced. By interaction with sodium sulphide and sulphur in alkaline solution a dithioglycollic acid is produced, which on reduction, yields thioglycollic acid (Kalle & Co. D. R. P. 180875; Chem. Soc. Abstr. 1907, i. 1008). By the electrolysis of the potassium salt acetic acid, carbon dioxide and chlorine are formed, hydrogen not being evolved until the potassium salt is completely decomposed (Lassar Cohn, Annalen, 251, 335; *cf.* Bunge, J. Russ. Phys. Chem. Soc. 24, 690). By heating the dry silver salt, silver chloride and glycollide are produced (Beckurts and Otto, Ber. 1884, 14, 576). The sodium salt or the ethyl ester react with potassium cyanide to yield the corresponding derivatives of cyanacetic acid (Phelps and Tillotson, Amer. J. Sci. 1908, [iv.] 26, 267, 275). For interaction with tertiary amines to yield betaïnes, *v.* Reitzenstein, Annalen, 1903, 326, 305; with aniline, *v.* Vallée, Bull. Soc. chim. 1905, [iii.] 33, 966; with hydroxylamine, *v.* Rivals, Compt. rend. 1896, 122, 1489; with thiocyanic acid or its salts, *v.* Nencki, J. pr. Chem. [ii.] 16, 1; Jäger, *ibid.* 17; with phenols, *v.* Saarbach, *ibid.* 21, 151; with nitrogen sulphide, *v.* Francis, Chem. Soc. Trans. 1905, 1839.

Methyl ester. Prepared by passing chlorine into methyl acetate at 110°–120° (Censi, Bull. Soc. Ind. Mulhouse, 70, 311), and as ethyl ester (*q.v.*); b.p. 115° (Censi, *l.c.*), 130° at 740 mm. (Schreiner, Annalen, 197, 8; *cf.* P. Meyer, Ber. 1875, 8, 1152); sp.gr. 1·2352 at 19·2° (Henry, J. 1885, 1329).

Ethyl ester. Prepared by the interaction of chloracetyl chloride and alcohol (Willm, Annalen, 102, 109), or by the action of alcohol on monochloroacetic acid in the presence of sulphuric acid (Conrad, *ibid.* 188, 218); b.p. 144·5°–144·9° at 754·2 mm.; sp.gr. 1·1585 at 20°/4° (Brühl, *ibid.* 203, 209). Condensation products are formed with ethyl sodiomalonate (Michael, Ber. 1905, 33, 3217); benzylamine (Mason and Winder, Chem. Soc. Trans. 1894, 628); phenylhydrazine (Reissert, Ber. 1895, 28, 1231; Busch, Schneider and Walter, *ibid.* 1903, 36, 3877; Meussdörffer, J. pr. Chem. 1907, [ii.] 75, 121); substituted ureas (Dixon, Chem. Soc. Trans. 1897, 628); magnesium ethyl bromide (Süsskind, Ber. 1906, 39, 225); magnesium phenylamine iodide (Bodroux, Compt. rend. 1905, 140, 1597).

Dichloroacetic acid $CHCl_2·COOH$. Prepared by chlorinating acetic acid (Maumene, Annalen, 133, 154; Müller, *ibid.* 159); by the interaction of chloral and potassium cyanide (Wallach, Ber. 1873, 6, 114; Annalen, 173, 295; Kötz, Chem. Soc. Abstr. 1910, i. 151); by passing chlorine into phloroglucinol (Hlaziwetz, Annalen, 155, 132; Zincke and Kegel, Ber. 1889, 22, 1476); by the interaction of perchlorethylene and sodium ethoxide at 120° (Geuther and Fischer, J. 1864, 316); of hexachlorotriketohexylene and water (Zincke and Kegel, *l.c.*); of pyrrol and sodium hypochlorite (Ciamician and Silber, Ber. 1885, 18, 1764); of trichloroacetic acid and sodium or barium hydroxides (Pinner, *ibid.* 757); by hydrolysing the ethyl ester (*q.v.*).

Colourless liquid, m.p. −10·8° (Pickering, Chem. Soc. Trans. 1895, 667); b.p. 189°–191°; sp.gr. 1·5724 at 13·5°; mag.rot. (Perkin, *ibid.* 1896, 1236); esterification constant (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 476). Slowly decomposed by heating with water in a sealed tube at 100°, more rapidly with sodium or barium hydroxides (*cf.* Timoféeff, J. Russ. Phys. Chem. Soc. 1904, 36, 255). By heating with silver oxide and a small quantity of water silver chloride and glyoxylic acid are produced (Beckurts and Otto, Ber. 1881, 14, 583). On electrolysis of an aqueous solution hydrogen, carbon monoxide, carbon dioxide, and an oil containing chlorine are produced (Troeger and Ewers, J. pr. Chem. [ii.] 58, 125). The potassium salt yields potassium chloride, trichloroacetic acid, and other products on dry distillation (Friedrich, Annalen, 206, 244). Dichloroacetic acid reacts with phosphorus pentachloride (Michael, Amer. Chem. J. 9, 215); aniline and its homologues (Cech and Schwebel, Ber. 1877, 10, 179; Heller, Annalen, 1904, 332, 247; 1908, 358, 349; Ber. 1908, 41, 4264; Ostromisslensky, *ibid.* 1907, 40, 4972; 1908, 41, 3019; Heller and Aschkenasi, Annalen, 1910, 375, 261); thiourea (Dixon, Chem. Soc. Trans. 1893, 816); nitrogen sulphide (Francis, *ibid.* 1905, 1838).

Methyl ester, b.p. 142°–144° (Wallach, Annalen, 173, 299); sp.gr. 1·3808 at 19·2° (Henry, *l.c.*).

Ethyl ester. Prepared by chlorinating alcohol (Altschul and Meyer, Ber. 1893, 26, 5757); by the interaction of chloral, alcohol, and potassium cyanide (Wallach, *ibid.* 1876, 9, 1212; 1877, 10, 1526); or of dichlorinated vinyl ethers and alcohol (D. R. PP. 209268, 210502, 212592; Chem. Soc. Abstr. 1909, i. 453, 694, 873); b.p. 157·7° at 754·6 mm. (Schiff, Annalen, 220, 108); sp.gr. 1·2821 at 20°/4° (Brühl, *ibid.* 203, 22). With sodium or silver it yields maleic ester (Tanatar, Ber. 1879, 12, 1563).

Trichloroacetic acid $CCl_3·COOH$. Prepared by chlorinating acetic acid in the sunlight (Dumas, Annalen, 32, 101); by the oxidation of chloral with fuming nitric acid (Kolbe, *ibid.* 54, 183; Clermont, Ann. Chim. Phys. [vi.] 6, 135; Judson, Ber. 1870, 3, 782; Thurnlackh, Annalen, 210, 63; Tommasi and Meldola, Chem. Soc. Trans. 1874, 314), chromic acid (Clermont, Compt. rend. 76, 774), or potassium permanganate (Clermont, *ibid.* 86, 1270).

M.p. 57° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 476); sp.gr. 1·6298 at 60·6°; heat of combustion (const. press.) 92·8 Cals. (Berthelot, Ann. Chim. Phys. [vi.] 28, 569); electrical conductivity (Rivals, Compt. rend. 125, 274; Ostwald, Zeitsch. physikal. Chem. 1, 100; 3, 177; Carrara, Gazz. chim. ital. 27, i. 207); esterification constant (Sudborough and Lloyd, *l.c.*; Kailan, Monatsh. 1908, 29, 799); mag.rot. (Perkin, Chem. Soc. Trans. 1896, 1236). At 300° it decomposes into triacetyl chloride, carbon dioxide, and hydrogen chloride (Engler and Steude, Ber. 1893, 26, 1443), whilst the silver salt yields the anhydride, silver chloride, carbon monoxide, and carbon dioxide (Beckurts and Otto, Ber. 1881, 14, 576); for sodium salt, *cf.* Henry, *ibid.* 1879, 12, 1844. At 200° with iodine trichloride perchloromethane, hydrogen chloride, and carbon dioxide are produced (Krafft, *ibid.* 1876, 9, 1049). Chloroform and carbon dioxide are produced by heating the acid with water or alkalis (Dumas, *l.c.*; Otto, Ber. 1871, 14, 589; Seubert, *ibid.* 1875, 18, 3342), potassium cyanide (Bourgoin, Compt. rend. 94, 448), aniline (Goldschmidt and Braüer, Ber. 1906, 39, 109), tertiary bases (Silberstein, *ibid.* 1881, 17, 2664), antipyrine (Stollé, Ber. Deut. pharm. Ges. 1910, 20, 371), or with resorcinol or cresol, but phenol or thymol yield hydrogen chloride, carbon monoxide, and phosgene (Anselmino, *ibid.* 16, 390). Reduction with potassium amalgam or hydriodic acid gives acetic acid. The sodium or zinc salt yields on electrolysis trichloromethyl trichloroacetate (Elbs and Kratz, J. pr. Chem. [ii.] 55, 502). For compounds with aldehydes and ketones, *v.* Koboseff, J. Russ. Phys. Chem. Soc. 1903, 35, 652; Plotnikoff, *ibid.* 1904, 36, 1088; 1905, 37, 875; Ber. 1906, 39, 1794).

Methyl ester. B.p. 152·3°–152·5° at 765·3 mm. (Schiff, Zeitsch. physikal. Chem. 1, 379; *cf.* Anschutz and Haslam, Annalen, 253, 124); sp.gr. 1·4892 at 19·2° (Henry, J. 1885, 1329).

Ethyl ester. Prepared by the interaction of trichloroacetic acid and alcohol with sulphuric acid (Clermont, Compt. rend. 1901, 133, 737), or with hydrogen chloride (Spiegel, Ber. 1907, 40, 1730); b.p. 164°; sp.gr. 1·369 at 15° (Claus, Annalen, 191, 58; Brühl, *ibid.* 203, 22; Schiff, *ibid.* 220, 108). With ammonia it yields the amide; with sodium ethoxide, orthoformic ester, sodium ethyl carbonate, and sodium chloride are the products (Klein, Chem. Soc. Trans. 1877, i. 291.

Bromoacetic Acids.

Monobromoacetic acid $CH_2Br{\cdot}COOH$. Prepared by the action of bromine on acetic acid, either alone (Perkin and Duppa, Annalen, 108, 106) or in the presence of carbon disulphide (Michael, Amer. Chem. J. 5, 202), or of sulphur (Genvresse, Bull. Soc. chim. [iii.] 7, 364); by the interaction of chloroacetic and hydrobromic acids at 150° (Demole, Ber. 1876, 561); by the oxidation of ethylene dibromide with fuming sulphuric acid (Kachler, Monatsh. 2, 559), or of monobromoacetylene in alcoholic solution by air (Glöckner, Annalen, Suppl. 7, 115).

M.p. 49°–50°; b.p. 117°–118°/15 mm. (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477), 196° (Lassar-Cohn, Annalen, 251, 342). On heating an aqueous solution of the acid it is slowly decomposed into glycollic acid (Senter, Chem. Soc. Trans. 1909, 1828). Electrical conductivity (Ostwald, Zeitsch. physikal. Chem. 3, 178; Kortright, Amer. Chem. J. 18, 368). By heating the acid with silver powder at 130°, succinic acid is formed, whilst with silver nitrate silver glycollate is produced (Senter, Chem. Soc. Trans. 1910, 346). Nitrogen sulphide yields bromoacetamide and bromodiacetamide (Francis, *ibid.* 1905, 1839). The sodium salt heated *in vacuô* yields glycollide. The potassium salt gives on electrolysis acetic acid, bromine, and carbon dioxide, no hydrogen being evolved until the potassium salt is completely decomposed (Lassar-Cohn, *l.c.*). Monobromoacetic acid has been used as a reagent for detecting albumin in urine (Boymond, J. Pharm. Chim. [v.] 20, 482).

Methyl ester. Prepared by heating methyl alcohol and monobromoacetic acid in sealed tubes at 100° (Perkin and Duppa, Annalen, 108, 109); b.p. 144°.

Ethyl ester. Prepared as methyl ester, or together with other products by the interaction of sodium ethoxide and bromine (Sell and Salzmann, Ber. 1874, 7, 496); b.p. 159°. It undergoes numerous condensations: with magnesium it yields ethyl acetoacetate and ethyl γ-bromoacetoacetate (Stolle, Ber. 1908, 41, 954); with ethyl oxalylacetate, ethyl citrate (Lawrence, Chem. Soc. Trans. 1897, 458); with ethyl sodioacetoacetate, ethyl acetosuccinate (Sprankling, *ibid.* 1165); with ethyl dimethylacetoacetate, ethyl ααβ-trimethyl-β-hydroxyglutarate (Perkin and Thorpe, *ibid.* 1178).

For other esters, *v.* Clarke, *ibid.* 1910, 428; Steinlen, Bull. Acad. roy. Belg. [iii.] 34, 101; Kunckell and Scheven, Ber. 1898, 31, 172).

Dibromoacetic acid $CHBr_2{\cdot}COOH$. Prepared by the action of bromine on acetic acid alone (Perkin and Duppa, Annalen, 110, 115), or in the presence of sulphur (Genvresse, Bull. Soc. chim. [iii.] 7, 478); by the hydrolysis of the ethyl ester (*q.v.*); m.p. 48°; b.p. 232°–234°; esterification constant, *v.* Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477. The silver salt, heated with water, yields silver bromide, glyoxylic acid, and dibromoacetic acid (Perkin, *ibid.* 1877, i. 91).

Ethyl ester. Prepared by the action of bromine on ethyl acetate at 160°; by passing bromine into alcohol (Schäffer, Ber. 1871, 4, 368); by the interaction of 4 parts of bromal hydrate with 1 part of alcoholic potassium cyanide (Remi, J. Russ. Phys. Chem. Soc. 7, 263); b.p. 192°.

Tribromoacetic acid $CBr_3{\cdot}COOH$. Prepared by the oxidation of bromal with fuming nitric acid (Schäffer, Ber. 1871, 4, 370; Gal, Compt. rend. 77, 786) or by heating an aqueous solution of malonic acid with bromine (Petriew, Ber. 1875, 8, 730). Monoclinic plates, m.p. 131° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477; *cf.* Gal, Annalen, 129, 56); electrical conductivity, *v.* Swartz, Chem. Zentr. 1898, ii. 703). On heating at 245° bromine and hydrogen bromide are evolved. By heating an aqueous solution of the acid or its salts, bromoform is produced. For compounds with aldehydes and ketones, *v.* Koboseff, J. Russ. Phys. Chem. Soc. 1903, 35, 652; Plotnikoff, *ibid.* 1908, 40, 64, 1238).

Ethyl ester. Prepared by passing hydrogen chloride into a cooled alcoholic solution of tribromoacetic acid (Broche, J. pr. Chem. [ii.] 50, 98); b.p. 225°.

Chlorobromoacetic Acids.

Chlorobromoacetic acid $CHClBr{\cdot}COOH$. Prepared by heating monochloroacetic acid (1 mol.) with bromine (1 mol.) in sealed tubes at 160° (Cech and Steiner, Ber. 1875, 8, 1174). Pungent liquid, b.p. 201°; *ethyl ester,* b.p. 160°–163°; *amide,* m.p. 126°.

Monochlorodibromoacetic acid $CClBr_2{\cdot}COOH$. Prepared by heating monochlorodibromoacetaldehyde with fuming nitric acid (Neumeister, Ber. 1882, 15, 603); rhombic plates, m.p. 89°; b.p. 232°–234°, with decomposition. Potassium hydroxide converts it, on heating, into monochlorodibromomethane.

Dichloromonobromoacetic acid $CCl_2Br{\cdot}COOH$. Prepared by heating dichloromonobromoacetaldehyde with fuming nitric acid (Neumeister, *l.c.*); prisms, m.p. 64°; b.p. 215° with decomposition; readily soluble in water or alcohol. Potassium hydroxide converts it, on heating, into dichloromonobromomethane.

Iodoacetic Acids.

Mono-iodoacetic acid $CH_2I{\cdot}COOH$. Prepared by decomposing the ethyl ester (*q.v.*) with baryta water (Perkin and Duppa, Annalen, 112, 125); by heating acetic anhydride with iodine and iodic acid (Schützenberger, Zeitsch. Chem. 1868, 484). Prismatic needles, m.p. 82°; electrical conductivity (Walden, Zeitsch. physikal. Chem. 1892, 10, 647); esterification constant (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 478).

Methyl ester. Prepared in the same manner as the ethyl ester (Aronstein and Kramps, Ber. 1881, 14, 604); b.p. 169°–171°.

Ethyl ester. Prepared by the interaction of ethyl chloro- or bromoacetate, potassium iodide, and alcohol (Perkin and Duppa, *l.c.*); together with other products by heating di-iodoacetylene with excess of alcoholic potassium hydroxide (Nef, Annalen, 298, 348). Colourless oil with a penetrating smell; b.p. 69°/12 mm.; 75°–78°/16 mm. (Tiemann, Ber. 1898, 31, 825).

Di-iodoacetic acid $CHI_2{\cdot}COOH$. Prepared by the interaction of 1 part of malonic acid with 1 part of iodic acid in 4 parts of water; carbon dioxide is evolved, the solution is cooled, filtered, and allowed to stand. After 2 or 3 days crystals of tri-iodoacetic acid separate; these are filtered off and, after heating the filtrate, the di-iodo compound separates on cooling; m.p. 110° (Angeli, Ber. 1893, 26, 596).

Ethyl ester. Prepared by the interaction of ethyl dibromoacetate and potassium iodide in alcoholic solution (Perkin and Duppa, Annalen, 117, 351), or of ethyl dichloroacetate and calcium iodide (Spindler, *ibid.* 231, 273). Yellow liquid, which cannot be distilled unchanged under atmospheric pressure.

Tri-iodoacetic acid $CI_3{\cdot}COOH$. For preparation, *v.* di-iodoacetic acid. Yellow plates, m.p. 150° with decomposition. By heating with acetic acid iodoform and carbon dioxide are produced.

HAMAMELIN. A preparation from the witch-hazel *Hamamelis virginiana* (Linn.), either green or brown in colour, depending upon whether the leaves or bark have been used.

HARDWICKIA RESIN *v.* Oleo-resins.

HARMALA. The seeds of the wild rue, *Peganum Harmala* (Linn.), or harmal seeds, have been employed from the earliest times in Eastern medicine as a stimulant, anthelmintic, or even as a narcotic. They are said to be the source of a red dye produced in Southern Russia, and they have been used in the manufacture of oil. Wild rue is an odoriferous herbaceous plant, 1–3 feet high, and inhabits Southern Europe, Asia Minor, Egypt, North-western India, and Southern Siberia (Flückiger, Pharm. J. [iii.] 2, 229).

Harmal seeds contain about 4 p.c. of two alkaloids (probably in combination with phosphoric acid), which are found for the most part in the outer portions of the seed. The first of these, *harmaline* $C_{13}H_{14}N_2O$ was discovered by Göbel (Annalen, 38, 363), the second, *harmine* $C_{13}H_{12}N_2O$ by Fritzsche (*ibid.* 64, 360; J. 1847–8, 639; Annalen, 68, 351; 68, 355; 72, 306; 88, 327; 88, 328; 92, 330; J. 1862, 377), who studied both alkaloids, and obtained numerous derivatives. Fritzsche extracts the seeds with water containing acetic or sulphuric acid, and saturates the solution obtained with common salt, which causes the alkaloids to precipitate in the form of hydrochlorides. The precipitate is dissolved in water, decolorised by treatment with animal charcoal, and the solution obtained is fractionally precipitated by ammonium hydroxide at 50°–60°. The first portion of the precipitate is harmine, and the last portion harmaline. The crude harmaline is best purified by recrystallisation from methyl alcohol (O. Fischer and Täuber, Ber. 18, 400). From methyl alcohol harmaline crystallises in small tables, or from ethyl alcohol in rhombic octahedra. It melts with decomposition at 238°. It is very slightly soluble in cold water or ether, but readily dissolves in hot alcohol. It forms a well-defined crystalline *hydrochloride*

$$C_{13}H_{14}N_2O,HCl,2H_2O\,;$$

hydrocyanide $C_{13}H_{14}N_2O,HCN$; *platinichloride* $(C_{13}H_{14}N_2O,HCl)_2PtCl_4$; *methiodide*

$$C_{13}H_{14}N_2O,MeI\,;$$

chromate $(C_{13}H_{14}N_2O)_2H_2CrO_4$; and *nitro derivative* $C_{13}H_{13}(NO_2)N_2O$. Both the hydrocyanide and the nitro derivative are bases, and combine with acids to form crystalline salts. Nascent hydrogen converts harmaline into a *dihydride* $C_{13}H_{16}N_2O$ (O. Fischer, Ber. 22, 638). Harmaline is shown by Fischer (*ibid.* 28, 2481) to be *dihydro- harmine*, and it can be converted into harmine by oxidation, which is best effected by potassium permanganate in dilute sulphuric acid solution. By oxidation with chromic acid in boiling acetic acid solution or by nitric acid both harmaline and harmine are converted into *harminic acid* $C_{10}H_8N_2O_4$. By the action of hydrochloric acid on harmaline, Fischer and Täuber obtained a brick-red crystalline powder *harmalol* $C_{12}H_{12}N_2O$, which melts at 212° with decomposition. This compound also occurs naturally in harmal seeds, and has been isolated from these by Fischer (Chem. Zentr. 1901, i. 957).

Harmine exists in harmal seeds in much smaller proportion than harmaline. It may, however, be prepared from the latter by simple oxidation, either by the action of heat on the dry chromate, or by heating an alcoholic solution of harmaline nitrate to which hydrochloric acid has been added. Harmine crystallises in four-sided prisms (Schabus, J. 1854, 525). It melts with decomposition at 257°–259°. It is very slightly soluble in water or alcohol, and slightly soluble in ether. The salts of harmine are crystalline and colourless, and in acid solution exhibit an indigo blue fluorescence. The more important are the *hydrochloride*

$$C_{13}H_{12}N_2O,HCl,2H_2O\ ;$$

the *platinichloride* $(C_{13}H_{12}N_2O,HCl)_2PtCl_4$; the *methiodide* $C_{13}H_{12}N_2O,MeI$ (F. and T.); and the two *sulphates* $(C_{13}H_{12}N_2O)_2,H_2SO_4,H_2O$, and $C_{13}H_{12}N_2O,H_2SO_4$. Fritszche prepared the following halogen and nitro derivatives of harmine all of which are bases and form crystalline salts: *dichloroharmine* $C_{13}H_{10}Cl_2N_2O$; *nitroharmine* $C_{13}H_{11}(NO_2)N_2O$; *chloronitroharmine* $C_{13}H_{10}Cl(NO_2)N_2O$; and *bromonitroharmine* $C_{13}H_{10}Br(NO_2)N_2O$. A *tetrabromide*

$$C_{13}H_{12}N_2OBr_4$$

has been obtained by Fischer.

When harmine is treated with concentrated hydrochloric acid at 140°, Fischer and Täuber find that it breaks up into methyl chloride and a new phenolic compound *harmol* $C_{12}H_{10}N_2O$, which crystallises in needles and melts at 321°. When harmol is fused with potash it yields a compound possessing both basic and acid properties, *harmolic acid*, $C_{12}H_{10}N_2O_5$, which melts at 247° (Fischer, Ber. 22, 637). Fischer and Täuber, by acting on harmine in acetic acid solution with chromic acid, obtained dibasic *harminic acid* $C_8H_6N_2(COOH)_2$. It forms silky needles, melting at 345°, at which point it decomposes into carbon dioxide and a crystalline basic sublimate of *apoharmine* $C_8H_8N_2$, m.p. 183°, from which Fischer obtained a well-defined gold salt. A *tetrabromide* $C_8H_8N_2Br_4$, and a *dihydride* $C_8H_8N_2H_2$, were also obtained. Other derivatives of harmine are described by Fischer and Buck (Ber. 38, 329). A. S.

HARMALIN. *Fuchsin v.* Triphenyl methane colouring matters.

HARMALINE, HARMALOL, HARMINE, HARMINIC ACID, HARMOL and **HARMOLIC ACID,** *v.* Harmala.

HARTIN *v.* Resins.

HARTITE *v.* Resins.

HAUERITE. *Manganese disulphide* MnS_2 *v.* Manganese.

HAUSMANNITE. *Trimanganic tetroxide* Mn_3O_4 (*v.* Manganese).

HAZELINE. Trade name for a fragrant essence obtained from the fresh bark of *Hamamelis virginiana* (Linn.) or witch-hazel. Is probably analogous to eucalyptol. Is a colourless oil, possessing a pleasant pungent smell and sweet astringent taste. Is used in the treatment of eczema, ulcers, burns, &c., and as a substitute for arnica.

HEAVY SPAR. Native barium sulphate *v.* Barytes and Barium.

HEBBAKHADE *v.* Gum resins.

HECLA POWDER *v.* Explosives.

HEDERIC ACID. An acid contained in ivy berries; *v. Ivy gum resin*, art. Gum resins.

HEDERINE. A poisonous glucoside $C_{64}H_{104}O_{19}$ found in ivy. Dextrorotary $[\alpha]_D = 16{\cdot}27°$. By hydrolysis yields rhamnose and *hederidine* $C_{26}H_{40}O_4$ crystallising in rhombic prisms, m.p. 324°, and subliming without decomposition. Hederine acts as a powerful cathartic (Houdas, Compt. rend. 128, 1463; Joanin, *ibid.* 128, 1476).

HEDERO-TANNIC ACID *v.* Gum resins.

HEDGE-MUSTARD OIL. An oil manufactured from the so-called hedge-mustard or bank-cresses (*Raphanus Raphanistrum* [Linn.]) cultivated in Hungary, and used as a substitute for rape-seed oil. The oil is brought to the market either by itself or mixed with rape-seed oil, and is occasionally sold under this latter name. The siliquous fruit of the plant mentioned bears little seeds which contain 30–35 p.c. oil. This can be for the most part obtained by pressing. It has a dark olive-green colour, and an odour and taste very similar to rape-seed oil; its density and faculty for saponifying with alkali is also nearly the same, so that it is difficult to recognise it in a mixture of the two oils. Valenta has tested the two oils as regards their behaviour with the usual reagents. On acting upon them with acids of different strength, such as sulphuric and nitric acids, a mixture of these, *aqua regia*, phosphoric acid, &c., as well as with oxidising mixtures, as potassium dichromate and sulphuric acid, or concentrated nitric acid saturated with nitric oxide, various colours are produced with both oils, by the shade and intensity of which they can be fairly readily distinguished. The following reaction is most characteristic for hedge-mustard oil: about 5 grams of the oil are saponified with potassium hydroxide and spirit with warming, and the soap thus obtained is filtered from the unchanged oil, which is golden-yellow, and almost odourless and tasteless. On adding a large excess of hydrochloric acid to the concentrated filtrate, it assumes a distinct green colour if a somewhat large portion of hedge-mustard oil be present (J. Soc. Chem. Ind. 11, 181).

HEDONAL *v.* Synthetic drugs.

HELCOSOL. *Bismuth pyrogallate v.* Bismuth, Organic compounds of; and Synthetic drugs.

HELIANTHIC ACID $C_{14}H_{18}O_3$. An acid found in sunflower seeds (Ludwig and Kromayer, Arch. Pharm. [ii.] 99, 1285).

HELIANTHIN *v.* Azo- colouring matters.

HELIOCHRYSIN *v.* Naphthalene colouring matters.

HELIOTROPE *v.* Azo- colouring matters.

HELIOTROPINE is a crystalline, volatile, poisonous alkaloid of bitter taste contained in *Heliotropium Europeum* (Linn.), and *H. Peruvianum* (Linn.) (Battandier, Répert de Pharm. 1876, 4, 648). The name is also applied to a perfume (*v.* Piperonal).

HELIUM. Sym. He. At. wt. 3·99 (Watson). This element is the lightest member of the group of inert gases discovered by Rayleigh and Ramsay. Its place in the periodic classification is before lithium.

History.—During the solar eclipse of 1868 Janssen observed in the spectrum of the solar chromosphere a line in the yellow, nearly coincident with the sodium lines D_1 and D_2, which was not attributable to any terrestrial substance. Lockyer and Frankland supposed it to be due to the presence in the sun of a new element to which they gave the name 'helium' (ἥλιος, the sun).

Helium was first obtained by Hillebrand, who found that the gas evolved from the mineral *uraninite* gave a fluted spectrum, by him attributed to nitrogen, but afterwards proved to be due to helium (Bull. U. S. Geol. Survey, 1889, 78, 43).

The discovery of terrestrial helium was made by Ramsay when searching for argon, &c., in the gases evolved from the mineral *cleveite*, and its presence in the atmosphere was first noticed by Kayser (Chem. News, 1895, 72, 89), who detected the helium line in the air-spectrum. For a complete bibliography and account of the earlier investigations on helium, *see* Ramsay, Ann. Chim. Phys. 1898, [vii.] 13.

Occurrence.—It is now known that helium is very widely distributed, though it occurs only in minute quantities. It is present in air in the proportion of 0·000056 p.c. by weight or 0·00040 p.c. by volume, *i.e.* about 1 volume of helium in 250,000 vols. of air (Ramsay, Proc. Roy. Soc. 1908, 80, A, 599). Helium also occurs in many minerals, of which the chief are *cleveite*, *brögerite*, *uraninite*, and *fergusonite*, and it has been detected in the gases of many mineral springs, *e.g.* Bath; in those of the Pyrenees (Bouchard, Compt. rend. 121, 392); of Wildbad (Kayser, Chem. Zeit. 19, 1549); and of Maizières, the gas from the latter containing 5·34 p.c. of helium (Moureux, Compt. rend. 121, 819).

The gas obtained from minerals usually consists principally of helium with about 10 p.c. of nitrogen and smaller amounts of argon, &c. In view of the chemical inertness of helium it is of interest to know in what state it exists in minerals. Ramsay and Travers have found that, by the action of heat alone, almost exactly half the total helium in the mineral is evolved, whilst by heating with sulphuric acid the whole is obtained. The evolution of gas is also in some cases accompanied by an evolution of heat, suggesting that the helium is present as an endothermic compound (Proc. Roy. Soc. 1898, 62, 325). Gray has investigated the conditions under which helium is liberated on grinding minerals, and finds that its evolution begins when the particles have a diameter of 10μ and attains a practical limit when the diameter is 3μ, 28 p.c. of the helium content being then liberated. He concludes that the helium is contained in a structure which is large compared with the molecular structure (Proc. Roy. Soc. 1909, 82, A, 301).

Strutt has investigated the accumulation of helium in rocks in geological time (Proc. Roy. Soc. 1908, 81, A, 272), and concludes that it is due to unknown favourable circumstances, as the rate of loss of helium from minerals under experimental conditions is much greater than the rate of production from radioactive emanations (*v.i.*) (Proc. Roy. Soc. 1909, 82, A, 166).

Helium occurs in the natural gas of Kansas in varying amounts: 1·84 p.c. was found in the gas at Dexter, Cowley Co., Kansas (Cady and McFarland, J. Amer. Chem. Soc. 1907, 29, 1523). It has also been found occluded in meteoric iron (Ramsay and Travers, Proc. Roy. Soc. 60, 442).

Preparation and *purification.*—The preparation of helium always involves its separation from a mixture with nitrogen, argon, krypton, &c. The mixed gases may be obtained by any of the following methods:—

(1) From 'atmospheric' nitrogen, by passing the gas over heated magnesium (Ramsay and Travers, Proc. Roy. Soc. 64, 183); or a heated mixture of magnesium and lime (Maquenne, Compt. rend. 121, 1147), when the nitrogen is absorbed and the inert gases can be collected.

(2) By fractional distillation of liquid air, according to the method of Ramsay and Travers (Phil. Trans. 1901, 197, 47). Claude has designed an apparatus for producing considerable quantities of the lighter constituents of the atmosphere (Compt. rend. 1908, 147, 624).

(3) From certain mineral springs (*v.s.*). (For methods of collecting the gases *see* Travers' Study of Gases, chap. iv., and Proc. Roy. Soc. 60, 442.) The gases from King's well, Bath, contain 0·12 p.c. of helium by volume, and have been used as a source of the gas by Rayleigh (Proc. Roy. Soc. 1896, 59, 198), the oxygen and nitrogen being separated as from air. It is calculated that this well produces about 1000 litres of helium annually.

(4) By heating certain minerals alone, or with dilute sulphuric acid or acid potassium sulphate. This is probably the best method of preparing helium, and may be carried out as follows:—

The mineral in fine powder is introduced into a wide tube of hard glass or iron sealed at one end and connected by a rubber joint with a manometer and a reservoir, in which the gas can be collected over mercury. The whole apparatus is completely evacuated and the tube slowly heated to redness. When, after some hours, the evolution of helium becomes very slow, the heating is stopped and the gas is pumped out of the reservoir (Travers' Gases, 111). Fusion with an equal weight of acid potassium sulphate in a hard glass tube gives a larger yield, but much frothing takes place, and a preferable method is to heat with dilute sulphuric acid in an evacuated flask (Travers, Proc. Roy. Soc. 1898, 64, 131). This is a comparatively cheap method of production as 1 gram of cleveite yields over 3·2 c.c. of helium, and a kilog. of the mineral can be obtained for £1.

From the mixture of gases thus obtained pure helium may be isolated by one of the following processes:—

Jacquerod and Perrot have found that quartz is permeable to helium at 1000°–1200°; therefore by surrounding a quartz tube with impure helium at that temperature and pumping away the gas from the interior it can be obtained free from nitrogen and other inert gases (Compt. rend. 1907, 144, 135). Watson has shown that this process is not practicable with some kinds of fused quartz (Chem. Soc. Trans. 1910, 812). Ramsay's method consists in introducing the impure gas into a vacuous tube containing charcoal at the temperature of liquid air (Proc. Roy. Soc. 1905, A, 76, 111). Under these conditions all gases except helium and neon are completely condensed, and the vapour pressure of neon is so much less than that of helium, that by systematic repetition of the process a perfectly pure product can be obtained (Watson, *l.c.*).

Properties.—Helium has so far resisted all efforts to cause it to combine with other elements. It appears, however, to be absorbed to some extent by the finely divided platinum deposited on the walls of a vacuum tube with platinum electrodes by the continued passage of an electric discharge (Travers, Proc. Roy. Soc. 60, 449). This affords a method of separating small amounts of helium and argon, as the latter is only slightly absorbed under these conditions. Cooke has found that zinc vapourised in helium has a vapour density 12 p.c. greater than when vapourised in nitrogen at the same temperature (Zeitsch. physikal. Chem. 1906, 55, 537). This indicates some tendency toward combination.

There is possibly some connection between the chemical inertness of the gas and the fact that its molecules are monatomic as shown by determinations of the ratio of the specific heats. Behn and Geiger, using a modification of Kundts' method, have found the value $C_p/C_v=1{\cdot}63$, which agrees with that required by theory and found experimentally in the case of other monatomic gases, *e.g.* mercury (Ber. deut. phys. Ges. 1907, 5, 657).

The following determinations of the density of helium have been made (0=16) :—

Ramsay and Travers (Phil. Trans. 1901, 197, 47) D=1·98
Olzewski (Ann. Physik. 1905, [iv.] 17, 997) D=2·00
Schierloh . . . . . . D=1·985
Onnes (Leyden, Comm. 1908, No. 108) D=2·02
Watson (Chem. Soc. Trans. 1910, 97, 827) D=1·997

The molecular weight is taken as 3·99, and as the gas is monatomic this is also the atomic weight.

The refractive index of helium is about 1·000035 for the whole of the visible spectrum, the dispersive power being very small (Scheel and Schmidt, Ber. deut. Phys. Ges. 1908, 6, 207; Hermann, *ibid.* 1908, 6, 211, 246). The accurate value of μ for the D lines is 1·00003500 (Burton, Proc. Roy. Soc. 1908, A, 80, 390; Cuthbertson and Metcalf, *ibid.* 411).

Helium is diamagnetic (Tänzler, Ann. Physik. 1907, [iv.] 24, 931). Its coefficient of solubility in water is less than that of hydrogen, being 0·0134 at 0° and 0·0138 at 20°, with a minimum at 10° (Antropoff, Proc. Roy. Soc. 1910, 83, A, 474). Helium resembles hydrogen also in that the product of pressure and volume increases with the pressure, and it is therefore used in thermometry at low temperatures.

Iron, platinum, palladium, and platinum-iridium are all impervious to helium at temperatures up to 1500° (Dorn, Phys. Ztg. 7, 312). The spectrum of helium is characterised by the presence of a strong line, D_3, in the yellow ($\lambda=5876$), which has been shown to be double, and a bright-green line ($\lambda=5016$). The colour of the glow given by the gas in a Plücker's tube varies with the pressure, being yellow at 7 mm. and green at 1–2 mm. pressure, according to the strength of one or other of these lines. This phenomenon led Runge and Paschen to assume that helium consists of two components (Nature, 1895, 52, 520). This idea has been disproved by subsequent experiments (Nature, 1897, 56, 380).

After many fruitless attempts helium was first liquefied by Onnes (Proc. K. Acad. Wetensch. Amsterdam, 1909, 11, 168; Compt. rend. 147, 421), who found that when cooled in solid hydrogen it gave the Joule-Kelvin effect on expansion through a small nozzle and could therefore be liquefied by the Linde process. From 200 litres of the gas he thus obtained over 60 c.c. of liquid helium in 3 hours.

It is a colourless mobile liquid of density 0·122, being thus the lightest liquid known. It boils at 4·5° absolute, and has a critical temperature about 5° absolute, with a critical pressure of 2·75 atmospheres. By the rapid evaporation of liquid helium a temperature below 2·5° absolute has been reached (−270·5°), but there was no indication of the formation of the solid (Onnes, Proc. K. Acad. Wetensch. Amsterdam, 1909, 12, 175). Liquid helium has a point of maximum density in the neighbourhood of 2° absolute (Onnes, Communication from Phys. Lab. of Leyden, No. 119).

A method has been described by Bordas (Compt. rend. 1908, 146, 628) for the detection of small amounts of helium by means of a Plücker tube connected with a Dewar tube containing charcoal (Dewar, Proc. Roy. Soc. 1904, 74, 127).

Tschermak has suggested the use of a vacuum tube containing helium as a standard in spectroscopy, and as a source of light in determining refractive indices, &c. (Chem. Soc. Abstr. 1902, ii. 189). Collie has found that the spectrum of helium is considerably modified by the presence of mercury vapour and recommends a helium-mercury tube containing a trace of hydrogen as a standard in spectroscopy (Proc. Roy. Soc. 1902, 71, 25).

Production of helium from radioactive elements. The gas evolved from a solution of radium bromide is a mixture of oxygen and hydrogen with a radioactive emanation, which can be obtained pure by condensation at a low temperature. When volatilised into a closed space the emanation phosphoresces and gives a characteristic spectrum, but in the course of about four days the radioactivity disappears and the spectrum changes to that of helium (Ramsay and Soddy, Proc. Roy. Soc. 1903, 72, 204; 1904, 73, 346). During this change the volume increases to three times that of the original emanation (Dewar and Curie, Compt. rend. 1904, 138, 190; Indrikson, Physikal. Zeitsch. 1904, 5, 214; Himstedt and Meyer, Ann. Physik. 1904, 15, 184).

It is probable that helium is the final product of the disintegration of radium. The rate of production of helium is 0·37 cub. mm. per day from 70 mgm. of radium chloride, and agrees with that calculated by Rutherford on the assumption that α-particles are helium atoms carrying two ionic charges (Dewar, Proc. Roy. Soc. 1908, 81, A, 280).

Helium is also a product of the disintegration of actinium (Giesel, Ber. 1907, 40, 3011), and of thorium radioactivity (Strutt, Proc. Roy. Soc. 1907, 80, A, 56). The rate of production in this case also supports the view that the α-

particle is identical with the helium atom (Soddy, Phil. Mag. 1908, [vi.] 16, 513; Physikal. Zeitsch. 1909, 10, 41).

HELKOMEN. Trade name for a basic bismuth dibromohydroxynaphthoate. Yellow odourless powder. Used as a substitute for iodoform.

HELLEBOREÏN, HELLEBORIN, HELLEBORESIN, HELLEBORETIN, *v.* BLACK HELLEBORE ROOT.

HELL-HOFFITE *v.* EXPLOSIVES.

HELMITOL. Trade name for a compound of hexamethylene tetramine (urotropine) and anhydromethylene citric acid (*v.* SYNTHETIC DRUGS).

HEMELLITHENOL *v.* PHENOL AND ITS HOMOLOGUES.

HEMIPINIC ACIDS $C_{10}H_{10}O_6$. *n-Hemipinic acid* (3 : 4-*dimethoxybenzene*-1 : 2-*dicarboxylic acid*) is a product of oxidation of narcotine (Wöhler, Annalen, 1844, 50, 17; Blythe, *ibid.* 43); of opianic acid (Beckett and Wright, J. 1876, 806); of berberine (Schmidt, Ber. 1883, 16, 2589); of corydaline (Dobbie and Lauder, Chem. Soc. Trans. 1894, 57; *ibid.* 1895, 18; *ibid.* 1897, 657; *ibid.* 1902, 146; Martindale, Arch. Pharm. 1898, 236, 214); and of other alkaloids. It is prepared by boiling the oxide of opianic anhydride with potassium hydroxide. The solution is then acidified and extracted with ether (Goldschmidt, Monatsh. 1888, 9, 766). It crystallises with ½ and also with 2 molecules of water.

Properties.—Both in the normal and the meta acids the m.p. varies with the rate of heating. When heated rapidly it has m.p. about 181° (Dobbie and Lauder, Chem. Soc. Trans. 1899, 678). It is sparingly soluble in cold water, readily so in alcohol; the aqueous solution gives an orange-yellow precipitate with ferric chloride, and no precipitate with silver nitrate solution. When heated with ammonia it yields an imide $C_{10}H_9NO_4$ (Kühn, Ber. 1895, 28, 809), the potassium salt of which when heated with ethyl iodide at 150° yields the characteristic *hemipinethylimide*; m.p. 92°–96° (Goldschmidt and Ostersetzer, Monatsh. 1888, 9, 762; Liebermann, Ber. 1886, 19, 2282; Freund and Heim, *ibid.* 1890, 23, 2906). When treated with phosphorus pentachloride at 140° hemipinic acid yields the anhydride, which is also obtained by the action of equal volumes of methyl alcohol and concentrated sulphuric acid on the acid (Beckett and Wright, *l.c.*; Wegscheider, Monatsh. 1897, 18, 649).

The *anhydride* $C_{10}H_8O_5$ forms brilliant needles; m.p. 166°–167°. It reacts with hydroxyquinol, forming *dihydroxydimethoxy fluorescein* (Liebermann and Wolbling, Ber. 1902, 35, 1782), and with resorcinol, forming *dimethoxy fluorescein* (Friedl, Weizmann, and Wyler, Chem. Soc. Trans. 1907, 1584).

Lagodzinski has synthesised alizarin from hemipinic acid by treating the latter with benzene in the presence of aluminium chloride. The aluminium compound so formed is decomposed with hydrochloric acid, and the resulting product $C_{15}H_{12}O_5,H_2O$ is dissolved in cold sulphuric acid and heated to 100°. The violet solution is poured on to ice and the mono-methyl ether of alizarin so obtained is decomposed with hydrogen iodide (Ber. 1895, 28, 1427).

The *methyl ester* exists in 2 modifications; m.p. 121°–122° and 138° respectively, the latter being the more stable form at ordinary temperature (Wegscheider, Monatsh. 1897, 18, 418, 589, 629).

Other esters (Wegscheider, *l.c.*; Monatsh. 1902, 23, 327, 381; Landau, Ber. 1898, 31, 2090; Cahn-Speyer, Monatsh. 1907, 28, 803); a number of metallic salts (Salzer, Ber. 1897, 30, 1102), and many other derivatives have been obtained (Goldschmidt, Monatsh. 1887, 8, 512; Mealen, Rec. trav. chim. 1896, 15, 282, 323; Claus and Predagi, J. pr. Chem. 1897, [ii.] 55, 171; Besterzycki and Fink, Ber. 1898, 31, 930; Wegscheider, *l.c.*, and Monatsh. 1903, 24, 375; Dobbie and Lauder, *l.c.*, amongst others).

On gentle nitration, hemipinic acid yields chiefly nitro derivatives, but on more energetic nitration 5 : 6-dinitro-2 : 3-dimethoxybenzoic acid is formed (Wegscheider, Monatsh. 1908, 29, 54, 557; *ibid.* 1910, 31, 709).

m-Hemipinic acid (4 : 5-dimethoxybenzene-2 : 3-dicarboxylic acid) is a product of the oxidation of papavarine (Goldschmidt, Monatsh. 1885, 6, 380); of laudanin (*ibid.* 13, 695); and of corydic acid (Dobbie and Marsden, Chem. Soc. Trans. 1897, 664). It is also obtained by the oxidation of trimethylbrazilin (Gilbody, Perkin, and Yates, Chem. Soc. Trans. 1901, 1400; *ibid.* 1902, 1045); of tetramethylhæmatoxylin (*ibid.* 1061); and of 4 : 5-dimethoxy-*o*-toluic acid (Luff, Perkin, and Robinson, *ibid.* 1910, 1136). It can be prepared according to the following method:—

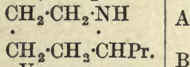
5 : 6-Dimethoxy-1-hydrindone (3 grams) is boiled with nitric acid (12 grams) and water (36 c.c.). The clear yellow solution is neutralised with sodium carbonate, mixed with hydrochloric acid until the solution turns Congo paper blue, evaporated to dryness, the residue mixed with sand and extracted in a Soxhlet apparatus with ether. The ethereal solution is dried over anhydrous sodium sulphate, evaporated, and the residue dissolved in hot water, and after digestion with animal charcoal and filtration, the solution is allowed to evaporate slowly in the air. It can also be obtained by the oxidation of *iso*-nitrosodimethoxyhydrindone with potassium permanganate, which gives an almost theoretical yield (Perkin and Robinson, Chem. Soc. Trans. 1907, 1083) and by heating aqueous dimethoxycarboxybenzoyl formic acid (Perkin, *ibid.* 1902, 1025; *see* also Perkin and Yates, *ibid.* 242).

m-Hemipinic acid crystallises with 1 and with 2 molecules of water, has m.p. about 199° (Dobbie and Lauder), and is much less soluble in water than the normal acid. Its aqueous solution gives a cinnabar orange precipitate with ferric chloride and a white precipitate with silver nitrate. On heating it forms an anhydride, m.p. 175°; when fused with potash it yields protocatechuic acid and carbon dioxide. When treated with nitric acid it gives dinitroveratrol, whilst on reduction it yields 4 : 5-dihydroxyphthalic acid (Rossin, Monatsh. 1891, 12, 488). Its *ethylimide* has m.p. 228°–230°, and unlike that from the normal acid, it is very sparingly soluble in methyl alcohol. The ethyl esters have been prepared by Rossin (*l.c.*).

HEMISINE *v.* SYNTHETIC DRUGS.

HEMLOCK. *Spotted hemlock*; *Conium. Grande ciguë*, Fr.; *Schierling*, Ger. Hemlock, *Conium maculatum* (Linn.) (Bentl. and T. 118) is an erect biennial herbaceous plant which inhabits the temperate portions of Europe and Asia as well as of North and South America. It was the essential ingredient in the poison potion administered to condemned criminals by the Greeks, and from that period to the present day it has been a well-known article of materia medica. The leaves gathered from wild British plants at the time when the fruit begins to form, and the fruits collected when fully developed, but before they have lost their green colour, are employed in medicine in this country (Brit. Pharm.; Smith, Pharm. J. [ii.] 10, 489; Harley, *ibid.* [iii.] 1, 584). The root possesses little or no activity (Lepage, J. Pharm. Chim. [v.] 6, 10). The action of hemlock on the system is that of a sedative to the motor nerves (Christison, J. Pharm. Chim. 22, 413; Hofmann, Ber. 14, 705; Kuhlmann, Arch. Pharm. [ii.] 23, 38), to which end the leaves are administered, preferably as juice or solid extract, and the fruits in the form of tincture. For further botanical and historical particulars, and the mode of detecting the accidental admixture of allied umbelliferous plants *v.* Flück. a. Hanb. 299–302.

The physiological activity of both the leaves and fruit of hemlock depends upon the presence of the strong-smelling volatile liquid alkaloid *coniine*, *conine*, *conicine*, or *circutine* $C_8H_{17}N$, together with smaller proportions of four nearly-related bases, methyl conine, conhydrine, ψ-conhydrine, γ-coniceïne (Geisecke, Brandes Arch. Pharm. 20, 97; Geiger, Berz. J. 12, 220; Planta and Kekulé, Annalen, 89, 129; Wertheim, *ibid.* 100, 328; 123, 157; Ladenburg and Adam, Ber. 24, 1161; Wolffenstein, *ibid.* 28, 302). Coniine has been prepared synthetically by Ladenburg (Ber. 19, 2579; 22, 1403) and proved to be *dextro*-(α) *propylpiperidine*



$$\begin{array}{l} CH_2\cdot CH_2\cdot NH \\ \cdot \qquad\qquad\qquad \cdot \\ CH_2\cdot CH_2\cdot CHPr. \end{array}$$

For properties and reactions *v.* VEGETO-ALKALOIDS. When hemlock leaves or fruit are triturated with an alkali a strong odour is given off, due to coniine and the other bases, with some ammonia, and by distilling such a mixture, using suitable precautions, the alkaloids are obtained. Geiger, for instance, distils the fruit with potassium carbonate or calcium hydroxide, and then by a series of operations separates the bases from the distillate. Christison distils in a similar way an alcoholic extract. Wertheim extracts with water acidulated with sulphuric acid, supersaturates the extract with lime or potash, and distils. The distillate is then neutralised with sulphuric acid, evaporated to a syrup, and treated with alcohol, which dissolves the alkaloidal sulphates, and leaves the ammonium salt, which is insoluble in that liquid. The alcohol is then removed by distillation, the residue supersaturated with potash, and extracted with ether. The ethereal solution is distilled. After the ether has come over, the distillation is conducted in a stream of hydrogen, when the first portions of the distillate contain the coniine, which may be purified by conversion into hydrochloride, recrystallisation, and regeneration by means of an alkali. Another method of isolating the alkaloids from the fruit is to extract with dilute acetic acid, evaporate the solution to a syrup in a vacuum, mix with excess of magnesia and extract with ether (Schorm, Ber. 14, 1766). V. Braun (Ber. 38, 3108) gives a method for the separation of the other bases present in the mixture of alkaloids remaining after the greater part of the conine has been removed by distillation. The percentage of alkaloids obtained varies, 0·2 p.c. of coniine being a good yield from the fruit.

Conhydrine, which is much less active physiologically than coniine, melts at 120·6°, and boils at 224·5° (719·8 mm.) (Wertheim, J. 1863, 435). Treated with phosphorus pentoxide or concentrated hydrochloric acid it loses the elements of water, and is converted into the two isomerides (α) and (β) *coniceïn* $C_8H_{15}N$ (Hofmann, Ber. 18, 7; Lellmann and Muller, *ibid.* 23, 680). γ-Coniceïne, discovered in impure conine by Wolffenstein, had been prepared previously by Hofmann (Ber. 18, 112) by treating bromconine with dilute caustic soda solution. It is a liquid, b.p. 173°, and has the same odour as conine. ψ-Conhydrine $C_8H_{17}NO$ has m.p. 100°–102°, and b.p. 229°–231°. For estimation of the alkaloids in hemlock *v.* Cripps (Pharm. J. [iii.] 18, 12 and 511) and Kremel (Ph. Post. 20, 521). Hofmann (Ber. 17, 1922) discovered *caffeïc* or *dihydoxycinnamic acid* $C_6H_3(OH)_2CH:CH\cdot COOH$ in hemlock. It contains also a *volatile oil*, said to be the product of fermentation (Landerer, Rep. Pharm. 94, 237) and the leaves yield on ignition 12·8 p.c. of *ash* (Wrightson, Pharm. J. 5, 40). A. S.

HEMLOCK SPRUCE RESIN *v.* RESINS.

HEMP. The name of various plants and of the fibres derived from them (*see* also BAST-FIBRES). The following list embraces these fibres under their commercial denominations, with the names of the plants which produce them:—

Common hemp	*Cannabis sativa* (Linn.).
African bowstring hemp	*Sansevieria guineensis* (Willd.) and others.
Bastard hemp	*Datisca cannabina* (Linn.).
Bengal or Bombay hemp	*Crotalaria juncea* (Linn.).
Bombay hemp (also)	*Hibiscus cannabinus.*
Bowstring (of India) hemp	*Sansevieria Roxburghii* and others.
Bowstring (of India) hemp (also)	*Calotropis gigantea* (Dryand.).
Brown hemp	*Crotalaria juncea* (Linn.).
Brown (Indian) hemp (also)	*Hibiscus cannabinus* (Linn.).
Florida bowstring hemp	*Sansevieria longiflora* (Sims).
Indian (in America) hemp	*Apocynum cannabinum* (Linn.).
Jubbalpore hemp	*Crotalaria juncea* (Linn.).
Madras hemp	*Crotalaria juncea* (Linn.).
Manilla hemp	*Musa textilis.*
Sisal hemp	*Agave rigida* (Mill.).
Sunn hemp	*Crotalaria juncea* (Linn.).
Virginian or Water hemp	*Acnida cannabina* (Linn.).

Of these, *Cannabis sativa*, nat. ord. *Urticaceæ*, allied to the hop plant, furnishes the true hemp. The plant is an annual, growing ordinarily to the height of 8 or 10 feet, but sometimes exceeding that limit by several feet; and it doubtless owes its origin to some part of temperate Asia. On extending its habitat, the character of the plant changed with soil and climate, giving origin to the supposed varieties *C. chinensis* and *C. indica*, the former of which is cultivated for its bast-fibres (hemp), while the latter is grown for its narcotics.

Hemp fibre examined by the microscope resembles that of flax in being round and ribbed; it has a mean diameter of 0·2 mm., and exhibits small, hairy appendages at the joints. According to Haberlandt, the breaking strain of a cord of 1 sq. mm. section is on the average 34·5 kilos. In *Manilla* hemp the fibrous bundles are oval, nearly opaque, and surrounded by a number of rectangular cells composing a dried tissue. The bundles are smooth. *Sisal* hemp forms oval fibrous bundles surrounded by cellular tissue; a few smooth ultimate fibres projecting from the bundles. It is more translucent than Manilla, and is characterised by the large quantity of spiral fibres in the bundle.

Hemp is cultivated (1) for its fibre; (2) for its resin; (3) for the oil contained in its seed; (4) for the seed itself. The tough, elastic, and durable fibre is better adapted for the manufacture of cordage and sail-cloth than any other known material. It is, moreover, employed for canvas, tarpaulin, and towelling. The finest qualities for these purposes are imported from Italy and Russia. The preparation of the fibre is similar to that of flax; the stems being bruised and 'retted' or fermented in water, after which they are again beaten out and finally 'scutched' and 'hackled' or combed (*v.* Flax). The water in which hemp has been steeped produces no evil effects on the health of a district when allowed to flow into running water, but it always destroys the fish together with certain vegetable growths (Renouard, Bied. Zentr. 1880).

The resin of hemp is employed in India as *charas*, *bhang* or *siddhi*, and *gánjá*, in which form it is used for its intoxicating and narcotic properties. *Charas* is the resin itself; *bhang* or *siddhi* consists of the dried resinous leaves and stalks; it is used for smoking, for making sweetmeats along with honey and sugar, or for forming a potable infusion. *Gánjá* is composed of the resinous fruiting heads of the female plant and is similarly employed. In 'A Report on Indian Fibres and Fibrous Substances,' Spon, 1887, it is stated that *Cannabis sativa* (var. *indica*) is chiefly, if not exclusively, cultivated on account of its narcotic principle. It has been found that the narcotic-yielding plant affords only a worthless fibre, and it is presumed that the climate of India favours the production of narcotic at the expense of the fibre. To attempt an extension of its cultivation, fiscal difficulties of a very formidable character would also have to be overcome, for the Government of India would never permit a plant of which the leaves and flowers yield so pernicious a narcotic to be widely grown. According to Hunter (The Indian Empire, and its People, History, and Products, 2nd ed. 455), excise duties are levied upon these resinous products; the hemp which furnishes them is chiefly confined to a limited area in Rájsháhí district, Bengal, and to the inner valleys of the Himalayas. The use of them is a frequent cause, not only of crime, but also of insanity. Government attempts to check consumption—first, by fixing the retail duty at the highest rate that will not encourage smuggling; and secondly, by continually raising that rate as experience allows.

The effect of hemp-resin and its compounds on the consumer is at first to exhilarate and to promote appetite. Further doses produce delirium, sleep, and sometimes catalepsy.

Hemp-resin examined by T. and H. Smith is soluble in alcohol, and has a warm, bitter, acrid taste with a slight odour. It melts between 70° and 90°, and has a pale-brown colour. It is called *cannabin*.

The oil is obtained by expression from the seed, which yields from 25 to 30 p.c. of oil, and 70–75 p.c. of residual cake used for cattle feeding, although sparingly on account of its laxative properties. This oil has a sp.gr. of 0·9307.

The essential oil of *C. sativa* was prepared by L. Valenta (Gazzetta, 10, 479–481) by distilling the fresh leaves with water and agitating the resulting milky distillate with ether. The oil dried over calcium chloride and distilled repeatedly from sodium is colourless and mobile (b.p. 256°–258°). The sp.gr. referred to water is 0·9292. The analysis agreed with the formula $C_{15}H_{24}$; the vapour density could not be determined, as it decomposes at 300°. The essential oil mixes in all proportions with alcohol, ether, or chloroform.

The seeds themselves are used as food for birds, some kinds of which are inordinately fond of them. They are roundish, ovate, of a grey colour, and contain 34 p.c. of oil and 16 p.c. of albuminoids.

HEMP SEED OIL. Hemp seed is obtained from the seeds of the hemp plant, *Cannabis sativa* (Linn.). The hemp plant is cultivated in France, Belgium, Germany, Northern Italy, Algeria, North America, India, Manchuria, and Japan. A large quantity of the seed is still grown in France, where the oil is expressed for commercial purposes. The seeds yield about 30 p.c. of oil. The colour of the freshly-expressed oil is light-green to greenish-yellow, which becomes brownish-yellow on keeping.

Hemp seed oil contains a few p.c. of solid glycerides, most likely palmitin, with a small amount of stearin or arachin. The liquid fatty acids in hemp seed oil consist of linolic acid, and smaller quantities of oleic, and linolenic (and *iso*linolenic (?)) acids.

Hemp seed oil is used as a paint oil, though less frequently in this country than on the Continent. Considerable quantities are used on the Continent for making soft soap, characterised by a dark-green colour. The lower qualities of hemp seed oil are stated to be used in the manufacture of varnishes. J. L.

HENBANE. *Hyoscyamus. Jusquiame*, Fr.; *Bilsenkraut*, Ger.

Henbane, *Hyoscyamus niger* (Linn.) (Bentl. a. Trim. 194), is one of the group of poisonous plants belonging to the natural order *Solanaceæ* and is nearly related to belladonna, stramonium, and duboisia. It has been employed in medicine since the 7th century and an allied species, having similar properties, *H. albus* (Linn.) was known to Dioscorides. There are two varieties of *H. niger*, one an annual and the other a biennial. Both are to be obtained in the market, but the leaves or green tops of second-year plants of the biennial variety are the most active and should alone be employed in medicine. The seeds possess still greater activity, but they are only used in the manufacture of alkaloid. Henbane is a coarse hairy erect herb with pale-yellow flowers marked with purple veins, and the whole plant evolves an unpleasant odour. It occurs wild throughout Britain and most parts of Europe, Asia, and Northern Africa, and has been naturalised in North and South America. Henbane is employed as a sedative, anodyne, or hypnotic, and, like belladonna and stramonium, it dilates the pupil of the eye. Its activity is destroyed by the presence of free alkali, with which it should therefore not be administered (Garrod, Pharm. J. 17, 462; 18, 174).

The active constituents of henbane are two isomeric alkaloids. The one, *hyoscyamine* $C_{17}H_{23}NO_3$, was first obtained in a pure state by Geiger and Hesse (Annalen, 7, 270) and more completely studied by Hohn and Reichardt (Annalen, 157, 98); the other, present in much smaller proportion, *hyoscine* $C_{17}H_{23}NO_3$, was discovered by Ladenburg (Annalen, 206, 282). Hyoscyamine also occurs together with atropine in belladonna and stramonium (*v.* DATURA), and 'duboisine,' the alkaloid of *Duboisia myoporoides* (R. Br.), is identical with hyoscine (Ladenburg and Petersen, Ber. 20, 1661). Both hyoscyamine and hyoscine, like atropine, are mydriatic alkaloids.

To obtain hyoscyamine from henbane seeds Höhn and Reichardt first deprive them of fixed oil by treatment with ether and then exhaust by means of alcohol acidified with sulphuric acid. The clear extract, after removal of the alcohol by distillation, is almost neutralised by soda and precipitated with tannic acid. The moist precipitate is mixed with lime and extracted with alcohol. The alcoholic solution is acidified, concentrated, and purified by washing with ether. The alkaloid is then set free by the addition of soda and isolated by extraction with ether. Other somewhat similar methods have been suggested by Rennard (Neues Rep. Pharm. 17, 91), Thorey (Pharm. J. [iii.] 12, 874), and Thibaut (Chem. Zentr. 1875, 565). Duquesnel (J. Pharm. Chim. [v.] 5, 131) extracts the seeds with hot 90 p.c. alcohol containing tartaric acid, and from the solution obtained removes the alcohol by distillation. There remains a residue of two layers, a lower syrupy and an upper oily layer, which latter is found to contain most of the alkaloid, perhaps in combination with a fatty acid. This is extracted by treating the oil with water acidified with sulphuric acid. The solution is nearly neutralised with potassium bicarbonate, concentrated to a syrup, and extracted with alcohol, which leaves potassium sulphate undissolved. The alcohol is removed from the solution by distillation, and the residue, diluted with water and treated with a slight excess of potassium bicarbonate, is extracted with chloroform. The crude hyoscyamine is removed from the chloroform solution by water acidified with sulphuric acid, is purified by treatment with animal charcoal, and the solution is then concentrated to a syrup. The alkaloid is set free by an excess of calcium carbonate, and mixed with sand, is dried over sulphuric acid. Finally, treatment with chloroform extracts the hyoscyamine and yields it on evaporation in large prismatic needles.

Hyoscyamine melts at 108·5° (Ladenburg) and dissolves more readily in water and dilute alcohol than atropine. It is lævorotatory. By the action of barium hydroxide or hydrochloric acid hyoscyamine yields, in the same manner as atropine, *tropine* $C_8H_{15}NO$ and *tropic acid* $C_9H_{10}O_3$ (Ladenburg, Ber. 13, 254 and 607), but is distinguished from that base by its metallic derivatives. *Hyoscyamine aurichloride*

$$C_{17}H_{23}NO_3,HCl,AuCl_3$$

melts at 159°, whilst the isomeric atropine aurichloride melts at 137°. The appearance and solubility of the two salts are also different (Ladenburg). Hyoscine, which is obtained from the mother liquors after crystallisation of hyoscyamine, is a syrupy liquid. It can, however, be obtained in crystals melting at about 55° (Hesse, Annalen, 271, 100). The aurichloride melts at 198°. Hyoscine is identical with scopolamine, but the commercial scopolamine is not obtained from this source (*cf.* VEGETO-ALKALOIDS).

Brandes, who analysed henbane seeds, found 24 p.c. of *fixed oil* (Berz. J. 21, 180); a substance 'hyoscypicrin,' supposed to be a glucoside, was obtained by Höhn and Reichardt; and the presence of potassium nitrate in the leaves was pointed out by Thorey and in the medicinal extract by Attfield (Pharm. J. 3, 447).

Hyoscyamus muticus (Linn.), a species of henbane occurring in certain parts of India, and used in Indian medical practice, has been examined by Dunstan and Brown (Chem. Soc. Trans. 75, 72), who find hyoscyamine to be the only alkaloid present in any notable quantity. A. S.

HENDECATOIC or UNDECATOIC ACIDS $C_{11}H_{22}O_2$.

1. *n-Undecylic acid* $CH_3[CH_2]_9COOH$ is a crystalline solid having a faint smell of caproic acid; it is obtained by the reduction of undecylenic acid or by the oxidation of methylundecylketone; m.p. 28·5°; b.p. 228° (160 mm.) (Krafft, Ber. 1879, 1664).

2. *Methyl dibutyl acetic acid*

$$[C(CH_3)_3]_2C(CH_3)COOH$$

is obtained with other products by the oxidation of *iso*tributylene. A white crystalline solid, insoluble in water, but soluble in alcohol or ether; m.p. 66°–70°; b.p. 260°.

3. *Umbellulic acid* $C_{11}H_{22}O_2$. The nuts of the Californian bay tree (*Umbellularia Californica* [Nutt.]) contain about 60 p.c. of a fat easily soluble in ether. It is a white, hard, tallowy mass m.p. 31°. By saponification with caustic potash and decomposition with hydrochloric acid, the acid is obtained as a white solid with a faint odour and very disagreeable and irritating taste; m.p. 31°–34°; b.p. 275°–280°. Its alkyl esters are colourless mobile liquids of agreeable odour (Spillman and O'Neill, Amer. Chem. J. 1882, 206). Possibly identical with *cocinic acid* found by Saint-Evre in cocoa-nut oil, and with the *undecylic acid* of Krafft (*v. supra*).

HENDECENOIC ACID $C_{11}H_{20}O_2$ an acid boiling at 258°–261° found in petroleum; known also as *petroleumic acid.* It is obtained from the petroleum distillate, b.p. 250°–270°, by adding sodium hydroxide and then to the alkaline extract, sulphuric acid. This is treated with alcohol and hydrochloric acid, and the resulting ester fractionated and hydrolysed with alcoholic potash (Hell and Medinger, Ber. 1874, 1217; 1877, 451).

HEPARADEN and **HEPARON** *v.* SYNTHETIC DRUGS.

HEPAR SICC. *v.* SYNTHETIC DRUGS.

HEPATIC CINNABAR *v.* CINNABAR.

HEPTOIC ACIDS $C_7H_{14}O_2$.

1. *n-Heptoic acid, œnanthylic acid*

$$CH_3(CH_2)_5COOH.$$

Obtained by the oxidation of œnanthol (Bussy, Annalen, 60, 248; Tilly, *ibid.* 67, 107; Krafft, Ber. 1882, 1717; Schorlemmer and Grimshaw, Annalen, 170, 141); also formed by the oxidation of castor-oil, of oleic acid, and of normal heptyl alcohol (Schorlemmer, Annalen, 161, 279; Tripier, Bull. Soc. chim. [iii.] 11, 99); from the normal hexyl cyanide (Franchimont, Annalen, 165, 237); and by the reduction of dextrose-carboxylic acid (Kiliani, Ber. 1886, 1130). An oily liquid; b.p. 222·4° (743·4 mm.), m.p. −10·5°, sp.gr. 0·9183, 20°/.

2. *isoHeptoic acid; α-methylhexoic acid*

$$CH_3[CH_2]_3CH(CH_3)COOH.$$

Obtained by boiling hexyl cyanide with alcoholic potash (Hecht, Annalen, 209, 309), or by the reduction of fructosecarboxylic acid (Kiliani, Ber. 1885, 3071). An oily rancid smelling liquid; b.p. 211·5° (745·8 mm.), sp.gr. 0·9138, 21°/. Soluble in 278 parts water.

3. *Isoœnanthylic acid* found among the products obtained by heating a mixture of sodium acetate and sodium *iso*valerate; b.p. 217°, sp.gr. 0·9260, 15°/ (Portsch, Annalen, 218, 66).

4. *isoAmyl acetic acid; δ-methylhexoic acid*

$$(CH_3)_2CH[CH_2]_3COOH.$$

Obtained by the action of sodium and *iso*amyl iodide upon ethyl acetate (Frankland and Duppa, Annalen, 138, 338), or by the distillation of *iso*amylmalonic acid (Paal and Hoffmann, Ber. 1890, 1498); b.p. 208°–210°, sp.gr. 0·9122, 13°/.

5. *Methyl diethyl acetic acid, αα-methylethylbutyric acid* $CH_3(C_2H_5)_2C\cdot COOH$. Obtained by prolonged heating of methyl diethyl carbinol cyanide with strong hydrochloric acid (Schdanow, Annalen, 185, 120); b.p. 207°–208° (753 mm.); almost insoluble in water.

6. *Methyl isopropyl propionic acid; βγ-dimethylvaleric acid*

$$CH_3(C_3H_7)CH\cdot CH_2\cdot COOH.$$

Obtained by heating sodium *iso*valerate with sodium ethoxide in a stream of carbon monoxide (Loos, Annalen, 202, 321); b.p. 220°.

7. *Ethylpropylacetic acid; α-ethylvaleric acid* $CH_3(CH_2)_2CH(C_2H_5)CO_2H$. Obtained by hydrolysing ethylpropylacetoacetic ester with alkali (Kiliani, Ber. 1886, 227); b.p. 209·2°.

8. *Active amylacetic acid; γ-methylhexoic acid* $CH_3(C_2H_5)CH\cdot CH_2\cdot CH_2\cdot COOH$. Obtained by heating active amylmalonic acid (Welt, Ann. Chim. Phys. [vii.] 6, 132); b.p. 221°; sp.gr. 0·9149, 20°/20°.

9. *Methylisobutylacetic acid; αγ-dimethylvaleric acid.* Obtained by heating methyl*iso*butylmalonic acid (Burrows and Bentley, Chem. Soc. Trans. 1895, 511); b.p. 204°–205°.

iso-**HEPTYLACETIC ACID** *v.* NONOIC ACIDS.

n-**HEPTYLSUCCINIC ACID**

$$C_7H_{15}\cdot CH(CO_2H)CH_2\cdot CO_2H.$$

Obtained by the reduction of hexylita-, -citra or -mesaconic acids with sodium amalgam (Fittig and Hoeffken, Annalen, 304, 337); m.p. 90°–91°.

HERCULES METAL *v.* ALUMINIUM.

HERCULES POWDER *v.* EXPLOSIVES.

HERMOPHENYL *v.* SYNTHETIC DRUGS.

HERNIARINE *v.* LACTONES.

HEROIN *v.* SYNTHETIC DRUGS.

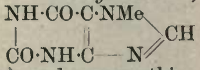
HERRING OIL is obtained from the several species of herring, *Clupea harengus* (North Sea), *C. Pallasi, C.* and *V.* (Japan). This oil is now extracted on a commercial scale in Japan, and genuine specimens of such oil have been prepared by Tsujimoto. The Japanese herring oil yields on brominating 3·82–6·5 p.c. of the octobromide of clupanodonic acid, which is a characteristic constituent of all fish oils. The herring oils produced in Europe (Norway) are not kept separate from other fish oils, and, therefore, do not represent such pure oils as those described by Tsujimoto. The iodine value of genuine herring oil lies in the neighbourhood of 130, whilst the commercial North Sea herring oil exhibits higher iodine values.

Like all other fish oils, herring oil is chiefly used in the leather industry. J. L.

HESPERIDIN *v.* GLUCOSIDES.

HESSIAN PURPLE, RED, YELLOW, *v.* AZO- COLOURING MATTERS.

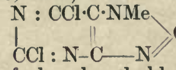
HETEROXANTHINE, *7-methylxanthine, 7-methyl-2 : 6-dioxypurine*



$$\begin{array}{l} \mathrm{NH\cdot CO\cdot C\cdot NMe} \\ \;|\qquad\qquad\;\; \| \qquad\quad \rangle \mathrm{CH} \\ \mathrm{CO\cdot NH\cdot C - N} \end{array}$$

occurs together with xanthine and paraxanthine as a constituent of normal human urine (Salomon, Ber. 1885, 18, 3406; Virchow's Archiv. 1891, 125, 554); 10,000 litres yielded 22·2 grams of the mixed bases, of which 11·36 grams was heteroxanthine (Salomon and Krüger, Zeitsch. physiol. Chem. 1898, 24, 364); it occurs also with xanthine in the urine of the dog (Salomon, *ibid.* 1887, 11, 410). Heteroxanthine appears to be a product of the metabolism of theobromine and caffeine, for when rabbits, dogs, or men are dosed with these alkaloids, heteroxanthine appears in the urine (Bondzynski and Gottlieb, Ber. 1895, 28, 1113). According to Albanese (Gazz. chim. ital. 1895, 25, ii. 298) heteroxanthine is an intermediate product in the transformation that caffeine undergoes in the organism, the methyl groups being removed one by one until xanthine is obtained, and this is converted into urea and ammonia. Heteroxanthine acts as a powerful diuretic on dogs and rabbits when hypodermically injected in small doses; larger doses are toxic, an injection of 1 gram killed a dog weighing 8 kilos. in 10 days (Albanese, *l.c.*). (*Cp.* also Krüger and Salomon, Zeitsch. physiol. Chem. 1895, 21, 169; Schmiedeberg, Ber. 1901, 34, 2556.)

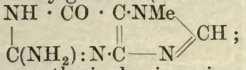
The synthesis of heteroxanthine from theobromine has been effected by Fischer (Ber. 1897, 30, 2400). When 2 : 6-dichloro-7-methylpurine



$$\begin{array}{l} \mathrm{N : CCl\cdot C\cdot NMe} \\ \;|\qquad\qquad\; \| \qquad\quad \rangle \mathrm{CH} \\ \mathrm{CCl : N{-}C - N} \end{array}$$

, obtained by the action of phosphoryl chloride on theobromine, is heated at 120°–125° with hydrochloric acid (sp.gr. 1·19), it is converted into the hydrochloride of 7-methylxanthine or heteroxanthine. Krüger and Salomon (Zeitsch. physiol. Chem. 1898, 26,

389) also obtained it by the action of nitrous acid on *epiguanine*, 7-methylguanine (2-amino-6-oxy-7-methylpurine) ; and as Fischer (*l.c.*) has synthesised epiguanine, this method of preparation is also synthetical.



Heteroxanthine is a crystalline powder; when heated gradually it melts and decomposes at 341°–342°, when heated rapidly it darkens at 360°, and melts and decomposes at 380°. It dissolves in 142 parts of boiling water (Fischer, *l.c.*), or in 7575 parts of alcohol at 17°, or in 2250 parts at the boiling temperature (Bondzynski and Gottlieb, Ber. 1895, 28, 1113). Heteroxanthine possesses both acidic and basic properties, the basic dissociation constant k_b being 3·754K; and the acidic dissociation constant k_a being 1276K, where K is the dissociation constant of water (Wood, Chem. Soc. Trans. 1906, 1840).

Heteroxanthine forms salts with acids that are readily dissociated in water, the *hydrochloride* crystallises in tufts of transparent crystals, and yields a microcrystalline platinichloride; the *sulphate* $C_6H_6O_2N_4{\cdot}H_2SO_4$ is decomposed by water. Heteroxanthine forms a characteristic *sodium* derivative $NaC_6H_5O_2N_4,5H_2O$, crystallising in plates or prisms, melting at about 300°, readily soluble in water, sparingly so in sodium hydroxide; the *potassium* derivative has similar properties and a higher melting-point (Salomon, Ber. 1885, 18, 3406; Virchow's Archiv. 1891, 125, 554). Heteroxanthine yields a crystalline precipitate with mercuric chloride, and forms a crystalline derivative with silver nitrate. It is also precipitated by copper acetate, phosphotungstic acid or lead acetate in the presence of ammonia (Salomon, *l.c.*). It is differentiated from hypoxanthine, xanthine, and guanine by the sparing solubility of its sodium derivative in sodium hydroxide; it differs from paraxanthine in being amorphous and sparingly soluble, and in not yielding a precipitate with picric acid in the presence of hydrochloric acid.

When a solution of heteroxanthine containing chlorine water and nitric acid is evaporated, the residue develops a red colour with ammonia, becoming blue on the addition of sodium hydroxide. On oxidation with potassium permanganate in concentrated sulphuric acid heteroxanthine yields three of its four nitrogen atoms as ammonia or carbamide, and the fourth as methylamine (Jolles, Ber. 1900, 33, 2126, 2120).

By electrolytic reduction in sulphuric acid solution, heteroxanthine yields 7-methyl-2-oxy-1:6-dihydropurine (Tafel and Weinschenck, Ber. 1900, 33, 3374). M. A. W.

HETOCRESOL, HETOFORM, HETOL CAFFEIN, HETRALIN *v.* SYNTHETIC DRUGS.

HEXADECYLENEDICARBOXYLIC ACID, *Tetradecylsuccinic acid* $C_{18}H_{34}O_4$. Prepared by heating hexadecylenedibromide, potassium cyanide, and alcohol at 160°–190°, and decomposing the nitrile thus formed with alcoholic potash (Krafft and Grosjean, Ber. 1890, 2355); m.p. 121°. The anhydride melts at 89°.

HEXAHYDROXYBENZENE *v.* PHENOL AND ITS HOMOLOGUES.

cyclo-**HEXANONE** *v.* KETONES.

HEXOIC ACIDS *v.* CAPROIC ACIDS.

HEXOSEPHOSPHORIC ACID *v.* FERMENTATION.

HEXOSES *v.* CARBOHYDRATES.

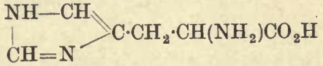
HIDDENITE. A transparent, emerald-green variety of the mineral spodumene $LiAlSi_2O_6$ (*q.v.*), used as a gem-stone. It is found with emerald in North Carolina, and has been popularly, but erroneously, known as 'lithia-emerald.' L. J. S.

HIGHGATE RESINS *v.* RESINS.

HING *v.* GUM RESINS.

HIPPURIC ACID, *Benzamino-acetic acid benzoylglycine* $NH(C_7H_5O)CH_2{\cdot}CO_2H$, an acid found in the urine of horses and cows and other herbivora and in human urine when benzoic acid is taken internally. The crude acid obtained from urine is strongly coloured; it may be purified by passing chlorine into the hot aqueous solution, filtering while hot, and rapidly cooling the filtrate. May be prepared by action of benzoic anhydride on glycocoll (Curtius, Ber. 1884, 1663). Crystallises in large trimetric prisms, soluble in water and alcohol; m.p. 187·5°. Has a slightly bitter taste and reddens litmus. Decomposes on heating, forming benzonitrile and benzoic acid (Limpricht and Uslar, Annalen, 88, 133). Its aqueous solution boiled with mineral acids yields glycocoll (glycine) and benzoic acid. Oxidation with potassium permanganate in acid solution yields carbamide (Jolles, Ber. 1900, 2834). Hippuric acid may be detected in urine by treating a few c.c. with sodium hypobromite, just sufficient being taken to decompose the carbamide and impart a permanent yellow colour to the solution. If hippuric acid is present, a characteristic orange- or brownish-red precipitate is formed (Dehn, J. Amer. Chem. Soc. 1908, 1508). For quantitative estimation in urine *v.* Henriques and Sörensen (Chem. Zentr. 1909, ii. 2043; 1910, i. 870).

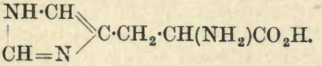
HISTIDINE, *glyoxaline-4-alanine, l-α-amino-β-glyoxaline-*4 (or 5)*-propionic acid, β-iminazole-α-aminopropionic acid*



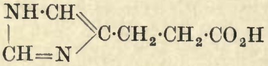
was discovered by Albrecht and Kossel (Zeitsch. physiol. Chem. 1896, 22, 176) among the hydrolytic products of the protamine sturine, which contain 12·9 p.c. histidine, 12 p.c. lysine, and 58·2 p.c. arginine (Kossel, *ibid.* 1900, 31, 207). Hedin (*ibid.* 1896, 22, 191) isolated it from the bases precipitated by silver nitrate from the decomposition products of other proteins. Kutscher (*ibid.* 1898, 25, 195) found it present in antipeptone obtained by the pancreatic digestion of fibrin. Lawroff (*ibid.* 1899, 28, 388) and Abderhalden and Rona (*ibid.* 1904, 41, 278) prepared it from thymus histon; and Koch (J. Biol. Chem. 1911, 9, 121) established its presence among the hydrolytic products of the globulin from pigs' thyroids. Histidine occurs also with arginine and lysine among the hydrolytic products of vegetable proteins, notably in the seeds and seedlings of *Picea excelsa* (Link.), *Pinus sylvestris* (Linn.), *Cucubita Pepo* (Linn.), *Lupinus luteus* (Linn.), and *Pisum sativum* (Linn.); in the case of conifer seeds 300 grams of the dry proteid yield 3 grams histidine hydrochloride, 19 grams arginine nitrate, and 3 grams lysine picrate (Schulze and

Winterstein, Zeitsch. physiol. Chem. 1899, 28, 459; 465; 1901, 33, 547).

The constitution of histidine as *α-amino-β-glyoxaline-*4 (or 5)*-propionic acid,* has been established by the work of Fränkel, Pauly, Knoop and Windaus, and Pyman. Fränkel (Monatsh. 1903, 24, 229) showed that histidine contains a *carboxyl* group, since it displaces carbon dioxide from silver and copper carbonates, and an *amino* group because on treatment with hypobromite or nitrous acid one nitrogen atom is removed and a hydroxyl group introduced. Frankel, therefore, represented histidine by the partially expanded formula $NH_2{\cdot}C_5H_6N_2{\cdot}CO_2H$, and gave the name *histine* to the complex —$C_5H_6N_2$—, and *hydroxydeaminohistidine* or *hydroxyhistinecarboxylic acid* to the compound $OH{\cdot}C_5H_6N_2{\cdot}CO_2H$ obtained from histidine by the action of nitrous acid. Pauly (Zeitsch. physiol. Chem. 1904, 42, 508) confirmed the presence of the carboxyl group in histidine by preparing the methyl ester, and proved that the *histine* complex —$C_5H_6N_2$— contains an *imino*-group, because histidine yields a *dinaphthalene-β-sulphone* derivative, and forms a red dye with diazobenzenesulphonic chloride. These considerations, and the stability of the compound towards oxidising agents led Pauly to conclude that the complex *histine* contains an iminazole or glyoxaline ring, and that histidine is *α-amino-β-glyoxaline-*4 (or 5)*-propionic acid*



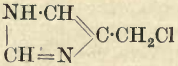
This conclusion has been confirmed by Knoop and Windaus (Beitr. Chem. Physiol. Path. 1905, 7, 144), who obtained *glyoxaline-*4 (or 5)*-propionic acid*



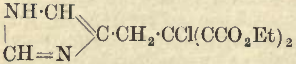
by reducing Fränkel's hydroxydeaminohistidine, and showed that it is identical with the synthetic product prepared by the action of formaldehyde and ammonia on Wolff's glyoxylpropionic acid (Annalen, 1890, 260, 79).

Knoop (Beitr. Chem. Physiol. Path. 1907, 10, 111) also showed that, by the successive oxidation of hydroxydeaminohistidine *glyoxaline-*4 (or 5)*-carboxylic acid*  is obtained, which, when heated at 286°, loses carbon dioxide and yields glyoxaline .

The complete synthesis of histidine from 4 (or 5)-chloromethylglyoxaline is described by Pyman (Chem. Soc. Trans. 1911, 1386). 4 (or 5)-Chloromethylglyoxaline (I), obtained from diaminoacetone (*ibid.* 668), condenses with ethyl sodiochloromalonate to form *ethyl* 4 (or 5)*-glyoxalinemethylchloromalonate* (II)

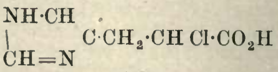


I.

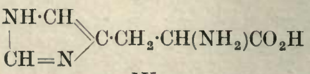


II.

This ester on hydrolysis is converted into *r-α-chloro-β-glyoxaline-*4 (or 5)*-propionic acid* (III), which reacts with ammonia to form *r-α-amino-β-glyoxaline-*4 (or 5)*-propionic acid* (IV), that is *r*-histidine



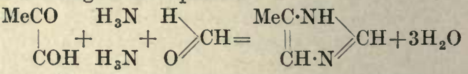
III.



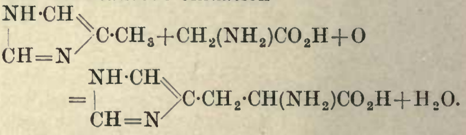
IV.

r-Histidine can be resolved by the fractional crystallisation of the salts it forms with *d*-tartaric acid into the *d*- and *l*- isomerides, and the *l*-histidine thus obtained is identical with the naturally occurring compound.

A possible explanation of the formation of histidine in the plant economy is afforded by the work of Knoop and Windaus (Beitr. Chem. Physiol. Path. 1905, 6, 392; Ber. 1906, 39, 3886; 1907, 40, 799) on the synthetic formation of iminazole derivatives from sugars and ammonia. These authors find that when a solution of glucose containing zinc hydroxide dissolved in ammonia is exposed to the sunlight at the ordinary temperature for some weeks, it is converted to the extent of 10 p.c. into 4- or 5-*methyliminazole.* It is probable that glyoxal and formaldehyde are produced as intermediate products and then react with the ammonia according to the equation



d-Mannose, *d*-fructose, *d*-sorbose, *l*-arabinose, or *l*-xylose also yield methyliminazole when similarly treated. The authors suggest that histidine may be formed naturally by the condensation of methyliminazole with glycocoll and simultaneous oxidation



Histidine crystallises from water in needles or tables, m.p. 287° (corr.); the aqueous solution has a sweet taste (Frankel, Monatsh. 1903, 24, 229; Pyman, Chem. Soc. Trans. 1911, 1397), is feebly alkaline (Hedin, Zeitsch. physiol. Chem. 1896, 22, 191), and is optically active $[\alpha]_D -39{\cdot}74°$ (Kossel and Kutscher, *ibid.* 28, 382); $[\alpha]_D -36{\cdot}7°$ (Pyman, *l.c.*).

r-Histidine crystallises in quadrilateral plates, and decomposes at 283° (corr.); *d-histidine* crystallises in monoclinic plates forming elongated hexagons; it decomposes at 287–288° (corr.). and has $[\alpha]_D + 39{\cdot}3°$ (Pyman, *l.c.*).

When histidine is administered as a food, or by intravenous injection very little (0·4 gram out of 10 grams) is recoverable as such in the urine; the urea and ammonia in the urine are largely increased, but the increase of allantoin is very slight (Abderhalden, Einbeck and Schmid, Zeitsch. physiol. Chem. 1909, 62, 322; 1910, 68, 395; Kowalewsky, Biochem. Zeitsch. 1909, 23, 1).

Salts. *l*-Histidine forms stable salts with acids and their solutions are dextrorotatory.

Monohydrochloride $C_6H_9O_2N_3{\cdot}HCl,H_2O$ forms large colourless rhombic crystals

$$a:b:c=0{\cdot}7665:1:1{\cdot}71104,$$

has $[\alpha]_D+1{\cdot}74°$, m.p. 80°, and loses H_2O at 140° (Albrecht and Kossel, Zeitsch. physiol. Chem. 1896, 22, 176; Hedin, *ibid.* 191; Kossel and Kutscher, *ibid.* 1899, 28, 382; Fränkel, Monatsh. 1903, 24, 229); the *di-hydrochloride* $C_6H_9O_2N_3{\cdot}2HCl$ is isomorphous with the mono-compound $[a:b:c=0{\cdot}76537:1:1{\cdot}77516]$, it has $[\alpha]_D+5{\cdot}3°$ to $6{\cdot}4°$ (Kossel and Kutscher, *l.c.*; Schwartze, Zeitsch. physiol. Chem. 1900, 29, 493). *Histidine cadmium chloride*

$$C_6H_9O_2N_3{\cdot}HCl,CdCl_2$$

melts and decomposes at 270°–275° (Schenck, *ibid.* 1904, 43, 72). *Histidine monopicrolonate* $C_6H_9O_2N_3{\cdot}C_{10}H_8O_5N_4$ is yellow. The *dipicrolonate* $C_6H_9O_3N_2{\cdot}2C_{10}H_8O_5N_4$ is orange (Steudel, Zeitsch. physiol. Chem. 1905, 44, 157; Brigl, *ibid.* 1910, 64, 337); the *dipicrate*

$$C_{18}H_{15}O_{16}N_9,2H_2O$$

has m.p. 86° (corr.), (Pyman, Trans. Chem. Soc. 1911. 343).

l-Histidine-d-hydrogen tartrate

$$C_6H_9O_2N_3,C_4H_6O_6$$

is easily soluble in water, crystallises in large well-defined prisms, and decomposes at 172°–173° (corr.); and has $[\alpha]_D+16{\cdot}3°$. *l-Histidine-l-hydrogen tartrate* is sparingly soluble in cold water, crystallises in clusters of prisms and decomposes at 234° (corr.), and has $[\alpha]_D-12{\cdot}1°$ (Pyman, *ibid.* 1397, 1400).

d-Histidine-d-hydrogen tartrate is sparingly soluble, decomposes at 234° (corr.), and has $[\alpha]_D+13{\cdot}3°$ (Pyman, *l.c.*).

r-Histidine mono-hydrochloride

$$C_6H_9O_2N_3{\cdot}HCl,2H_2O$$

has m.p. 117°–119° (corr.); *sesquihydrochloride*

$$(C_6H_9O_2N_3)_2{\cdot}3HCl,H_2O$$

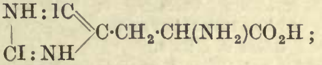
has m.p. 168°–170° (corr.); the *dihydrochloride* has m.p. 235°–236° (corr); *r-histidine monopicrate* $C_{12}H_{12}O_9N_6,H_2O$ decomposes at 180°–181° (corr.); the *dipicrate* $C_{18}H_{15}O_{16}N_9,2H_2O$ decomposes at 190° (corr.), (Pyman, *ibid*, 339).

Derivatives. *Histidine methyl ester hydrochloride* $C_5H_8N_3{\cdot}CO_2Me{\cdot}2HCl$ forms flat rhombic prisms, m.p. 196° (decomp.), the free ester is an oil (Pauly, Zeitsch. physiol. Chem. 1904, 42, 508). *Chlorohistinecarboxylic acid* (*α-chloro-β-glyoxaline-* 4 (or 5)*-propionic acid*) forms thick prisms, m.p. 191° (decomp.), the corresponding *racemic* compound decomposes at 201° (corr.) (Pyman, *ibid.* 1394), the *oxalate* of the *ester* has m.p. 161° (Windaus and Vogt, Beitr. chem. Physiol. Path. 1908, 11, 406). *Histidine anhydride* $C_{12}H_{14}O_2N_6$ forms glittering prisms, m.p. 340° (Fischer and Suzuki, Sitzungsber. K. Akad. Wiss. Berlin, 1904, 1333); the *l*-anhydride has m.p. 328° in a closed evacuated tube, crystallises with $2\frac{1}{2}H_2O$, and has $[\alpha]_D^{20°}-66{\cdot}24°$ in normal hydrochloric acid solution; the *dl-anhydride* also has m.p. 328°, and is obtained by heating the ethyl ester of histidine at 160° (Pauly, Zeitsch. physiol. Chem. 1910, 64, 75); the *picrate* decomposes at 255° (corr.); the *hydrochloride* at 320°. The *tetraiodo* derivative has m.p. 240°, and is amphoteric and forms a *silver* salt (Pauly, Ber. 1910, 43, 2243). *Histidylhistidine* $C_{12}H_{16}O_3N_6$ forms a yellow *picrate*, m.p. 165°–175° (Fischer and Suzuki, *l.c.*).

Of the *acyl* derivatives of histidine the *benzoyl* has m.p. 249° (decomp.) (Pauly, *l.c.*; Fränkel, *l.c.*); the *dinaphthalene β-sulphone*

$$C_6H_7O_2N_3(SO_2{\cdot}C_{10}H_7)_2$$

melts at 149°–150° (Pauly); *p-Nitrobenzoyl* $C_6H_8N_3O_2{\cdot}CO{\cdot}C_6H_4{\cdot}NO_2$ m.p. 251°–252° (Pauly). *Benzoyldiiodohistidine*, m.p. 161°–164°, in an evacuated tube; and *p-nitrobenzoyldiiodohistidine*, m.p. 172° (decomp.) are derivatives of the unknown diiodohistidine



they give orange-red colourations with diazobenzenesulphonic acid and sodium carbonate, and form silver salts (Pauly, Ber. 1910, 43, 2243). *d-α-Bromoisohexoyl-l-histidine methyl ester*

$$C_4H_9{\cdot}CHBr{\cdot}CO{\cdot}NH{\cdot}CH(C_4H_5N_2)CO_2Me$$

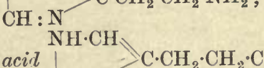
has m.p. 175° (corr.); *d-α-bromoisohexoyl-l-histidine* $C_{12}H_{18}O_3N_3Br$ has m.p. 118° (corr.); *l-leucyl-l-histidine*

$$C_4H_9{\cdot}CH(NH_2){\cdot}CO{\cdot}NH{\cdot}CH(C_4H_5N_2)CO_2H$$

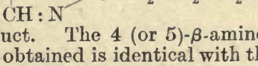
crystallises in plates or prisms, containing H_2O, which it loses at 100°/15–20 mm., and has m.p. 178° (corr.) (decomp.), the *copper* salt forms deep violet crystals; *formyl-l-histidine* has m.p. 203° (corr.) (Fischer and Cone, Annalen, 1908, 363, 107).

Colour reactions. Histidine gives the *biuret* reaction (Herzog, Zeitsch. physiol. Chem. 1903, 37, 248). It also gives the Weidel pyrimidine reaction under the following conditions: a solution of histidine hydrochloride and a little potassium chlorate is evaporated to dryness, hydrochloric acid containing one drop of nitric acid added and the solution again evaporated; on exposing the residue to ammonia fumes an intense red colour is produced, becoming reddish-violet on the addition of sodium hydroxide (Frankel, *l.c.*). With diazobenzenesulphonic chloride in the presence of sodium carbonate histidine gives a dark cherry-red colouration, becoming orange on the addition of an acid. This is an extremely delicate test for histidine, and with the exception of tyrosine no other product of protein hydrolysis gives a similar reaction (Pauly, Zeitsch. physiol. Chem. 1904, 42, 508). Histidine develops a yellow colour with bromine water; this disappears on warming, but after a time a pink colour appears, which afterwards deepens to a wine red. The reaction is sensitive with solutions of 1 : 1000, but is destroyed by too large excess of bromine water (Knoop, Beitr. Chem. Physiol. Path. 1908, 11, 356).

Decomposition. When histidine undergoes anærobic bacterial cleavage by the action of putrefying pancreas, it is converted almost quantitatively by the loss of carbon dioxide into 4 (or 5)-*β-aminoethylglyoxaline* (*β-iminazolylethylamine*)



; *iminazolylpropionic acid*



being the other product. The 4 (or 5)-*β*-aminoethylglyoxaline thus obtained is identical with the base prepared synthetically by Windaus and Vogt (Ber. 1907, 40, 3691) from ethyl iminazolylpropionate; or by Pyman (Chem. Soc. Trans. 1911, 668) from diaminoacetone, and is also identical with one of the *ergot* bases isolated by Barger and Dale (Phil. Trans. 1910, 2592), and which is also present in Popielski's *vaso-dilatin* (Barger and Dale, J. Physiol. 1911, 41, 499). It has a direct stimulating action on plain muscle; cardiac muscle is mildly stimulated, and skeletal muscle is not affected. The drug produces narcosis, and is a mild stimulant to the salivary glands and pancreas. M. A. W.

HOANG-NAN *v.* Nux vomica.

HOFMANN'S VIOLET *v.* Triphenyl methane colouring matters.

HOG GUM *v.* Gums.

HOLLANDITE. A manganese ore of essentially the same composition as psilomelane, but occurring in a crystallised condition, usually as fibrous masses and sometimes as crystals. It is a manganate with the general formula

$$mR_2''MnO_5+nR_4'''(MnO_5)_3,$$

where R″ is Mn, Ba, K_2, H_2, (Fe, Ca, Mg, Na, Co, Ni, Cu), and R‴ is Mn, Fe_2(Al). It contains about 70–75 p.c. of manganese dioxide. The colour is greyish-black, and the lustre submetallic; sp.gr. 4·70–4·95; H. 4–6. The mineral occurs abundantly in the manganese ore deposits at several places in Central India, and is largely exported from the mines at Sitapár and Bálághát. (L. L. Fermor, The Manganese Ore Deposits of India, Mem. Geol. Survey India, 38.) L. J. S.

HOLOCAINE *v.* Synthetic drugs.

HOMBERG'S PHOSPHORUS *v.* Calcium.

HOMOANTHRANILIC ACID *v.* Amino acids (aromatic).

HOMOCATECHOL *v.* *Homopyrocatechol*, Phenol and its homologues.

HOMOGENTISIC ACID *v.* Phenylacetic acid.

HOMORENON *v.* Synthetic drugs.

HOMOTERPENYLIC ACID *v.* Lactones.

HONEY. Honey is the substance secreted by the working-bee (*Apis mellifica*) from the nectar of flowers, and deposited by the insect in the wax-cells forming the honeycomb. Its essential constituents are varying quantities of the sugars, dextrose, lævulose, and sometimes cane-sugar, together with a small quantity of water. It also contains very small quantities of wax, colouring matters, aromatic substances, phosphoric acid, nitrogenous compounds, and occasionally mannitol.

The relative proportions in which the three above-named sugars occur is very variable. Thus Hehner (Analyst, 9, 164) obtained the following results from the analysis of 25 different varieties:

	Maximum	Minimum	Mean
Water . .	23·26	12·43	19·3
Glucose . .	75·34	61·42	67·2
Other constituents	16·51	8·48	13·5

In 8 cases the amount of glucose was unaltered by inversion, in 7 increased, and in the remainder slightly diminished.

Sieben (Bied. Zentr. 1885, 134) analysed 60 specimens of honey, and states that the quantity of cane-sugar may amount to as much as 4 or even 8 p.c., and that the ratio of dextrose to lævulose varies considerably, the total amount of these two sugars being 68–78 p.c. The average composition of the 60 specimens was as follows:—

Dextrose	34·71 p.c.
Lævulose . . .	39·24 „
Sucrose . . .	1·08 „
Water . . .	19·98 „
Non-saccharine matter .	5·02 „

Turning now from average results to the composition of the several varieties, we find the following table of the analysis of 9 specimens of honey from different localities (J. C. Brown, Analyst, 1878, 257).

—	England	Wales	Normandy	Germany	Greece	Lisbon	Jamaica	California	Mexico
Water expelled at 100° .	19·10	16·40	15·50	19·11	19·80	18·80	19·46	17·90	18·47
Water expelled at a high temperature and loss	7·60	6·56	4·95	11·00	7·80	6·66	7·58	8·13	10·03
Lævulose . . .	36·60	37·20	36·88	33·14	40·00	37·26	33·19	37·85	35·96
Dextrose . . .	36·55	39·70	42·50	36·58	32·20	34·94	35·21	36·01	35·47
Sucrose . . .	?	—	—	—	—	1·20	2·20	—	?
Wax, pollen, and insoluble matter . .	trace	trace	trace	trace	0·05	1·00	2·10	trace	trace
Mineral matter . .	0·15	0·14	0·17	0·17	0·15	0·14	0·26	0·11	0·07

The characteristic composition of ordinary honey can be judged from the analysis of 10 samples of genuine honey by Hoitsema (Zeitsch. anal. Chem. 1899, 439) which gave the following results:—

Specific gravity . .	1·102–1·140
Water . . .	8·3–17·8 p.c.
Rotation . . .	−9·1° to −3·0°
Ash . . .	0·12–0·34 p.c.
Pollen and wax . .	0·02–0·46 „
Reducing sugars .	71·2–74·4 „
Sucrose . . .	0·2–6·4 „

The amount of water present in honey varies with the dryness of the season and the conditions of storage, evaporation being much lessened when all the cells of the comb are closed (Graftian, Analyst, 1895, 251).

Erlenmeyer and v. Plata (Rep. Pharm. 23, 610) found that in 6 samples of good honey the amount of water varied from 17·5 to 19·5 p.c., whilst a liquid honey from Senegal contained as much as 25·6 p.c. The amount of phosphoric acid present (calculated on the dried substance) varied from 0·0123 to 0·883 p.c.

Sumatra honey, formed by *Apis indica*, contains water, dextrose, lævulose, a little wax and pollen, and 0·23 p.c. ash, but no cane-sugar or dextrin (Franchimont, Rec. trav. chim. 1, 223). An Ethiopian honey, made in hollows without wax by a kind of mosquito, gave the following result on analysis (Compt. rend. 88, 292):—

Water	25·5
Lævulose and dextrose $(\frac{1}{6})$.	32·0
Mannitol	3·0
Dextrin	27·9
Ash	2·5
Other constituents . . .	9·1

It has also been shown (Vogel, Ber. 15, 2271) that all honey contains a small quantity of formic acid, derived from the stings of the bees, and that to this is due the fact that honey keeps so well. It amounts only to 0·0011–0·0024 p.c., therefore most of the acidity of honey must be due to some other acid, possibly malic acid (Farnsteiner, Zeitsch. Nahr. Genussm. 1908, 15, 598).

The formic acid may be estimated by conversion into sodium formate, heating with conc. sulphuric acid, and measuring the volume of carbon monoxide evolved. As lactic acid also gives this gas it must be oxidised with potassium permanganate and estimated as oxalate and a correction applied (Merl, Zeitsch. Nahr. Genussm. 1908, 16, 385).

If bees be fed on dextrose only, the honey formed contains that sugar alone. Heather-fed honey, on the other hand, contains invert sugar only, whilst Cuban honey contains dextrose in larger quantity than lævulose (Röders, Chem. Zentr. 1864, 1002).

Eucalyptus honey is produced in Australia by a black bee which builds large hives on the *Eucalypti* containing as much as 5000 kilogs. of honey. The honey is a thick syrup, having a strong aromatic odour (Maquenne, Ann. Chim. Phys. [vi.] 17, 495).

Marck has given the following figures for the composition of East Indian honeys (Analyst, 1890, 196):—

Glucose, about 30 p.c. ; lævulose, 23–37 p.c. ; ash, 0·12–0·54 p.c. ; sp.gr. 1·3099–1·3586 ; rotation +13° to −2° 54′.

In the honey of *Polybia apicipennis* large crystals of cane-sugar are frequently found (J. pr. Chem. [i.] 71, 314). The honey of the Mexican honey-ant is almost a pure solution of lævulose, and when dried *in vacuô*, has the composition $C_6H_{12}O_6,H_2O$. It contains traces of a volatile acid which reduces silver salts (J. pr. Chem. [i.] 58, 430).

To obtain honey the syrup is first simply allowed to flow from the comb at the ordinary temperature, the portion thus collected being known as 'virgin-honey.' As soon as the flow ceases, the residual comb is heated and pressed, by which means a darker and less pure variety is obtained. According to Zwilling (Bied. Zentr. 1885, 67) it is best to gather the honey when it has thickened and the cells are sealed, as then sufficient sugar and formic acid are present.

The honey-syrup remains clear for a long time if kept in the dark, but on exposure to light dextrose gradually separates, and such varieties as contain that sugar in the largest quantity become sufficiently solid to be cut with a knife into pieces which are not hygroscopic. As, however, the composition of honey is so variable, the consistency and colour likewise differ considerably in the different samples. Thus Narbonne honey has a light yellow colour, and forms an almost solid mass, whereas Cuban honey is a clear and almost colourless syrup.

Honey has a sp.gr. of from 1·439 to 1·448. When diluted with water it gives a somewhat cloudy, faintly acid solution, the cloudiness being due to small quantities of proteid matter. Its specific rotatory power varies from −5·5 to +2, but dextrorotatory honey is exceptional.

Frühling has shown (Zeitsch. öffentl. Chem. 4, 410) that freshly prepared solutions of honey in cold water show an abnormal rotation, which, after some hours, becomes normal. This behaviour, which is due to 'bi-rotation,' may lead to erroneous observations unless care is taken to dissolve the honey in boiling water and to add about 0·1 p.c. of ammonia.

A pure solution of honey does not readily undergo alteration in the air, but when impure, both acid and alcoholic fermentation speedily take place. An alcoholic liquor known as 'mead' (Ger. *Meth*; Fr. *Hydromel*) has long been prepared from honey by fermentation. The process is, however, frequently unsuccessful, owing to the fact that honey does not usually contain sufficient nitrogenous food for the sustenance of the ferment. If a suitable food be added, the fermentation proceeds smoothly and with certainty (Gastine, Compt. rend. 109, 479). According to Boussingault (Ann. Chim. Phys. [iv.] 26, 362) the quantity of carbon dioxide formed during fermentation is greater, and the quantity of alcohol less, than would be expected from the amount of sugar fermented. Thus, instead of the calculated quantities of 193·6 parts of alcohol and 170 parts of carbon dioxide, he obtained 177·6 parts of alcohol, and 190 parts of carbon dioxide.

For medicinal purposes honey is purified by warming on the water-bath, and straining it through flannel which has been previously moistened with hot water. The purified compound is known as *Mel depuratum.* Dietrich (Chem. Zentr. 1877, 318) brought a filtered solution of 1 part of honey in 3 parts of water on to a dialyser, and found that 50 p.c. of the honey passed through. The solution of the crystalloids gave on evaporation a honey having an unusually pleasant aromatic taste. The colloidal liquid, in which gummy flocculæ remained suspended, gave on evaporation a syrup possessing a purely sweet, insipid, non-aromatic taste.

In order to purify honey Riecker (J. 1873, 1066) adds a little precipitated aluminium hydroxide, which carries down any foreign substances present. If ordinary honey be shaken with absolute alcohol, dextrose remains behind. Ether precipitates lævulose from the alcoholic solution, and the ethereal solution when shaken with lime loses tannic acid, whilst wax remains in solution.

Honey is frequently adulterated with starch-sugar, invert-sugar, molasses, water, &c., and owing to the wide variations in the composition of genuine honey such adulteration is frequently difficult to detect (Racine, Zeitsch. öffentl. Chem. 1902, 281).

Dextrorotatory honey was formerly regarded with suspicion (Haenle, Zeitsch. anal. Chem. 1894, 99), but it has been shown that pine-honey, and honey made by bees using honey-dew, contain a dextrin which can be isolated by precipitation with alcohol, and is strongly dextrorotatory (König and Karsch, Zeitsch. anal. Chem. 1895, 1; Raumer, *ibid.* 1896, 397; Hilger, Zeitsch. Nahr. Genussm. 1904, 189). For a detailed account of the 'honey-dextrins' of pine-honey, *see* Haenle and Scholz (Zeitsch. Nahr. Genussm. 1903, 1027).

Several methods have been recommended for distinguishing between genuine and adulterated honey. Brautigam states that genuine honey contains an albumin by the reactions of which it can be distinguished (Pharm. Zeit. 47, 109). Methods for the microscopic examination of honey have been described by Dietrich (Analyst, 1896, 255). Langer has found in natural honey an inverting ferment which can be precipitated by alcohol and tested on cane-sugar (Zeitsch. angew. Chem. 1902, 1041).

Adulteration with starch-syrup, which usually contains erythro-dextrin and amylo-dextrin can usually be detected by adding methyl alcohol to the conc. aqueous solution, when the dextrins are precipitated. The addition of molasses is best detected by testing for raffinose with basic lead acetate (Beckmann, Zeitsch. anal. Chem. 1896, 263).

Ley's reagent, an ammoniacal solution of silver oxide, when warmed with a strong solution of pure honey gives a greenish colouration, but if the honey is adulterated the liquid becomes dark-brown or black (Utz, Zeitsch. angew. Chem. 1907, 993).

If 1 gram of honey be rubbed down with ether in a mortar, the ether filtered off and evaporated, and the residue treated with a drop of a solution of 1 gram resorcinol in 100 c.c. of hydrochloric acid of sp.gr. 1·19, only a momentary pink colour will be obtained with pure honey, whilst adulterated or artificial honey will give an orange-red colour changing through cherry-red to a strong brown-red (Fiehe, Zeitsch. Nahr. Genussm. 1908, 75; Keiser, Analyst, 1909, 399).

Adulteration with cane-sugar may be detected by determining the reducing power of the honey for Fehling's solution, both before and after inversion. This, however, is not very reliable, as in cases where the bees feed on sucrose considerable quantities are found in the honey, though the larger proportion undergoes inversion in the insect's stomach (Raumer, Zeitsch. anal. Chem. 1902, 333; *see* also Lipmann Analyst, 1889, 20).

Sugar in honey is estimated by diluting with twice its volume of water, and ascertaining the sp.gr. This varies between 1·101 and 1·115. The first number corresponds to 24 p.c., and the latter to 27 p.c. of sugar in the solutions, or to 72 p.c. and 82 p.c. in the original honey (Flückiger, Pharmaceut. Chemie, [ii.] 267).

Wiley has described a process for the estimation of lævulose in honey, &c., based on the fact that its optical rotation is much diminished with rise of temperature. The observation tube of the polarimeter is jacketed, and can be cooled to zero or heated to 88° at which temperature a mixture of molecular proportions of dextrose and lævulose becomes optically inactive (J. Amer. Chem. Soc. 1896, 81).

HONTHIN *v.* SYNTHETIC DRUGS.

HOPEÏNE is a crystalline alkaloid said to be contained in wild American hops. It melts below 100° and partially sublimes below 160°. It is doubtful, however, whether it really exists (Ladenburg, Ber. 1886, 19, 783; J. Pharm. Chim. [v.] 12, 460; Williamson, Chem. Zeit. 1886, 10, 20, 38, 207, 238, 491).

HOPS *v.* BREWING.

HORDEIC ACID *v.* DODECATOIC ACID.

HORDEIN *v.* *Barley*, art. BREWING.

HORDENINE (p-*Hydroxyphenylethyldimethylamine*) $C_{10}H_{15}NO$ was discovered by Léger (Compt. rend. 1906, 142, 108) in malt culms from which it is extracted by Stas' method. The ethereal solution of the alkaloid thus obtained is evaporated to dryness and the hordenine residue is purified by repeated recrystallisation from alcohol. Its constitution was determined by Léger (Compt. rend. 1906, 143, 234, 916) and by Gaebel (Arch. Pharm. 1906, 244, 435).

Hordenine has also been synthesised from phenyl ethyl alcohol (Barger, Chem. Soc. Trans. 1909, 2194; Léger, Bull. Soc. chim. 1910, [iv.] 7, 172), and by the methylation of β-*p*-methoxyphenylethylamine hydrochloride with alcoholic potash and methyl iodide at 100° (Rosenmund, Ber. 1910, 43, 306).

Properties.—Hordenine forms colourless, almost tasteless anhydrous orthorhombic prisms, m.p. 117·8° and subliming like camphor at 140°–150°. It is readily soluble in alcohol, ether, or chloroform, but sparingly so in benzene, xylene, or toluene. It is a strong base, is alkaline towards litmus and phenolphthalein, liberates ammonia from its salts, reduces acid solutions of potassium permanganate in the cold and ammoniacal solutions of silver nitrate and iodic acid on warming. It is not attacked by concentrated sulphuric acid or by potash, but readily forms soluble salts with acids. When boiled with nitric acid it yields picric acid, and when methylated and oxidised with alkaline permanganate it gives anisic acid (Léger, J. Pharm. Chim. 1907, 25, 5; Compt. rend. 1907, 144, 488).

Hordenine sulphate crystallises in needles and has a slightly bitter taste. It forms brown crystals with iodine, but gives no precipitate with the tannins of vegetable infusions. In small doses it has a tonic action on the heart, but in toxic doses (1–2 grams per kilo) it produces the reverse effect.

It has been employed as a remedy in cases of typhoid, dysentery, enteritis, &c. It is not so energetic as digitalis, sparteine, or strophanthus, but is less toxic than any of these (Sabrazès and Guéreve, Compt. rend. 1908, 147, 1076; *see* also Camus, *ibid.* 1906, 142, 110, 237).

Hordenine methiodide, which probably possesses a similar physiological action to that of adrenaline, has been synthesised from *p*-methoxyphenylethylamine by treatment with methyl iodide, an almost quantitative yield being obtained. It crystallises in colourless prisms, m.p. 229°–230° (Rosenmund, *l.c.*). Other organic and inorganic compounds of hordenine have also been obtained (Léger, *l.c.*, and Compt. rend. 1907, 144, 208).

Detection.—A few drops of hordenine are dissolved in a few c.c. of acetic acid and boiled with a few drops of formaldehyde; 3 c.c. of sulphuric acid is now added when a green colouration is produced (Denigés, Bull. Soc. chim. 1908, [iv.] 3, 786).

1 c.c. of 1 p.c. hordenine sulphate solution is boiled with an equal volume of urotropine solution of the same strength, and 2 c.c. of strong

sulphuric acid, a fine emerald green colour is produced even with 0·0001 gram of hordenine sulphate (Labat, J. Pharm. Chim. 1909, 29, 433).

HOREHOUND *v.* Marrubium.

HORN LEAD *v.* Lead.

HORN QUICKSILVER. *Calomel v.* Mercury.

HORNSILVER. Native silver chloride *v.* Cerargyrite, Silver.

HORSE-CHESTNUT. *Hippocastanum. Marronier d'Inde*, Fr.; *Rosscastanien*, Ger. The well-known horse-chestnut tree, *Æsculus hippocastanum* (Linn.), is a native of Persia and Northern India. It was introduced into Europe in the 16th century, and is now largely cultivated for ornament throughout the temperate regions of the world. It is unimportant in medicine; but it is interesting chemically as the source of several glucosides and allied compounds.

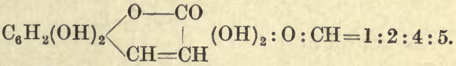
Besides tannin (Rochleder, Zeitsch. Chem. 1867, 76), fat, and constituents common to plants, horse-chestnut bark contains the glucoside *æsculin* $C_{15}H_{16}O_9$ (Minor, Berz. J., 12, 274; Jonas, Annalen, 15, 266) and in smaller proportion *æsculetin* $C_9H_6O_4$ (Rochleder, J. 1863, 589) which is also a product of the action of dilute acids or emulsin on æsculin (Rochleder and Schwartz, Annalen, 88, 356). *Fraxin* or *paviin* $C_{16}H_{18}O_{10}$ a glucoside occurring in the bark of the common ash, *Fraxinus excelsior* (Linn.), is another constituent of horse-chestnut bark (Stokes, Chem. Soc. Trans. 11, 17; 12, 126) accompanied by *fraxetin* $C_{10}H_8O_5$ (Rochleder, Chem. Zentr. 1864, 415), also produced when fraxin is boiled with dilute acids.

To obtain *æsculin*, Rochleder extracts the bark with hot water, precipitates the solution with alum and a slight excess of ammonia, filters, and evaporates the filtrate to dryness at 100°. The residue yields æsculin to hot alcohol, when it may be purified by successive crystallisations. Another method (Fairthorne, Chem. News, 26, 4) consists in exhausting the bark with dilute ammonia, evaporating to dryness, mixing the residue with alumina, and extracting with 95 p.c. alcohol. The alcoholic solution yields crystals of æsculin which are purified by washing with water, ether, and benzene. Æsculin forms colourless prisms which lose water of crystallisation at 120°–130°, and melt with decomposition at 160° (Zwenger, Annalen, 90, 65). It is soluble in glacial acetic acid, acetic ester, and in hot alcohol; very slightly soluble in cold water and nearly insoluble in ether. The aqueous solution has a blue fluorescence. Emulsin or dilute acids convert it into *æsculetin* and *glucose* (Rochleder and Schwartz). Heated with baryta water it yields *æsculetic acid* and *glucose* (Rochleder, J. 1856, 678). Sodium amalgam reacts forming *hydræsculin* (Rochleder, Zeitsch. Chem. 1868, 727). A characteristic colour reaction is obtained by agitating æsculin with nitric acid, when a yellow solution results which on the addition of ammonia turns deep red (Sonnenschein, Ber. 9, 1182). Concentrated sulphuric acid followed by solution of sodium hypochlorite strikes a violet colour (Raby, J. Pharm. Chim. [v.] 9, 402).

Æsculetin is usually prepared by the action of dilute acid on æsculin (Zwenger, Annalen, 90, 63). It crystallises in shining needles or scales containing a molecule of water. It melts with decomposition above 270°. It is soluble in hot but only slightly soluble in cold water and alcohol, and nearly insoluble in ether. The aqueous solution has a slight blue fluorescence.

By reduction with sodium amalgam, æsculetin yields *hydroæsculetin* $C_{18}H_{14}O_8$ and *æsculetin dihydride* $C_9H_8O_4$. Hydroæsculetin appears to be identical with the *æscorcin* of Rochleder (J. 1867, 751). It is converted by gaseous ammonia into *dehydroæscorcein* $C_{18}H_{13}O_7N_3$, a deep violet coloured mass. Æsculetin dihydride, similarly, when treated with ammonia, exhibits a striking series of colour reactions. Æsculetin unites with sodium hydrogen sulphite forming *sodium dihydroæsculetinsulphonate*. This compound is not decomposed by dilute acids; by the action of gaseous ammonia it is converted into the deep violet coloured compound described by Rochleder as *æscorceïn* $C_9H_7O_5N$, but which is in reality *sodium æscorceïnsulphonate* $C_{18}H_{12}O_{16}N_2S_2Na_6$ (Liebermann and Wiedermann, Ber. 34, 2608; Liebermann and Lindenbaum, *ibid.* 35, 2919).

The diacetyl derivative of æsculetin has been prepared by Gattermann and Köbner (Ber. 32, 287) by the action of sodium acetate and acetic anhydride on 2:4:5-trihydroxybenzaldehyde. Æsculetin is thus shown to have the constitution



$$C_6H_2(OH)_2\left\langle\begin{matrix}O\text{—}CO\\ \quad\ \ |\\ CH{=}CH\end{matrix}\right.(OH)_2:O:CH=1:2:4:5.$$

Fraxin crystallises in colourless needles containing half a molecule of water of crystallisation. By the action of dilute acids it is converted into *fraxetin* and *glucose* (Salm, J. 1859, 576). Fraxetin consists of tables (from alcohol) very slightly soluble in water, but soluble in ether and hydrochloric acid.

Horse-chestnut cotyledons were found by Rochleder (J. pr. Chem. [i.] 87, 1; [i.] 101, 415) to contain three compounds. *Argyræscin* $C_{27}H_{42}O_{12}$ a crystalline glucoside converted by dilute acids into *glucose* and *argyræscetin* $C_{21}H_{30}O_6$, and by potash into *propionic acid* and *æscinic acid* $C_{24}H_{40}O_2$, a compound found ready formed in the cotyledons. The third constituent of the cotyledons is the glucoside *aphrodæscin* $C_{52}H_{82}O_{23}$, which, acted on by potash, also yields *æscinic acid*, the second product being in this case *butyric acid*, or when heated with dilute acids *glucose*, and *telæscin* $C_{18}H_{30}O_7$. Telæscin acted on by hydrochloric acid gas gives up another molecule of *glucose* and forms *æscigenin* $C_{12}H_{20}O_2$ (Rochleder, J. 1862, 491; 1867, 751).

The leaves of the horse-chestnut contain the glucoside *quercitrin* $C_{36}H_{38}O_{20}$ and the flowers *quercetin* $C_{24}H_{16}O_{11}$ (Rochleder, J. 1859, 522). *Quercitrin* is usually prepared from black oak bark, *Quercus discolor* (Ait.) (Liebermann and Hamburger, Ber. 12, 1179) and from this compound by treatment with dilute acids *quercetin* together with *isodulcite* is obtained.

For other reactions and the constitution of these compounds *v.* Glucosides.

For examination of horse-chestnuts *see* Laves (Chem. Zentr. 1903, ii. 1133). The oil present in them was at one time used in medicine; it has been investigated by Stillesen (Chem. Zentr. 33, 497). A. S.

HORSE-RADISH. The root of *Cochlearia Armoracia* (Linn.), used as a condiment. Its pungent flavour is due to the presence of *iso*butyl *iso*thiocyanate, $C_4H_9\cdot NCS$. The root contains—

Water	Nitrogenous substances	Fat	*N*-free extract	Crude fibre	Ash	Organic sulphur
76·7	2·7	0·3	15·9	2·8	1·5	0·08

The following is an analysis of the ash of horse-radish:—

Per cent. of ash in the dry subst.	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
7·1	30·8	4·0	8·2	2·9	1·9	7·8	30·8	12·7	0·9

H. I.

HUMIC ACID. The substance produced by the decay of vegetable matter and found in the soil. Various humic acids have been described; an octobasic acid $C_{60}H_{54}O_{27}$ (Detmer, J. 1873, 844); an acid $C_{24}H_{10}O_{10}$ (Thenard, J. 1873, 844); an acid $C_{26}H_{22}O_{10}$, from brown coal (Hoppe, Zeitsch. physiol. Chem. 13, 108); and an acid $C_{46}H_{46}O_{25}$ from coal (John, Zeit. Kryst. Min. 23, 289). According to Robertson, Irvine, and Dobson (Bio-Chem. J. 1907, 2, 458), the natural humic acid from peat varies greatly in composition, according to the method of preparation. The artificial acid from sugar, according to them, has the composition $C_{39}H_{32}O_{14}$, but Berthelot and André (Compt. rend. 112, 916) state that this acid is tribasic and has the composition $C_{18}H_{16}O_7$. Humic acid is capable of absorbing ammonia, which is then removed by the acid of sprouting seeds, humic acid being regenerated (Borntraeger, Chem. Zentr. 1900, ii. 1202). Gautreau, Charbonnier, and Serrant (Eng. Pat. 22028; J. Soc. Chem. Ind. 1895, 977) treat peat or vegetable refuse with dilute sulphuric acid, to produce humic acid. The mass after the removal of the liquid matter is treated with excess of lime, potassium sulphate is added and the resulting substance sold as a manure.

HUNGARIAN TURPENTINE *v.* OLEO-RESINS.

HUNGARY BLUE. *Cobalt blue v.* PIGMENTS.

HUNGARY GREEN. *Malachite green v.* PIGMENTS.

HYACINTH *v.* ZIRCON and ZIRCONIUM.

HYÆNASIC ACID $C_{24}H_{49}\cdot COOH$, m.p. 77·5°, is found as a glyceride in the anal glandular pouches of the striped hyaena (Carius, Annalen, 129, 168).

HYALINE CORUNDUM *v.* ALUMINIUM.

HYDANTOIN, *glycolylcarbamide*  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NH\cdot CH_2}\\ \quad\;|\\ \mathrm{NH\cdot CO}\end{array}\right.$ was found together with allantoin in the leaf buds of *Platanus orientalis* (Linn.) (Schulze and Barbieri, Ber. 1881, 14, 1834); and also in beet juice (v. Lippmann, Ber. 1896, 29, 2652). It is prepared (1) by reducing allantoin or alloxanic acid with concentrated hydrogen iodide at 100° (Baeyer, Annalen, 1864, 130, 158); (2) by the action of excess of alcoholic ammonia on bromacetylurea at 100° (Baeyer, Ber. 1875, 8, 612); (3) by the condensation of sodium dihydroxytartrate and carbamide in the presence of hydrochloric acid at 50°–60° (Anschütz, Annalen, 1889, 254, 258); (4) by the condensation of glyoxal and carbamide in the presence of hydrochloric acid (Siemonsen, Annalen, 1904, 333, 101); (5) from ethyl hydantoate by heating at 135° for 7 hours, or by warming with 25 p.c. hydrochloric acid (Harries and Weiss, Ber. 1900, 33, 3418), or by heating with alcoholic ammonia at 100° (Harries, Annalen, 1908, 361, 69); the ethyl hydantoate is prepared by the condensation of the hydrochloride of the ethyl ester of glycine with potassium cyanate (Harries and Weis, *l.c.*) or by the interaction of glycollic ester and ethyl sodiocarbonate (Diels and Heintzel, Ber. 1905, 38, 305).

Hydantoin crystallises in colourless needles, m.p. 216° (Schulze and Barbieri, Anschütz, *l.c.*); 217°–220° (Harries and Weiss, *l.c.*); its heat of combustion at constant volume is +312·4Cal., and heat of formation +109Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 70). Its dissociation constant *Ka* is $7{\cdot}59\times10^{-10}$ (Wood, Phil. Trans. 1906, 1833). It is sparingly soluble in cold, readily so in hot water, and the solution has a sweetish taste. Hydantoin is not attacked by ammonia, hydrochloric, or dilute nitric acid; when boiled with baryta water it is converted into the barium salt of *hydantoic acid*

$$NH_2\cdot CO\cdot NH\cdot CH_2\cdot CO_2H,$$

the heat of combustion of which is 308·9Cal. and heat of formation +181·6Cal. (Matignon, *l.c.*).

The *silver derivative* $C_3H_3O_2N_2Ag,H_2O$ is precipitated by silver nitrate from an ammoniacal solution of hydantoin.

Substituted derivatives of hydantoin are referred to the ring  $\overset{2}{\mathrm{CO}}\left<\begin{array}{l}\mathrm{NH\cdot CH_2}\\ \;\,{}^{3}\;\;{}^{4}|\\ \;\,{}_{1}\;\;{}_{5}|\\ \mathrm{NH\cdot CO}\end{array}\right.$.

Nitrohydantoin  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NH\cdot CH(NO_2)}\\ \quad\;\;|\\ \mathrm{NH\cdot CO}\end{array}\right.$, prepared by the action of nitric acid on hydantoin, forms shining crystals, melting and decomposing at 170° (Franchimont and Klobbie, Rec. trav. chim. 1888, 7, 12).

1 : 3-Diacetylhydantoin  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NAc\cdot CH_2}\\ \mathrm{NAc\cdot CO}\end{array}\right.$, obtained by the action of acetic anhydride on hydantoin, has m.p. 104°–105°, and yields 3-*acetylhydantoin*  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NAc\cdot CH_2}\\ \quad\;\;|\\ \mathrm{NH\cdot CO}\end{array}\right.$, m.p. 143°–144°, when boiled with water, and this forms a sparingly soluble *lead salt* (Harries and Weiss, Annalen, 1903, 327, 355; Siemonsen, Annalen, 1904, 333, 101).

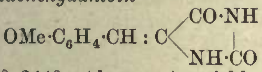
Dichlorohydantoin  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NH\cdot CCl_2}\\ \mathrm{NH\cdot CO}\end{array}\right.$ or  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NCl\cdot CH_2}\\ \quad\;\;|\\ \mathrm{NCl\cdot CO}\end{array}\right.$ obtained in the form of lustrous crystalline leaves, m.p. 120°–121° by the action of chlorine on an aqueous solution of hydantoin (Harries and Weiss, Annalen, 1903, 327, 355; Siemonsen, Annalen, 1904, 333, 101; Biltz and Behrens, Ber. 1910, 43, 1984). Attempts to prepare bromine derivatives of hydantoin have been unsuccessful; by the action of ½ molecule of bromine hydantoin is converted into iso*allituric acid*  $\mathrm{CO}\left<\begin{array}{l}\mathrm{NH\cdot CH{-}N{-}CH_2}\\ \qquad\;\;|\quad\;\;|\\ \mathrm{NH\cdot CO\quad CO\cdot NH}\end{array}\right>\mathrm{CO}$, m.p. 258°–260°, when a larger proportion of bromine is employed, parabanic acid (oxalylcarbamide), is formed, the bromo derivative  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH{\cdot}CBr_2}\\ \mathrm{NH{\cdot}CO}\end{array}$ being probably first produced.

Condensation with aldehydes. Hydantoin condenses with formaldehyde (1–3 mols.) in aqueous solution to form *hydroxymethylhydantoin*  $\mathrm{OH{\cdot}CH_2{\cdot}N}\Big\langle\begin{array}{l}\mathrm{CH_2{\cdot}CO}\\ \mathrm{CO{\cdot}NH}\end{array}$ or  $\mathrm{OH{\cdot}CH_2{\cdot}N}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}CH_2}\\ \mathrm{CO{\cdot}NH}\end{array}$ m.p. 125°–135°, it yields *chloromethylhydantoin* $C_4H_5O_2N_2Cl$, m.p. 150°–157°, when treated with phosphorus pentachloride or concentrated hydrochloric acid. When hydantoin is warmed with formaldehyde in the presence of acids more complex products are obtained (Behrend and Niemeyer, Annalen, 1909, 365, 38).

Hydantoin condenses with aromatic aldehydes in the presence of glacial acetic acid and sodium acetate to form compounds of the type  $\mathrm{RHC:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH,}\\ \mathrm{NH{\cdot}CO}\end{array}$ which, on reduction, yield the corresponding 4-*aryl*-substituted hydantoin  $\mathrm{RH_2C{\cdot}HC}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$. The following compounds are described:—

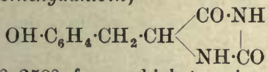
Benzylidenehydantoin  $\mathrm{PhHC:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$ m.p. 220°, yields 4-*benzylhydantoin* (*phenylalaninehydantoin*)  $\mathrm{PhH_2C{\cdot}CH}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$, m.p. 188°–190° on reduction, from which phenylalanine is obtained by boiling with baryta water (Ruhemann and Stapleton, Phil. Trans. 1900, 246).

Anisylidenehydantoin



$$\mathrm{OMe{\cdot}C_6H_4{\cdot}CH:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

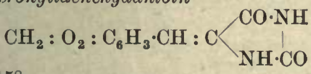
m.p. 243°–244° (decomp.) yields a *bromo* derivative, m.p. 247°; and on reduction with hydrogen iodide forms 4-*p*-*hydroxybenzylhydantoin* (*tyrosinehydantoin*)



$$\mathrm{OH{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

m.p. 257°–258°, from which *tyrosine* is obtained by prolonged boiling with hydrogen iodide. The tyrosinehydantoin, m.p. 275°–280°, described by Blendermann (Bied. Zentr. 1883, 209) is probably the optically active isomeride of this compound.

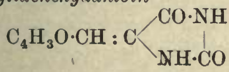
Piperonylidenehydantoin



$$\mathrm{CH_2:O_2:C_6H_3{\cdot}CH:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

m.p. 245°.

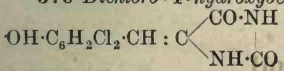
Furfurylidenehydantoin



$$\mathrm{C_4H_3O{\cdot}CH:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

m.p. 232°.

3 : 5-*Dichloro*-4-*hydroxybenzylidenehydantoin*



$$\mathrm{OH{\cdot}C_6H_2Cl_2{\cdot}CH:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

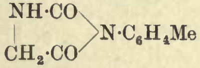
m.p. 300°.

p-Nitrobenzylidenehydantoin

$$\mathrm{NO_2{\cdot}C_6H_4{\cdot}CH:C}\Big\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO}\end{array}$$

m.p. 254° (Wheeler and Hoffmann, Amer. Chem. J. 1911, 45, 368).

Alkyl and aryl substituted derivatives. 1-*Methylhydantoin*  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH{\cdot}CH_2}\\ \mathrm{NMe{\cdot}CO}\end{array}$ by methylating hydantoin by means of methyl iodide, potassium hydroxide, and methyl alcohol at 100° (Franchimont and Klobbie, Rec. trav. chim. 1889, 8, 289); from methylcarbamide and glycine (Guareschi, Chem. Zentr. 1892, i. 140); crystallises in prisms, m.p. 182°. The *nitro* derivative  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{N(NO_2){\cdot}CH_2}\\ \mathrm{NMe\text{——}CO}\end{array}$ has m.p. 168° (Franchimont and Klobbie, *l.c.*). 1-*p-tolylhydantoin*



$$\begin{array}{l}\mathrm{NH{\cdot}CO}\\ \mathrm{CH_2{\cdot}CO}\end{array}\Big\rangle\mathrm{N{\cdot}C_6H_4Me}$$

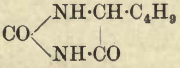
from *p*-tolylcarbamide and glycine (Quenda, Chem. Zentr. 1892, i. 140).

3-*Methylhydantoin*  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NMe{\cdot}CH_2}\\ \mathrm{NH{\cdot}CO}\end{array}$ prepared (1) by fusing sarcosine and urea (Huppert, Ber. 1873, 6, 1278; Horbaczewski, Monatsh. 1887, 8, 586); (2) by passing cyanogen chloride through fused sarcosine (Traube, Ber. 1882, 15, 2111); (3) by heating caffuric acid with baryta water (Fischer, Annalen, 1882, 215, 286); or (4) by reducing 3-methylallantoin with hydrogen iodide (Fischer and Ach, Ber. 1899, 32, 2748); forms soluble prisms, m.p. 156°; the *silver* derivative $AgC_4H_5N_2O_2$ is crystalline.

3-*Phenylhydantoin* from phenylglycine and urea has m.p. 191°; 3-*tolylhydantoin* has m.p. 210° (Schwebel, Ber. 1877, 10, 2045; 11, 1128).

Homologues of hydantoin containing the substituent in position 4- are most numerous; and are prepared by the following general methods: (1) by interaction between the cyanohydrin of an aldehyde and carbamide (Pinner, Ber. 1887, 20, 2351; 21, 2320; 22, 685); (2) by the action of dilute hydrochloric acid on the hydantoic acid obtained by evaporating to dryness a solution of an *α*-amino acid and potassium cyanate (Dakin, Amer. Chem. J. 1910, 44, 48); or by the interaction of carbamide, the *α*-amino acid and baryta water (Lippich, Ber. 1908, 41, 2953); (3) by reducing the compound obtained by the condensation of hydantoin and an aromatic aldehyde (Wheeler and Hoffmann, *l.c.*).

4-*Methylhydantoin* (*lactylurea*)  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH{\cdot}CHMe}\\ \mathrm{NH{\cdot}CO}\end{array}$ (Heintz, Annalen, 1873, 169, 125; Urech, Ber. 1873, 6, 1113), m.p. 140° or 145°. The *nitro*-derivative  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH{\cdot}C(NO_2)Me}\\ \mathrm{NH{\cdot}CO}\end{array}$ m.p. 148° (Franchimont and Klobbie, Rec. trav. chim. 1888, 7, 13). 4-*isoButylhydantoin*



$$\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH{\cdot}CH{\cdot}C_4H_9}\\ \mathrm{NH{\cdot}CO}\end{array}$$

has m.p. 209°–210° (Pinner and Lifschütz, Ber

1887, 20, 2351), 212° (Lippich, *ibid.* 1908, 41, 2953). *l*-4-*iso Butylhydantoin* has m.p. 212°, $[\alpha]_D^{20°}-68{\cdot}2°$ in normal sodium hydroxide solution, becoming zero in 30 hours owing to the enol-keto desmotropy of the group

$$CH{\cdot}CO \rightleftarrows C:C{\cdot}OH.$$

-4:4-*Methylethylhydantoin*  $CO\!<\!\begin{array}{l} NH{\cdot}CMeEt \\ \qquad | \\ NH{\cdot}CO \end{array}$ has m.p. 172°–173°, and $[\alpha]_D^{20}+32°$, and this is constant in normal sodium hydroxide solution (Dakin, *l.c.*). 4-*Phenylhydantoin*, m.p. 178°; the *acetyl* derivative has m.p. 145° (Pinner, *l.c.*); the *bromo* derivative  $CO\!<\!\begin{array}{l} NH{\cdot}CBrPh \\ \qquad | \\ NH{\cdot}CO \end{array}$ melts above 200°, and is decomposed by hot water yielding 4-*hydroxy*-4-*phenylhydantoin* (Gabriel, Annalen, 1906, 350, 118). 4-*Cinnamylhydantoin*  $CHPh:CH{\cdot}CH\!<\!\begin{array}{l} CO{\cdot}NH \\ \qquad | \\ NH{\cdot}CO \end{array}$ m.p. 171°–172° (Pinner and Spilker, Ber. 1889, 22, 685). 4-*Ethylhydantoin*, m.p. 117°–118°, yields 4-*bromoethylidenehydantoin*  $CO\!<\!\begin{array}{l} NH{\cdot}C:CBrMe \\ \qquad | \\ NH{\cdot}CO \end{array}$ m.p. 230°–236°, on bromination; the corresponding methyl compound yields 4-*bromomethylenehydantoin*  $CO\!<\!\begin{array}{l} NH{\cdot}C:CHBr, \\ \qquad | \\ NH{\cdot}CO \end{array}$ m.p. 241°–242° (Gabriel, Annalen, 1906, 348, 50).

4:4-*Dimethylhydantoin* (acetonylcarbamide)  $CO\!<\!\begin{array}{l} NH{\cdot}CMe_2 \\ \qquad | \\ NH{\cdot}CO \end{array}$ formed by the action of hydrocyanic acid, and cyanic acid on acetone has m.p. 175°; the *nitro* derivative has m.p. 161°–162° (Urech, Annalen, 1872, 164, 264; Errera, Gazz. chim. ital. 1896, 26, 1, 210); 4:4-*diethylhydantoin* has m.p. 165°, and 4:4-*dipropylhydantoin*, m.p. 199° (Errera, *l.c.*). By the action of sodium hypochlorite and free hypochlorous acid on 4:4-disubstituted hydantoins, the corresponding 1:3-*dichloro* compounds  $CO\!<\!\begin{array}{l} NCl{\cdot}CRR' \\ \qquad | \\ NCl{\cdot}CO \end{array}$ are obtained. These compounds can be crystallised from chloroform, but are decomposed by water, alcohol, or hydrogen iodide, regenerating the original hydantoin (Biltz and Behrens, Ber. 1910, 43, 1984).

1:3-*Dichloro*-4:4-*diphenylhydantoin*  $\begin{array}{l} CPh_2{\cdot}NCl \\ | \\ CO{-\!\!-}NCl \end{array}\!\!>\!CO$ has m.p. 164° with decomposition, it yields 4:4-*diphenyl*-1:3-*dimethylhydantoin* when treated with methyl sulphate.

1-*Methyl*-4-*phenylhydantoin* has m.p. 161°–162° (Pinner, Ber. 1888, 21, 2320). 4-*Methyl*-3-*ethylhydantoin* forms volatile plates (Duvillier, Bull. Soc. chim. 1895, [iii.] 13, 487).

3:4-*Dimethylhydantoin* has m.p. 120°–121°, and yields 3-*methyl*-4-*bromomethylenehydantoin*  $CO\!<\!\begin{array}{l} NMe{\cdot}C:CHBr \\ \qquad | \\ NH{\cdot}CO \end{array}$ m.p. 143°–144°, by the action of bromine (Gabriel, Annalen, 1906, 348, 50).

M. A. W.

HYDNO-CARPIC ACID, HYPOGALIC ACID, *v.* OILS, FIXED, and FATS.

HYDRACRYLIC ACID *v.* LACTIC ACID.

HYDRÆSCULIN *v.* HORSE-CHESTNUT.

HYDRARGOL, HYDRARGOTIN, HYDRARGYROSEPTOL, *v.* SYNTHETIC DRUGS.

HYDRASTINE $C_{21}H_{21}NO_6$ occurs, together with berberine and canadine, in the roots of the golden seal (*Hydrastis canadensis* [Linn.]), a plant belonging to the *Ranunculaceæ* and indigenous to North America (Durand, Amer. J. Pharm. 23, 13; Perrins, Pharm. J. May, 1862; Power, Jahrb. 1884, 1396; Freund and Will, Ber. 1886, 19, 2798; Linde, Arch. Pharm. 1898, 236, 696, 698; Schmidt, *ibid.* 232, 136). It was first isolated by Durand in 1850, but was obtained pure for the first time by Perrins in 1862.

Preparation.—The aqueous or alcoholic extract of the root is treated with dilute sulphuric acid to precipitate the berberine, and after filtration, the filtrate (if alcohol has been used for extracting) is treated with ammonia water until nearly neutral, the ammonium sulphate is filtered off and the liquid after concentration is mixed with cold water to precipitate resinous and oily matter. The filtrate is then treated with excess of ammonia water and the hydrastine thus precipitated, is recrystallised from alcohol or ethyl acetate (*see* also Freund and Will, *l.c.*; Ough, Chemist and Druggist, 1901, 59, 152).

Properties.—Hydrastine is closely related to narcotine, of which it is probably a methoxyl derivative. Our knowledge of its structure is mainly due to the work of Schmidt and of Freund (Annalen, 1892, 271, 311; Fritsch, *ibid.* 1895, 286, 18; Rabe and McMillan, *ibid.* 1910, 377, 223). It forms colourless, almost odourless and tasteless 4-sided prisms, which melt at 132°, to a light amber coloured liquid. It is almost insoluble in water but is readily soluble in ether, alcohol, chloroform, and benzene. It is lævorotatory. When oxidised with potassium permanganate opianic acid is formed (Labat, Bull. Soc. chim. 1909, [iv.] 5, 743), and when heated with nitric acid at 50°–60°, it yields opianic acid and *hydrastinine* (Freund and Will, Ber. 1887, 20, 94), whilst when oxidised in alkaline solution, it yields hemipinic and nicotinic acids.

When fused with potash, it yields protocatechuic and formic acids. Hydrastine forms a faint yellow solution in sulphuric acid, which turns reddish purple on warming and which decolorises potassium permanganate. With platinum chloride hydrastine gives an orange-yellow precipitate; with gold chloride, a yellow-red; with picric acid, a yellow; and with potassium dichromate, a yellow precipitate, which turns red on addition of sulphuric acid. In contact with a potassium iodide solution containing free iodine it yields a brown hexaiodide, or a hydriodide pentiodide $C_{21}H_{21}NO_6HI{\cdot}I_5$ (Prescott and Gordin, J. Amer. Chem. Soc. 1899, 21, 732).

Hydrastine combines readily with ketones, forming condensation products with elimination of water (Liebermann and Kropf, Ber. 1904, 37, 211). It also forms similar condensation products with most compounds containing methylene groups between carbonyl groups and also with such compounds as hydroquinone, phloroglucinol, and pyrogallol (Liebermann and Glawe, *ibid.* 2738). When heated with carbamide it forms meconin (Beckurts and Frerichs, Arch. Pharm. 1903, 241, 259). When 0·1 c.c. of a hydrastine solution in alcohol is added to 2 c.c. of pure sulphuric acid (sp.gr. 1·84), and 0·1 c.c. of a phenolic substance is added, the mixture, on warming, develops beautiful colourations. Thus with gallic acid the colour is emerald green, which gradually becomes blue. With guaiacol or catechol, a red colour is produced which turns violet, and with morphine the mixture becomes violet (Labat, Bull. Soc. chim. 1909, [iv.] 5, 742).

Hydrastine may be distinguished from most other alkaloids by the fact that when a few drops of Nessler's reagent are added to a solution of its hydrochloride, a precipitate which instantly blackens is produced. Only morphine, apomorphine, and picrotoxin precipitate mercury more or less quickly from the reagent (Jorissen, Ann. Chim. anal. 1903, 8, 127). When chlorine is added to the hydrochloride, a blue fluorescence appears.

For the estimation of hydrastine in extract and tincture of hydrastis, *see* Gordin and Prescott, *l.c.*; Maben, Chem. and Druggist, 1901, 59, 234; Matthes and Rammstedt, Arch. Pharm. 1907, 245, 112; Packner, Chem. Zentr. 1908, ii. 266; Roeder, J. Soc. Chem. Ind. 1908, 1037; Rupp, *ibid.* 1910, 449.

Hydrastine and its salts, which form hygroscopic crystalline powders of bitter taste, are used in medicine chiefly for external use in the treatment of subacute and of chronic inflammatory conditions of the mucous membrane; also in uterine catarrh and more rarely, internally for gastro-intestinal catarrh and catarrhal jaundice (Falk, Virchow's Arch. 1895, 142, 360; Bunge, Chem. Zentr. 1895, i. 1173; Phillips and Pembrey, Proc. Physiol. Soc. 1896–7, 4).

For the salts and derivatives of hydrastine, *see* Merck, Chem. Zeit. Rep. 1893, 17, 30; Freund, *l.c.*; Ber. 1889, 22, 456; *ibid.* 1890, 23, 404, 416, 2897, 2907; *ibid.* 1893, 26, 2488; Norton and Newman, J. Amer. Chem. Soc. 1897, 19, 838; Schmidt, Arch. Pharm. 1898, 236, 334; D. R. P. 58394; Rabe and McMillan, *l.c.*

Hydrastinine $C_{11}H_{13}O_3N$, which is formed by the oxidation of hydrastine with dilute nitric acid, can also be prepared by the dry distillation of a mixture of hydrastine and soda lime in an atmosphere of hydrogen (Schmidt, Arch. Pharm. 231, 541). It forms needle shaped crystals, m.p. 116°–117°, and is readily soluble in alcohol, ether, and chloroform, more sparingly in hot water. When reduced with zinc and hydrochloric acid, or when boiled with potash, or electrolysed in dilute sulphuric acid, it forms *hydrohydrastinine*, m.p. 171° (Freund; Bandow and Wolfenstein, Ber. 1898, 31, 1578). Oxidised with nitric acid, it yields apophyllic acid. By the continued oxidation of hydrastinine with potassium permanganate, *hydrastinic acid* $C_{11}H_9NO_6$, m.p. 164° (decomp.), is obtained in fine white needles. Hydrastinic acid when boiled with nitric acid, yields a crystalline substance, $C_{10}H_7NO_4$, m.p. 233°, which, on boiling with potash, yields *hydrastic acid*, m.p. 175°. a dibasic acid which readily forms an anhydride (Freund, Ber. 1889, 22, 1156, 2322, 2329; Annalen, 1892, 271, 375; Perkin, Chem. Soc. Trans. 1890, 1095; Perkin and Robinson, *ibid.* 1907, 1086).

Hydrastinine hydrochloride, m.p. 212° (decomp.), forms a light yellow granular or crystalline deliquescent powder. It is odourless, has a bitter saline taste, is very soluble in cold and hot water and alcohol, and is said to be an efficient oxytoxic. It has also been recommended in the treatment of uterine hæmorrhage (Merck, J. Soc. Chem. Ind. 1892, 545).

HYDRAULIC CEMENTS *v.* CEMENTS.

HYDRAULIC LIME *v.* CEMENTS.

HYDRAZINES. The name 'hydrazine' was applied by Emil Fischer to the then unknown diamide $H_2N{\cdot}NH_2$, which he regarded as the parent substance of the hydrazines, a large and important class of bases which had been prepared by him and the reactions of which showed them to possess a structural formula derived from diamide by the replacement of one or two hydrogen atoms by hydrocarbon radicles. The name was intended to indicate the connection of these compounds with the azo and diazo compounds and particularly with hydrazobenzene, $C_6H_5{\cdot}NH{\cdot}NH{\cdot}C_6H_5$, the oldest known member of this class, which itself may be regarded as a symmetrically disubstituted hydrazine.

It is apparent that there are five different ways in which the four hydrogen atoms of diamide may be replaced by hydrocarbon radicles, thus: (1) $RNH{\cdot}NH_2$, (2) $RRN{\cdot}NH_2$, (3) $RHN{\cdot}NHR$, (4) $RRN{\cdot}NHR$, (5) $RRN{\cdot}NRR$, but the name hydrazine was formerly only applied to those derivatives of diamide which had the hydrocarbon radicle or radicles asymmetrically attached to the molecule, that is to say, those which are constituted in accordance with formulæ (1) and (2).

This was mainly owing to the fact that the compounds constituted as in formula (3) had already been named, as for example, hydrazobenzene, $C_6H_5NH{\cdot}NH{\cdot}C_6H_5$, and that no substances of the formulæ 4 and 5 had as yet been prepared. At the present time compounds of all five classes are known, and therefore the name hydrazine is applied to all derivatives of diamide.

The hydrocarbon radicles forming the hydrazines may belong either to the aliphatic or aromatic series, although the most important members of the group belong to the aromatic series. Like the amines, they are divided into primary and secondary hydrazines, according as one or two hydrocarbon radicles are contained in them; that is to say, the primary hydrazines are constituted as in formula (1), the secondary hydrazines as in formula (2). The secondary hydrazines may be symmetrical or asymmetrical as in formula (2) or (3): compounds constituted as in formula (4) are tertiary hydrazines, whilst quarternary hydrazines have a structure represented by formula (5).

General methods of preparation.—The primary and secondary hydrazines can be considered as being derived from the primary and secondary amines respectively by the replacement of one of the hydrogen atoms attached to the nitrogen by the primary amino group—

$$RNHH \longrightarrow RNH{\cdot}NH_2, \quad RRNH \longrightarrow RRN{\cdot}NH_2$$

These compounds are therefore prepared from the primary and secondary amines through the agency of nitrous acid.

Since the primary aromatic amines yield diazonium salts when treated with nitrous acid, these salts are always intermediate products in the formation of the primary aromatic hydrazines and are converted into them by the action of reducing agents. For general purposes this reduction may be effected in one of two ways—

(1) By the reduction of the solution of the diazonium salt by stannous chloride (V. Meyer and Lecco, Ber. 1883, 16, 2976)—

$$C_6H_5\cdot N_2Cl+4H=C_6H_5\cdot NH\cdot NH_2,HCl.$$

(2) By treating the diazonium salt with alkali sulphite, in order to prepare the alkali salt of the sulphonic acid, and then by reducing this with zinc dust and acetic acid to form the alkali salt of the hydrazine sulphonic acid thus—

$$C_6H_5\cdot N_2SO_3K+2H=C_6H_5\cdot NH\cdot NH\cdot SO_3K.$$

Finally, by boiling this salt with hydrochloric acid to convert it into the hydrochloride of the hydrazine and potassium hydrogen sulphate (E. Fischer, Annalen, 1877, 190, 71; Reychler, 1887, 20, 2463).

$$C_6H_5\cdot NH\cdot NH\cdot SO_3K+H_2O+HCl$$
$$=C_6H_5\cdot NH\cdot NH_2,HCl+KHSO_4.$$

These reactions can only be applied to the aromatic amines because those of the aliphatic series do not form diazonium salts.

Primary aliphatic hydrazines have, however, been prepared by E. Fischer (Ber. 1884, 2841; Annalen, 1877, 199, 281) from the symmetrical dialkyl ureas by transforming them into their nitroso derivatives by the aid of nitrous acid and then by converting the hydrazinureas, formed from these on reduction, into the primary hydrazines by the action of fuming hydrochloric acid.

$$RHN\cdot CO\cdot NHR+NOOH=RHN\cdot CO\cdot N(NO)R$$
$$RHN\cdot CO\cdot N(NO)R+4H$$
$$=RHN\cdot CO\cdot N(NH_2)R+H_2O$$
$$RHN\cdot CO\cdot N(NH_2)R+H_2O$$
$$=CO_2+(NH_2)NH\cdot R+NH_2\cdot R.$$

Primary hydrazines of the aromatic series are also formed when certain diazoamino compounds are reduced in alcoholic solution with zinc dust and acetic acid. Thus diazoaminobenzene passes in this manner into phenylhydrazine (E. Fischer, Annalen, 1887, 90, 77).

$$C_6H_5\cdot N_2\cdot NH(C_6H_5)+4H$$
$$=C_6H_5\cdot NH\cdot NH_2+C_6H_5NH_2.$$

The secondary hydrazines both of the aromatic and aliphatic series are prepared from the corresponding secondary amines. The amines are converted into their nitroso derivatives, by the aid of nitrous acid, which are then transformed into the hydrazines by reduction.

$$R_2NH+NOOH=R_2N\cdot NO+H_2O$$
$$R_2N\cdot NO+4H=R_2N\cdot NH+H_2O.$$

Phenylhydrazine $C_6H_5\cdot NH\cdot NH_2$, the most important member of the hydrazine group, can be prepared by either of the methods mentioned above.

(1) *From aniline by the aid of stannous chloride.* Ten grams of aniline are dissolved in 100 grams of concentrated hydrochloric acid and the semi-solid mass of aniline hydrochloride is then cooled, externally, by means of ice. A solution of 10 grams of sodium nitrite dissolved in 50 c.c. of water is then gradually added until a test portion diluted with water shows, by means of starch and potassium iodide paper, the presence of excess of nitrous acid. The solution of benzene-diazonium chloride formed in this manner is then treated with a solution of 60 grams of stannous chloride dissolved in 50 c.c. of concentrated hydrochloric acid, the reducing agent being cooled by means of ice and added gradually with constant stirring to the solution of the diazonium salt. After standing for one hour, the phenylhydrazine hydrochloride is filtered at the pump, dissolved in water and converted into the free base by the addition of excess of aqueous caustic potash. The liberated base is extracted with ether, dried by potassium carbonate and purified by distillation under diminished pressure.

(2) *From aniline by the aid of sodium sulphite.* A solution of 50 grams of aniline in 2½ molecules of hydrochloric acid and 300 c.c. of water is diazotised by the addition of the calculated quantity of sodium nitrite solution, and is then mixed with a cold concentrated aqueous solution of 2½ molecules of sodium sulphite. The whole is then gently warmed on the water bath and treated with zinc dust and a little acetic acid until colourless, when it is heated to the boiling-point and filtered, whilst hot, from the unchanged zinc. One-third of its volume of concentrated hydrochloric acid is then added to the hot solution and the phenylhydrazine hydrochloride, which separates on cooling, is removed by filtration and treated in the same manner as in the previous preparation.

For the preparation of phenylhydrazine and its derivatives from urea and substituted ureas by the action of alkaline hypobromites, *cp.* Schestakow, D. R. P. 164755; Patentol. 26, 1869.

Tertiary aromatic hydrazines of the general formula $RNH\cdot NR_2$ may be prepared by the interaction of β-arylhydroxylamine and magnesium halogen aryl (Busch and Hobein, Ber. 1907, 40, 2099). Thus triphenylhydrazine $C_6H_5NH\cdot N(C_6H_5)_2$ is formed when phenylmagnesium bromide reacts with β-phenylhydroxylamine. The corresponding quaternary hydrazine tetraphenylhydrazine

$$(C_6H_5)_2N\cdot N(C_6H_5)_2$$

has been prepared by Chattaway and Ingle (Trans. 1895, 67, 1090) by the action of iodine on the sodium compound of diphenylamine, and by Weland and Gambarjan (Ber. 1906, 39, 1501) by the oxidation of diphenylamine.

Certain compounds belonging to the group of the dihydrazines have been prepared by V. Braun (Ber. 1908, 41, 2169; *ibid.* 2604; 1910, 1495), and are recommended as reagents for compounds containing carbonyl oxygen. Thus diphenylmethandimethyldihydrazine

$$[NH_2\cdot N(CH_3)C_6H_4]_2CH_2$$

is prepared by condensing methylaniline with formaldehyde to give *p*-dimethyldiaminodiphenylmethane $[HN(CH_3)C_6H_4]_2CH_2$, the nitroso compound of which gives the dihydrazine on reduction with zinc and acetic acid.

Properties and reactions of the hydrazines. The primary aromatic hydrazines are mono-acid bases which form well-defined, stable salts with both mineral and organic acids. Unlike the corresponding aliphatic primary hydrazines they do not form salts containing two equivalents of a mono-basic acid. The secondary aromatic hydrazines are also mono-acid bases but their salts are partially decomposed by water. The primary aromatic hydrazines, for example phenylhydrazine, react with metallic sodium forming a sodium compound from which alkyl derivatives can be prepared by the action of alkyl iodides—

$$C_6H_5\cdot NNa\cdot NH_2+RI=C_6H_5\cdot NR\cdot NH_2+NaI$$

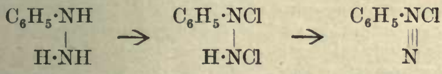
(*cp.* Michaelis, Ber. 1886, 19, 2448; 1887, 20, 43; also Annalen, 1889, 252, 267). The pure sodium compound can be prepared by acting on sodamide with a dilute benzene solution of phenylhydrazine (Titherley, Chem. Soc. Trans. 1897, 71, 461)—

$$NaNH_2+C_6H_5\cdot NH\cdot NH_2=C_6H_5\cdot NNa\cdot NH_2+NH_3$$

The corresponding potassium salt may be obtained as large colourless rhombic crystals when phenylhydrazine is treated with a saturated alcoholic solution of potassium hydroxide in the absence of air (Chattaway, Chem. Soc. Trans. 1907, 91, 1326).

The primary hydrazines are readily affected by oxidising agents and are consequently strong reducing agents. Phenylhydrazine reduces Fehling's solution in the cold, even in very dilute solution, a reaction which distinguishes this compound from the secondary base, diphenylhydrazine, which reduces Fehling's solution only on warming. (For the behaviour of phenylhydrazine on oxidation, *cp.* Fischer, Annalen, 1878, 190, 67; 1879, 199, 281; Fischer and Ehrhard, Annalen, 1879, 199, 333; Haller, Ber. 1885, 18, 90; Zincke, *ibid.* 1885, 18, 786; Strache, Monatsh. 1891, 12, 523; 1892, 13, 316; Murster, Ber. 1887, 20, 2633.)

The original statement by Fischer that the oxidation of phenylhydrazine by mercuric oxide leads to a partial production of the diazonium salt has been modified by Chattaway (Chem. Soc. Trans. 1908, 93, 270), who finds that diazonium salts are not produced when the action is carried out in alkaline solution but only in the presence of a large excess of strong acid. Azoimides are formed when alkali is absent and the hydrazines are present in excess. The quantitative conversion of phenylhydrazine into benzenediazonium chloride may be effected by dissolving the hydrazine in glacial acetic acid, cooling the solution to about −15° by the addition of crushed ice and either by passing in a rapid stream of chlorine or (if the diazonium bromide is desired) adding the calculated quantity of bromine dissolved in acetic acid and similarly cooled by ice. The reaction evidently proceeds in accordance with the scheme



$$\begin{array}{c} C_6H_5\cdot NH \\ | \\ H\cdot NH \end{array} \rightarrow \begin{array}{c} C_6H_5\cdot NCl \\ | \\ H\cdot NCl \end{array} \rightarrow \begin{array}{c} C_6H_5\cdot NCl \\ ||| \\ N \end{array}$$

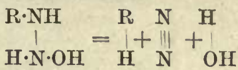
(Chattaway, Chem. Soc. Trans. 1908, 93, 853).

The mechanism of the reaction involved in the oxidation of phenylhydrazine either by oxygen or an oxidising agent, is explained in the following way (Chattaway, Trans. 1908, 93, 270):—

In the first instance, one of the hydrogen atoms of the hydrazino group is attacked and a hydroxyhydrazine is produced

$$RNH\cdot NH_2+O=RNH\cdot NH(OH).$$

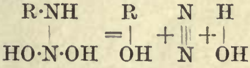
This substance, however, not being stable in the presence of alkali, undergoes disruption in accordance with the scheme



$$\begin{array}{c} R\cdot NH \\ | \\ H\cdot N\cdot OH \end{array} = \begin{array}{c} R \\ | \\ H \end{array} + \begin{array}{c} N \\ ||| \\ N \end{array} + \begin{array}{c} H \\ | \\ OH \end{array}$$

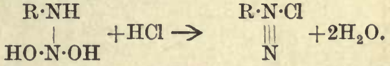
the splitting off of the hydrocarbon and water occurring in either one or two stages.

If, however, a very energetic oxidising agent is used, a certain number of molecules may, before breaking down, undergo a further oxidation thus:—



$$\begin{array}{c} R\cdot NH \\ | \\ HO\cdot N\cdot OH \end{array} = \begin{array}{c} R \\ | \\ OH \end{array} + \begin{array}{c} N \\ ||| \\ N \end{array} + \begin{array}{c} H \\ | \\ OH \end{array}$$

yielding a phenol and free nitrogen. In the absence of alkali, which acts as a catalytic agent and much accelerates the decomposition of these hydroxyhydrazines, the introduction of the second hydroxyl group takes place to a much greater extent and in the presence of strong acid and at a low temperature a diazonium salt is formed thus—



$$\begin{array}{c} R\cdot NH \\ | \\ HO\cdot N\cdot OH \end{array} +HCl \rightarrow \begin{array}{c} R\cdot N\cdot Cl \\ ||| \\ N \end{array} +2H_2O.$$

The oxidation of phenylhydrazine by basic metallic oxides leads to the formation of the free metal. The following process is recommended for producing a film of metallic copper on glass vessels (Chattaway, Chem. Soc. Trans. 1908, 93, 275; *see* also Proc. Roy. Soc. 1908, A, 80, 88). One part of freshly distilled phenylhydrazine and 2 parts of water are heated until a clear solution is obtained, when it is mixed with about half its bulk of a warm saturated solution of cupric hydroxide in strong ammonia. Nitrogen is freely evolved during the addition, and the cupric hydroxide is reduced to cuprous hydroxide, which remains dissolved in the ammoniacal liquid and does not undergo any immediate further reduction. A hot 10 p.c. solution of potassium hydroxide is then added until a slight permanent precipitate of cuprous hydroxide is produced and the clear liquid is then cautiously heated in contact with a perfectly clean glass surface. Metallic copper is deposited on it in the form of a thin reflecting coherent lamina. To obtain a film of sufficient thickness, it is best not to pour off the warm reducing fluid but to allow it to remain in contact with the glass until cold. When the liquid is poured off, the film of copper should be well washed with water and afterwards with alcohol and ether. It should then be protected by one or two coats of quickly drying varnish.

When phenylhydrazine is oxidised with copper sulphate or ferric chloride, the parent hydrocarbon is formed and the whole of the nitrogen is eliminated in the free state (Haller, Ber. 1885, 18, 90; Zincke, *ibid.* 786)—

$$C_6H_5\cdot NH\cdot NH_2+CuSO_4+H_2O$$
$$=C_6H_6+Cu_2O+N_2+2H_2SO_4.$$

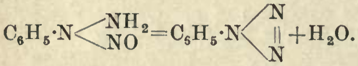
This reaction can be used as a means of estimating phenylhydrazine by measuring the amount of nitrogen evolved (Gallinek and V. v. Richter, Ber. 1885, 18, 3177; Strache, Monatsh.

1891, 12, 524; Strache and Kitt, *ibid.* 1892, 13, 316). (For other methods of estimating hydrazines, *cp.* Denigès, Ann. Chim. Phys. 1895, [vii.] 6, 381; Causse, Compt. rend. 1897, 125, 712, and Forster, Chem. Soc. Trans. 1898, 74, 792.)

Phenylhydrazine also reacts with hydrogen peroxide, yielding benzene together with some diazobenzeneimide; it moreover acts as a strong reducing agent towards nitro compounds, reducing them to the corresponding amino derivatives (Barr, Ber. 1887, 20, 1498). (For the reduction of nitro compounds, *cp.* also Walter, J. pr. Chem. 1896, [ii.] 53, 433. Reduction of 1:5-dinitroanthraquinone, Schmidt and Gattermann, Ber. 1896, 29, 2941. Reduction of nitro derivatives of phenanthraquinone, Schmidt and Kampf, Ber. 1902, 35, 3124. Reduction of hydroxyazo compounds, Oddo and Puxeddo, Ber. 1905, 38, 2752. Reduction of 5-nitrosalicylic acid, Puxeddo, Gazz. chim. ital. 1906, 36, ii. 87.) The hydrazines resist the action of reducing agents but pass on protracted treatment with zinc dust and hydrochloric acid into aniline and ammonia (E. Fischer, Annalen, 1887, 239, 248)

$$C_6H_5{\cdot}NH{\cdot}NH_2+2H=C_6H_5{\cdot}NH_2+NH_3.$$

Primary hydrazines yield with nascent nitrous acid in ice cold solution unstable nitroso derivatives which pass into diazo-imides and water, when warmed with alkali—



$$C_6H_5{\cdot}N\left<\begin{matrix}NH_2\\NO\end{matrix}\right.=C_6H_5{\cdot}N\left<\begin{matrix}N\\ \|\\ N\end{matrix}\right.+H_2O.$$

The diazoimide is formed directly if the above reaction is carried out at a higher temperature (E. Fischer, Annalen, 1877, 190, 89, 158, 181). Phenylhydrazine yields *iso*diazobenzene salts with amyl nitrite in the presence of sodium or potassium ethoxide (Stolle, Ber. 1908, 41, 2811). The primary aliphatic hydrazines are hygroscopic liquids readily soluble in water and which possess a smell resembling that of ammonia. The aromatic primary hydrazines are usually solids at the ordinary temperature. They possess a faint aromatic smell and are only sparingly soluble in water.

Phenylhydrazine $C_6H_5{\cdot}NH{\cdot}NH_2$ when freshly distilled is a practically colourless, highly refracting oil which distils under diminished pressure without decomposition, or at 240°–241° (780 mm.) with slight evolution of ammonia. When cooled it sets to a mass of tabular monoclinic crystals which melt at 17·5°. According to E. Fischer (Ber. 1908, 41, 73), the melting point of phenylhydrazine is 19·6°, after the substance has been purified first by fractional distillation at 15–20 mm., then by solidification and removal of the liquid portion, an operation repeated four times, then by recrystallisation from anhydrous ether, and finally by distillation under a pressure of 0·5 mm. For ordinary purposes it is sufficient to crystallise the base once or twice from its own volume of pure ether and then distil under a pressure of 10–20 mm. The base should be coloured pale yellow and should dissolve in 10 times its volume of a mixture of 50 p.c. acetic acid (1 part) and water (9 parts). Phenylhydrazine is rather less volatile with steam than aniline and rapidly becomes brown when exposed to the air. It has a sp.gr. of 1·097 at 23°. The base is sparingly soluble in water but forms a hydrate of the formula $2(C_6H_5{\cdot}NH{\cdot}NH_2),H_2O$ which melts at 24·1°. It is almost insoluble in concentrated aqueous caustic alkali, but is very readily soluble in certain alkaline salts, such as the alkali salts of the sulphinic and sulphonic acids, soaps, &c. (Otto, Ber. 1894, 27, 2131). For some time it has been prepared on the large scale from diazotised aniline by the sulphite method, and is used commercially for the production of antipyrine, &c., and in the form of its sulphonic acid for the production of the so-called tartrazine colouring matters. Phenylhydrazine is a valuable reagent in organic chemistry, owing to the ease with which it forms crystalline compounds with substances containing carbonyl oxygen. These compounds, which belong to the class of the hydrazones and osazones, are dealt with elsewhere (*see* HYDRAZONES).

When taken internally phenylhydrazine acts as a violent poison, and when brought in contact with the skin causes painful inflammation. Chemists who work much with this substance usually suffer from ill health, of which the most prominent feature is a kind of eczema. It seems to form a definite green compound with the blood to which the name *hæmoverdin* has been given (*cp.* Lewin, Compt. rend. 1901, 133, 599; Zeit. Biol. 1901, 42, 107).

Of the salts of phenylhydrazine, the *hydrochloride* $C_6H_5{\cdot}NH{\cdot}NH_2,HCl$ is the most important. It crystallises as colourless glistening leaflets which dissolve readily in hot water but separate from the solution on cooling. It can be recrystallised from alcohol and by careful heating can be sublimed unchanged. Other aromatic hydrazines of importance are—

Diphenylhydrazine $(C_6H_5)_2N{\cdot}NH_2$. This compound is produced by the reduction of nitrosodiphenylamine $(C_6H_5)_2N{\cdot}NO$, which is obtained from diphenylamine $(C_6H_5)_2NH$ by the action of nitrous acid (E. Fischer, Annalen, 1877, 190, 174; Stahel, *ibid.* 1890, 258, 242; Overton, Ber. 1893, 26, 19). It forms colourless plates which melt at 34·5° and is partially decomposed on distillation under diminished pressure. The hydrazine yields well-defined crystalline compounds with sugars and can be used for the quantitative estimation of arabinose (Neuberg and Wohlgemuth, Ber. 1894, 27, 3106).

Methylphenylhydrazine $C_6H_5(CH_3)N{\cdot}NH_2$ may be prepared either by the reduction of the nitroso compound $C_6H_5(CH_3)N{\cdot}NO$ (E. Fischer, Annalen, 1877, 190, 150), or by the alkylation of sodium phenylhydrazine by means of methyl iodide (A. Michaelis, Ber. 1886, 19, 2450; Phillips, *ibid.* 1887, 20, 2485). It is a colourless liquid, boiling with slight decomposition and evolution of ammonia at 227° (745 mm.); under a pressure of 75 mm. it boils without decomposition at 131°. Methylphenylhydrazine is a valuable reagent for the isolation of certain ketones (Neuberg, Ber. 1902, 35, 959).

Phenylbenzylhydrazine

$$C_6H_5(CH_2{\cdot}C_6H_5)N{\cdot}NH_2$$

(Ofner, Monatsh. 1904, 25, 593) is prepared by the direct action of benzyl chloride on phenylhydrazine and is a colourless liquid boiling at 216°–218° at 38 mm. It is a useful reagent for the isolation of the sugars, as the hydrazones formed from it are less soluble and more easily produced than those from simpler hydrazines (*cp.* Ruff and Ollendorf, Ber. 1899, 32, 3255; Lobry de Bruyn, Rec. trav. chim. 15, 97, 227).

p-**Bromophenylhydrazine** $H_2N{\cdot}NH{\cdot}C_6H_4Br$ may be prepared by brominating phenylhydrazine hydrochloride in the presence of a large excess of strong hydrochloric acid (Neufeld, Annalen, 1888, 248, 94; L. Michaelis, Ber. 1893, 26, 2191). It crystallises from hot water as long needles which melt at 107° and is a useful reagent for the characterisation of sugars. It has been used for the preparation of hydrazones from certain naturally occurring ketones, as for example camphor (Tiemann and Kruger, Ber. 1895, 28, 1756; Tiemann, *ibid.* 2191).

Phenylhydrazine-*p*-sulphonic acid

$C_6H_4(SO_3H)NH{\cdot}NH_2$

is of historical interest as being the first derivative of hydrazine to be prepared, and was obtained from diazotised *p*-amidobenzenesulphonic acid by reduction with sodium hydrogen sulphite (Strecker and Römer, Ber. 1871, 4, 784; Römer, Zeitsch. Chem. 1871, 482). It may be prepared by the direct sulphonation of phenylhydrazine and when pure crystallises as glistening needles containing ½ a molecule of water of crystallisation. It is prepared on the large scale from *p*-sulphanilic acid by diazotisation and reduction with sodium sulphite, and is used for the production of the tartrazine colouring matters (*q.v.*).

p-**Nitrophenylhydrazine** $C_6H_4(NO_2)NH{\cdot}NH_2$. This substance is recommended by Bamberger (Ber. 1899, 32, 1806) for the investigation of aldehydes and ketones as being more stable than *p*-bromophenylhydrazine. It is prepared from the sodium salt of *p*-nitrophenylhydrazinesulphonic acid by the action of concentrated hydrochloric acid (Purgotti, Ber. 1892, 25, 119; Bamberger and Sternitzki, *ibid.* 26, 1306), and also by boiling the potassium salt of *p*-nitrophenylhydrazinedisulphonic acid with dilute hydrochloric acid (Hantzsch and Borghaus, Ber. 1897, 30, 91). It may also be prepared from *p*-nitraniline by diazotisation and reduction. The base forms orange red leaflets and needles from hot alcohol, which melt with decomposition at 157°. (For the use of this base in the preparation of hydrazones of the aldehydes and ketones, *cp.* Bamberger, Ber. 1899, 32, 1806; Hyde, *ibid.* 1810.)

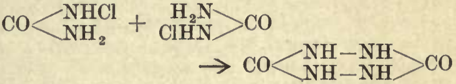
The naphthylhydrazines. Both the α- and β-naphthylhydrazines can be used for the preparation of hydrazones from compounds containing carbonyl oxygen, but the β- compound is especially recommended by Hilger and Rothenfusser (Ber. 1902, 35, 2627) for the isolation of numerous sugars. The two bases are prepared in a similar manner from the corresponding diazonaphthalenes on reduction with stannous chloride, or by heating the naphthol with hydrazine hydrate at 160° (Hoffmann, Ber. 1898, 31, 2909). α-Naphthylhydrazine forms leaflets from water which melt at 116°–117° and boil almost without decomposition at 203° (20 mm.) (Knorr, Ber. 1884, 17, 551). β-Naphthylhydrazine forms glistening leaflets from water which melt at 124°–125° (*cp.* also Franzen, Ber. 1905, 38, 266).

HYDRAZINE AND SOME OF ITS DERIVATIVES USED AS REAGENTS FOR THE ISOLATION OF ALDEHYDES AND KETONES.

Hydrazine $H_2N{\cdot}NH_2$. This substance was first prepared by Curtius by the action of hot dilute acids on triazoacetic acid (Ber. 1887, 20, 1632). It has since been obtained by other methods of which the more important are (1) from aminoguanidine $H_2N{\cdot}C(NH)NH{\cdot}NH_2$ on treatment with caustic alkali (Thiele, Annalen, 270, 1). (2) From sodium hypochlorite and ammonia (Raschig, D. R. PP. 192783, 198307; Chem. Zentr. 1908, i. 427, 1957). (3) From dichlorocarbamide (Chattaway, Chem. Soc. Trans. 1909, 95, 237). The last-named preparation is carried out in the following way:—

Dichlorocarbamide $NHCl{\cdot}CO{\cdot}NHCl$ (Chattaway, Chem. Soc. Trans. 1909, 95, 465). Six grams of carbamide are dissolved in 50 c.c. of distilled water and 10 grams of finely divided zinc oxide are added. The mixture is cooled to about −5° in a freezing mixture and a rapid stream of chlorine passed through the liquid. If the operation is carried out in a small flask, and this is well shaken in the freezing mixture during the passage of the gas, the temperature does not rise above zero. The zinc oxide quickly dissolves and a clear liquid results, from which in a short time crystals of dichlorocarbamide begin to separate. When the liquid has become a thick pulp from the separated solid and crystals no longer appear to separate, the dichlorocarbamide is rapidly collected at the pump, washed twice with 5 c.c. of ice-cold distilled water and then several times with chloroform. The yield is 77·5 p.c. of the theory.

p-**Urazine.** This substance is formed by the elimination of hydrogen chloride from two molecules of monochlorocarbamide, which may be regarded as the initial product formed by the action of ammonia on dichlorocarbamide—



$$CO{<}\begin{matrix}NHCl\\NH_2\end{matrix} + \begin{matrix}H_2N\\ClHN\end{matrix}{>}CO \rightarrow CO{<}\begin{matrix}NH-NH\\NH-NH\end{matrix}{>}CO$$

p-Urazine.

the condensation is therefore effected by the action of ammonia (Chattaway, Chem. Soc. Trans. 1909, 95, 237). Crude dichlorocarbamide free from all adhering mother-liquor is dissolved in from 10 to 20 times its weight of water and rapidly added to excess of strong ammonia, the mixture being thoroughly stirred. A vigorous evolution of nitrogen takes place and a white crystalline powder separates; a little more crystallises out on keeping and a still further small quantity on evaporating the mother-liquor after neutralising with hydrochloric acid.

Hydrazine sulphate. When *p*-urazine is mixed with about 5 times its weight of concentrated sulphuric acid and warmed to about 80°, it dissolves apparently without change; on heating the solution to about 95°–100°, hydrolysis slowly takes place with evolution of carbon dioxide. On raising the temperature still higher, the rate of evolution of carbon dioxide increases, until, at about 120°–130°, it is very rapidly liberated; at this temperature, hydrolysis is soon complete and a clear colourless liquid is obtained which deposits crystals of hydrazine sulphate on cooling. It is best, however, to add to the cooled liquor its own bulk of water, when pure hydrazine sulphate at once separates as a white crystalline powder.

Free hydrazine has been prepared by Lobry de Bruyn (Ber. 1895, 27, 3085) by the action of sodium methoxide in methyl alcohol on hydrazine hydrochloride, and also by heating the hydrate N_2H_4,H_2O with barium oxide at 100°. It is a very stable liquid which boils without decomposition at 113·5° (761 mm.), and at 56° (71 mm.). It solidifies when cooled below 0°, and then melts at 1·4°. It has a sp.gr. of 1·003 at 23° (*cp.* Raschig, Ber. 1910, 43, 1927).

Hydrazine hydrate N_2H_4,H_2O is the form in which hydrazine is liberated from its salts by the action of aqueous alkalis. It is a strongly refracting, almost odourless liquid, which boils without decomposition at 118·5° (739·5 mm.) and solidifies when placed in a mixture of solid carbon dioxide and ether, but melts again below −40°. It is advisable when preparing this substance to employ a silver retort and to avoid the use of rubber connections, as the hydrate, when hot, attacks glass strongly and quickly destroys cork and rubber.

Semicarbazide $H_2N{\cdot}CO{\cdot}NH{\cdot}NH_2$. This substance was first used for the preparation of derivatives of ketones by Baeyer acting on the suggestion of Thiele (Ber. 1894, 27, 1918), the compound having been prepared earlier in the year by Thiele and Strange (Ber. 1894, 27, 31; Annalen, 1894, 283, 19), who obtained it by the action of potassium cyanate on hydrazine sulphate, and by Curtius and Heidenreich (Ber. 1894, 27, 56), who prepared it by the interaction of hydrazine hydrate and urea. Semicarbazide may be conveniently prepared in the following way: 225 grams of nitrourea in 1700 c.c. of concentrated hydrochloric acid are mixed at 0° with excess of zinc dust and are then left for a short time after all action has subsided. The filtered solution, after being saturated with sodium chloride, is treated with 200 grams of sodium acetate and 100 grams of acetone. The acetonesemicarbazone zinc chloride, which separates after some time, is washed with salt solution and decomposed by strong ammonia (350 c.c. to 200 grams of the compound) (Thiele and Heuser, Annalen, 1895, 288, 312).

Semicarbazide crystallises from absolute alcohol as prisms which melt at 96°. It readily reacts with substances containing carbonyl oxygen, in accordance with the scheme

$$H_2N{\cdot}CO{\cdot}NH{\cdot}NH_2+OCR_2 \\ =H_2N{\cdot}CO{\cdot}NH{\cdot}N:CR_2+H_2O$$

forming semicarbazones which possesses the advantage of being readily decomposed into their components on treatment with dilute acids. The method recommended by Baeyer (Ber. 1894, 27, 1918) for the preparation of a carbazone is as follows:—

Semicarbazide hydrochloride is dissolved in a little water and the requisite amount of alcoholic potassium acetate together with the ketone are added, as well as sufficient alcohol and water to effect complete solution. The length of time required for the reaction depends on the nature of the ketone and varies from a few minutes to 4–5 days; it is finished when the addition of water precipitates a crystalline solid. Semicarbazide is usually met with in the form of its hydrochloride. The free base slowly alters on keeping.

Thiosemicarbazide $NH_2{\cdot}CS{\cdot}NH{\cdot}NH_2$. This substance, like semicarbazide, reacts with compounds containing carbonyl oxygen in accordance with the equation—

$$H_2N{\cdot}CS{\cdot}NH{\cdot}NH_2+OCR_2 \\ =H_2N{\cdot}CS{\cdot}NH{\cdot}N:CR_2+H_2O$$

forming thiosemicarbazones, which possess the property of forming insoluble salts with the heavy metals from which the ketone or aldehyde can be readily regenerated (Neuberg and Neimann, Ber. 1902, 2049).

The base can be prepared from hydrazine sulphate in the following manner (Freund and Schander, Ber. 1896, 29, 2501; Freund and Imgart, *ibid.* 1895, 28, 948). 50 grams of hydrazine sulphate and 27 grams of anhydrous potassium carbonate are dissolved in 200 c.c. of water and mixed with 40 grams potassium thiocyanate. The mixture is boiled for some minutes and is then treated with 200–300 c.c. of hot alcohol and filtered. The filtrate is freed from alcohol by vigorously boiling and, when cooled, deposits long needles of the base which melt at 181°.

Semioxamazide $H_2N{\cdot}CO{\cdot}CO{\cdot}NH{\cdot}NH_2$ (Kerp and Unger, Ber. 1897, 30, 586). This substance may be prepared by gently heating oxamethane with an alcoholic solution of hydrazine for a short time on the water bath. It crystallises in slender lustrous leaflets which melt and decompose at 220–221°. Semioxamazones are produced in quantitative yield from aldehydes, but the ketones react in a less general manner and seem to require special conditions for their formation.

Aminoguanidine $H_2N{\cdot}C(NH)NH{\cdot}NH_2$ is prepared from nitroguanidine on reduction (Thiele, Annalen, 270, 23; D. R. P. 59241; Frdl. iii. 16), and from cyanamide, hydrazine hydrochloride and alcohol (Pellizari and Cuneo, Gazz. chim. ital. 1894, 24, 453). The hydrochloride forms long prisms from dilute alcohol which melt at 163°.

The base is recommended by Baeyer (Ber. 1894, 27, 1919) for the preparation of derivatives of ketones, the following method being used.

Aminoguanidine hydrochloride is dissolved in a little water containing a trace of hydrochloric acid and is then mixed with the ketone together with sufficient alcohol to effect solution. The reaction is finished after warming for a short time on the water bath, when water and caustic potash solution are added and the base is extracted by ether. The oil which remains after evaporating the ether is suspended in hot water and heated with an aqueous solution of picric acid. The picrate separates as a crystalline precipitate which is recrystallised either from dilute or absolute alcohol, according to its solubility.

J. F. T.

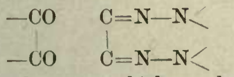
HYDRAZONES. Substances containing the complex $>N{\cdot}NH_2$ react with those compounds which have in their molecule an oxygen atom doubly bound to carbon, forming condensation products in accordance with the general equation

$$>C:O+H_2N{\cdot}N< \;\rightarrow\; >C:N{\cdot}N<+H_2O.$$

Such condensation products are termed hydrazones. Only the carbonyl compounds which belong to the groups of the aldehydes and ketones react, however, in this manner; the carboxylic acids containing the group COOH do not react as if they contained carbonyl oxygen, but give hydrazides in accordance with the scheme

$$R{\cdot}COOH+H_2N{\cdot}N{<}\longrightarrow R{\cdot}CO{\cdot}NH{\cdot}N{<}+H_2O.$$

One or more carbonyl-groups present in the compound may enter into combination with the hydrazine residue, forming—for example, in the case of the dicarbonyl derivatives—dihydrazones, thus:



$$\begin{array}{ll}-CO & C=N-N{<}\\ & |\\ -CO & C=N-N{<}\end{array}$$

Those dihydrazones, which are derived from dicarbonyl compounds having the two carbonyl-groups on contiguous carbon atoms, are termed osazones. Thus in the case of the two compounds formed from glyoxal CHO·CHO and phenylhydrazine

$$\begin{array}{l}CHO\\ |\\ CH:N{\cdot}NHC_6H_5\end{array}$$ is glyoxalphenylhydrazone;

$$\begin{array}{l}CH:N{\cdot}NHC_6H_5\\ |\\ CH:N{\cdot}NHC_6H_5\end{array}$$ is glyoxalphenylosazone

(Fischer, Ber. 1888, 21, 985).

Phenylhydrazine $C_6H_5{\cdot}NH{\cdot}NH_2$ was the first member of the class of the hydrazines to be applied to the characterisation and isolation of the carbonyl compounds (comp. E. Fischer, Ber. 1884, 17, 572), but since that time the reaction has been shown to be a general one for all derivatives of hydrazine having a primary amino group intact.

Hydrazine $H_2N{\cdot}NH_2$ itself reacts with aldehydes and ketones, as Curtius has shown, forming either hydrazones of the type

$$R{\cdot}CH:N{\cdot}NH_2$$

(or $RRC:N{\cdot}NH_2$), in which one molecule of the carbonyl compound reacts, or azines of the formula $R{\cdot}CH:N{\cdot}N:CHR$) or

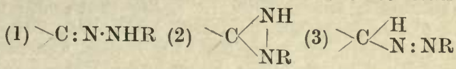
$$RRC:N{\cdot}N{\cdot}CRR)$$

in which two molecules of the carbonyl derivative take part. The azines from the aldehydes are known as aldazines, those from the ketones as ketazines. In the aliphatic series, the aldehydes pass directly into the aldazines when treated with hydrazine, whilst the hydrazones, $RRC:N{\cdot}NH_2$, which can be isolated from the product of the interaction of ketones and hydrazine, readily pass into the ketazine and hydrazine in accordance with the equation

$$2(R_2C:N{\cdot}NH_2)\longrightarrow R_2C:N{\cdot}N{\cdot}R_2+H_2N{\cdot}NH_2.$$

It is apparent that azine formation in the manner described above cannot occur with the substituted derivatives of hydrazine of the general formulæ $RNH{\cdot}NH_2$ and $R_2N{\cdot}NH_2$, and it is therefore compounds of this type which are of such great importance as reagents for the preparation of the hydrazones, osazones, and semicarbazones.

Constitution of the hydrazones. The constitution of the hydrazones formed from carbonyl compounds by the action of secondary asymmetric hydrazines $R_2N{\cdot}NH_2$, admits of only one formula, namely, $R_2N{\cdot}N:CR_2$; but the hydrazones formed from the primary hydrazines may conceivably be constituted in accordance with one or other of the three forms



$$(1)\ {>}C:N{\cdot}NHR\quad (2)\ {>}C{<}\begin{array}{l}NH\\ \,|\\ NR\end{array}\quad (3)\ {>}C{<}\begin{array}{l}H\\ N:NR\end{array}$$

Of these, formula (2) may be discarded, because the same compound is formed by the interaction of benzaldehyde and phenylethylhydrazine

$$C_6H_5{\cdot}CHO+H_2N{\cdot}N(C_2H_5)C_6H_5 =C_6H_5{\cdot}CH:N{\cdot}N(C_2H_5)C_6H_5$$

as by the ethylation, by means of sodium ethoxide and ethyl iodide, of the hydrazone formed by the condensation of benzaldehyde and phenylhydrazine

$$C_6H_5{\cdot}CHO+H_2N{\cdot}NH{\cdot}C_6H_5 =C_6H_5{\cdot}CH:N{\cdot}NH{\cdot}C_6H_5$$

$$C_6H_5{\cdot}CH:N{\cdot}NH{\cdot}C_6H_5+NaO{\cdot}C_2H_5 =C_6H_5{\cdot}CH:N{\cdot}NNa{\cdot}C_6H_5+HO{\cdot}C_2H_5$$

$$C_6H_5{\cdot}CH:N{\cdot}NNa{\cdot}C_6H_5+C_2H_5I = C_6H_5{\cdot}CH:N{\cdot}N(C_2H_5)C_6H_5+NaI.$$

The azo formula (3) would appear, at first sight, to be untenable, because the hydrazone prepared from phenylhydrazine and acetaldehyde is different from ethaneazobenzene

$$CH_3{\cdot}CH_2{\cdot}N:N{\cdot}C_6H_5$$

which is prepared by the oxidation of ethanehydrazobenzene. It has been shown, however, that there is an intimate connection between these two substances, and that the change

$$C_6H_5{\cdot}N:N{\cdot}C_2H_5\longrightarrow C_6H_5{\cdot}NH{\cdot}N:CHCH_3$$

is readily effected by mineral acids (Fischer, Annalen, 1879, 199, 328; Ber. 1896, 29, 703), or by sodium ethoxide (Bamberger, Ber. 1903, 36, 56); whereas the reverse change

$$C_6H_5{\cdot}NH{\cdot}N:CHCH_3\longrightarrow C_6H_5{\cdot}N:N{\cdot}CH_2CH_3$$

is effected by the action of light (Chattaway, Chem. Soc. Trans. 1906, 89, 462). The question as to the azo or hydrazone structure of these compounds has given rise to a great deal of controversy, and is even at the present time not definitely settled. The discussion may be said to have arisen owing to the discovery made by Japp and Klingemann (Ber. 1887, 20, 3284, 3398), that the hydrazone of pyruvic acid

$$C_6H_5NH{\cdot}N:C(CH_3)CO_2H$$

was identical with benzene-α-azopropionic acid $C_6H_5N:N{\cdot}CH(CH_3)CO_2H$. R. Meyer (Ber. 1888, 21, 118) also showed that the dicarboxylic acid obtained by the hydrolysis of the ethyl salt which is formed by the interaction of benzenediazonium chloride and ethyl malonate, thus:

$$C_6H_5{\cdot}N_2Cl+CH_2(CO_2R)_2 =C_6H_5{\cdot}N:N{\cdot}CH(CO_2R)_2+HCl$$

$$C_6H_5{\cdot}N:N{\cdot}CH(CO_2R)_2+2H_2O =C_6H_5{\cdot}N:N{\cdot}CH(CO_2H)_2+2R{\cdot}OH$$

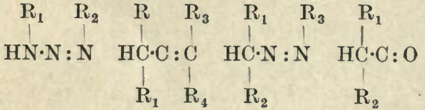
was identical with the compound prepared by the condensation of mesoxalic acid and phenylhydrazine, thus:

$$C_6H_5{\cdot}NH{\cdot}NH_2+CO(CO_2H)_2 =C_6H_5{\cdot}NH{\cdot}N:C(CO_2H)_2+H_2O.$$

That is to say, the question arose as to whether these compounds were true hydrazones having the structure $R{\cdot}NH{\cdot}N:C{<}$ or whether they were azo compounds having the structure $R{\cdot}N:N{\cdot}CH{<}$.

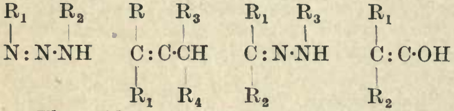
Since that time many other instances of the same kind as that recorded by these chemists have been investigated, and repeated attempts have been made to establish either one or other of these constitutional formulæ for the hydrazones (R. Meyer, Ber. 1891, 24, 1241; Japp and Klingemann, Annalen, 1888, 247, 190; V. Meyer, Ber. 1888, 21, 11; Haller, Compt. rend. 1888, 106, 1173; Beyer and Claisen, Ber. 1892, 25, 746; v. Pechmann, Ber. 1892, 25, 3190; Bamberger and Wheelwright, *ibid.* 1892, 25, 3201; Bamberger, *ibid.* 1894, 27, 2591).

Much of the evidence falls under the head of the constitution of the azo compounds, and the article under this heading should be consulted for further information; but it is evident that much still remains to be learnt regarding the conditions controlling the tendency of a hydrogen atom attached to the terminal atom of any system such as



$$\mathrm{H}\overset{R_1}{\mathrm{N}}\cdot\mathrm{N}:\overset{R_2}{\mathrm{N}}\qquad \mathrm{H}\underset{R_1}{\overset{R}{\mathrm{C}}}\cdot\mathrm{C}:\underset{R_4}{\overset{R_3}{\mathrm{C}}}\qquad \mathrm{H}\underset{R_2}{\overset{R_1}{\mathrm{C}}}\cdot\mathrm{N}:\overset{R_3}{\mathrm{N}}\qquad \mathrm{H}\underset{R_2}{\overset{R_1}{\mathrm{C}}}\cdot\mathrm{C}:\mathrm{O}$$

to pass to the other terminal atom with a consequent shifting of the double bond, thus:



$$\overset{R_1}{\mathrm{N}}:\overset{R_2}{\mathrm{N}}\cdot\mathrm{NH}\qquad \underset{R_1}{\overset{R}{\mathrm{C}}}:\mathrm{C}\cdot\underset{R_4}{\overset{R_3}{\mathrm{CH}}}\qquad \underset{R_2}{\overset{R_1}{\mathrm{C}}}:\mathrm{N}\cdot\overset{R_3}{\mathrm{NH}}\qquad \underset{R_2}{\overset{R_1}{\mathrm{C}}}:\mathrm{C}\cdot\mathrm{OH}$$

The evidence at present available seems to show that the hydrogen atom in compounds of this type may assume either one or other of these positions, in which case definite compounds are formed, having, as in the case under discussion, either the azo or hydrazone form: on the other hand, there may be tautomerism between the two forms, in which case the hydrogen atom acts as if it vibrated between the two terminal atoms of the system (*cf.* Bulow and Hopfner, Ber. 1901, 34, 71; Bulow and Hailer, *ibid.* 1902, 35, 915). There is, however, little doubt that in the majority of cases the compounds formed from benzenediazonium chloride and substances of the type of ethyl malonate as well as those produced by the action of phenylhydrazine on carbonyl compounds have the hydrazone structure.

The formation of phenylhydrazones. As a rule, phenylhydrazine readily reacts with ketones and aldehydes, yielding phenylhydrazones, which are crystalline and of definite melting-point. The following method generally gives the phenylhydrazone in a pure condition. Phenylhydrazine is dissolved in 50 p.c. aqueous acetic acid and diluted with three times its volume of water. The carbonyl compound diluted when necessary by a suitable solvent is then added and the whole is warmed. The phenylhydrazone then separates either in the crystalline condition or as an oil which usually crystallises when scratched with a glass rod.

Derivatives of phenylhydrazine, such as phenylhydrazine-*p*-sulphonic acid

$$C_6H_4(SO_3H)NH\cdot NH_2,$$

p-nitrophenylhydrazine $C_6H_4(NO_2)NH\cdot NH_2$ or *p*-bromophenylhydrazine

$$C_6H_4(Br)NH\cdot NH_2,$$

may be used for the production of hydrazones; moreover other hydrazines, such as β-naphthylhydrazine $C_{10}H_7\cdot NH\cdot NH_2$, methylphenylhydrazine $C_6H_5(CH_3)N\cdot NH_2$, *asym*-diphenylhydrazine $(C_6H_5)_2N\cdot NH_2$, and benzylphenylhydrazine $C_6H_5\cdot CH_2(C_6H_5)N\cdot NH_2$ are often used for this purpose (*cp.* HYDRAZINES).

Reaction of the hydrazones. When warmed with mineral acids, the hydrazones are more or less readily hydrolysed into the carbonyl compound and the hydrazine. This reaction proceeds, however, much more readily when the hydrazone is warmed with an aqueous solution of pyruvic acid, when the following reaction often occurs (Fischer and Ach, Annalen, 1889, 253, 57):—

$$R_2C:N\cdot NH\cdot C_6H_5+CH_3\cdot CO\cdot CO_2H$$
$$=R_2CO+CH_3\cdot C(:N\cdot NH\cdot C_6H_5)CO_2H.$$

The hydrazones of the aliphatic aldehydes and ketones form addition products with hydrocyanic acid, yielding nitriles in accordance with the equation

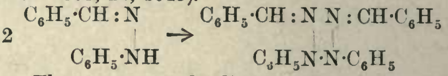
$$C_6H_5\cdot NH\cdot N:CR_2+HCN$$
$$=C_6H_5\cdot NH\cdot NH\cdot C(CN)\cdot R_2$$

(*cp.* V. Miller and Plöchl, Ber. 1892, 25, 2023).

Hydrazones when reduced break at the point of union of the two nitrogen atoms and pass into amines. This method has been made use of by Tafel (Ber. 1886, 19, 1924; 1889, 22, 1854) for the formation of primary amines from aldehydes and ketones. Thus the hydrazone of acetaldehyde yields in this manner a mixture of aniline and ethylamine

$$CH_3\cdot CH:N\cdot NH\cdot C_6H_5+4H$$
$$=CH_3\cdot CH_2NH_2+C_6H_5NH_2.$$

When oxidised by amyl nitrite, hydrazones are converted into hydrotetrazines (V. Pechmann, Ber. 1893, 26, 1045).

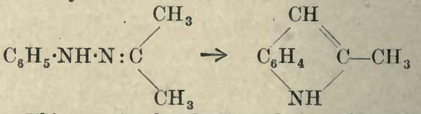


$$2\begin{array}{l}C_6H_5\cdot CH:N\\ \qquad\quad\ |\\ \quad C_6H_5\cdot NH\end{array}\rightarrow\begin{array}{c}C_6H_5\cdot CH:N\ \ N:CH\cdot C_6H_5\\ |\qquad |\\ C_6H_5N\cdot N\cdot C_6H_5\end{array}$$

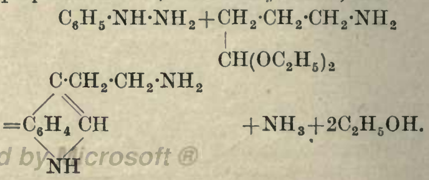
These compounds dissolve in concentrated sulphuric acid, forming intensely coloured solutions. It is probable that Bulow's reaction for hydrazides and hydrazones, which depends on the formation of a coloured solution, when the hydrazone, dissolved in concentrated sulphuric acid, is treated with a drop of ferric chloride solution, is due to the production of the hydrotetrazine.

The action of zinc chloride on hydrazones causes the elimination of ammonia and leads to the formation of derivatives of indole (E. Fischer and Hess, Ber. 1884, 17, 559; E. Fischer, *ibid.* 1886, 19, 1563; Annalen, 1886, 236, 116; Brunner, Monatsh. 1895, 16, 183, 849).

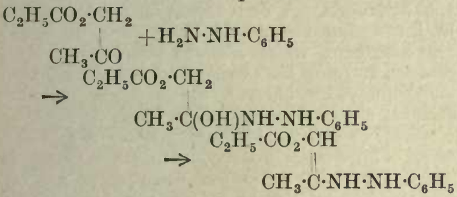
The reaction may be expressed by the following general equation but is difficult to follow by means of structural formulæ:—



This reaction has been made use of by Ewins (Chem. Soc. Trans. 1911, 99, 270) for the preparation of 3-β-aminoethylindole, thus—

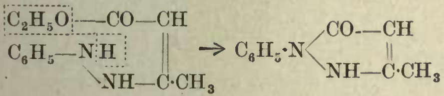


This compound was found to be identical with the base obtained by the action of putrefactive bacteria on tryptophan. It will be noticed that, owing to the unstable character of the aldehyde, it could not be used in the free state for the production of the hydrazone and that the acetal derivative was used in its place. Hydrazones which are formed from β-ketonic ethyl salts pass, when heated, into alcohol and a derivative of pyrazolone. Thus the phenylhydrazone of ethyl acetoacetate, which is a colourless crystalline substance and is therefore probably ethyl benzenehydrazocrotonate formed in accordance with the equation



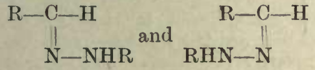
$$\begin{array}{l} C_2H_5CO_2\cdot CH_2 \\ \quad\; | \qquad\quad + H_2N\cdot NH\cdot C_6H_5 \\ CH_3\cdot CO \end{array} \rightarrow \begin{array}{l} C_2H_5CO_2\cdot CH_2 \\ \qquad\quad | \\ CH_3\cdot C(OH)NH\cdot NH\cdot C_6H_5 \end{array} \rightarrow \begin{array}{l} C_2H_5\cdot CO_2\cdot CH \\ \qquad\quad \| \\ CH_3\cdot C\cdot NH\cdot NH\cdot C_6H_5 \end{array}$$

passes when heated at 200° under diminished pressure into phenylmethylpyrazolone



In many cases the formation of the pyrazolone derivative takes place immediately without the intermediate formation of the hydrazone.

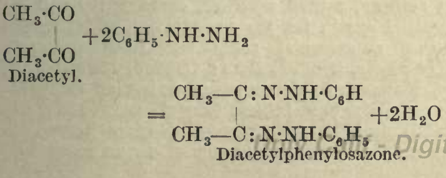
Stereoisomerism, in accordance with the Hantzsch-Werner hypothesis, has been observed among the hydrazones, and in certain instances the two forms



$$\begin{array}{c} R—C—H \\ | \\ N—NHR \end{array} \quad \text{and} \quad \begin{array}{c} R—C—H \\ \| \\ RHN—N \end{array}$$

have been isolated (*cp.* E. Fischer, Ber. 1884, 17, 575; Biltz, *ibid.* 1894, 2288; Hantzsch and Hornbostel, *ibid.* 1897, 30, 3003; Bamberger and Schmidt, *ibid.* 1901, 34, 2001).

As already mentioned, the name 'osazone' denotes a compound containing in its molecule two hydrazine residues, R—NH—N=, attached to two contiguous carbon atoms. E. Fischer (Ber. 1884, 17, 579) obtained from carbohydrates a series of characteristic compounds formed by the introduction of two phenylhydrazone groups into the molecule of a carbohydrate. The compound from dextrose was termed 'phenylglucosazone'; that from galactose 'phenylgalactosazone,' and so on. Later, when it was found that in these compounds the two phenylhydrazine residues were in contiguous positions, the name 'osazone' was applied to all compounds containing this particular grouping (E. Fischer, Ber. 1888, 21, 985). Osazones are formed by the action of two molecules of phenylhydrazine on α-dicarbonyl compounds, namely, such as contain the group CO·CO;



$$\begin{array}{l} CH_3\cdot CO \\ \quad | \qquad + 2C_6H_5\cdot NH\cdot NH_2 \\ CH_3\cdot CO \end{array} = \begin{array}{l} CH_3—C:N\cdot NH\cdot C_6H \\ \qquad | \\ CH_3—C:N\cdot NH\cdot C_6H_5 \end{array} + 2H_2O$$

Diacetyl. Diacetylphenylosazone.

The yellow colouring matters known as 'tartrazines' are derived from osazones, formed in this way from dihydroxytartaric acid.

Osazones are also formed by the action of phenylhydrazine on compounds containing the group —CH(OH)·CO—, thus on α-keto-alcohols and α-aldehydo-alcohols; and it is the members of the carbohydrate family belonging to these classes which yield osazones. In the cold, unless on long standing, only the carbonyl group reacts with phenylhydrazine, and a hydrazone containing the group

$$—CH(OH)C(N_2H\cdot C_6H_5)—$$

is formed; but this compound, on heating with excess of phenylhydrazine, is converted into an osazone, the alcohol group also taking part in the reaction. The molecule of hydrogen which is removed in this process reduces a molecule of phenylhydrazine to aniline and ammonia. Thus with dextrose—

$$CH_2OH[CHOH]_4CHO+3C_6H_5NH\cdot NH_2$$
$$\rightarrow CH_2OH[CHOH]_3C(N_2H\cdot C_6H_5)CH(N_2HC_6H_5)$$
Phenylglucosazone.
$$+NH_2C_6H_5+NH_3+2H_2O.$$

These osazones have proved of great use in identifying various sugars. Sometimes, however, two distinct sugars yield the same osazone: thus lævulose, like dextrose, gives phenylglucosazone:—

$$CH_2OH[CHOH]_3CO\cdot CH_2OH+3C_6H_5NH\cdot NH_2$$
Lævulose.
$$\rightarrow CH_2OH[CHOH]_3C(N_2H\cdot C_6H_5)CH(N_2H\cdot C_6H_5)$$
Phenylglucosazone.
$$+NH_2C_6H_5)+NH_3+2H_2O$$

the α-aldehyde alcohol and the α-keto alcohol-yielding the same osazone.

The osazones are crystalline compounds, of a yellow colour, and generally have a definite melting point, by means of which they may be identified. Concentrated sulphuric acid dissolves the various osazones, giving characteristic colourations, and the solution generally exhibits some particular colour change on standing (Japp and Klingemann, Ber. 1888, 21, 549). Fuming hydrochloric acid hydrolyses the osazones in the cold into phenylhydrazine and the α-dicarbonyl compound from which they are derived (E. Fischer, *ibid.* 1888, 21, 2631).

HYDROGEN. At.wt. 1·008. Symbol H. The existence of this gas was recognised in the 16th century; its combustible property was discovered in the following century by Turquet de Mayerne, and in 1700 Lemery observed the detonating property of a mixture of air and hydrogen.

Cavendish, in 1766, showed that when the gas was produced from dilute acid and one of the metals, iron, zinc, or tin, it was obtained in amount varying with the metal used.

Hydrogen was for a time confounded with other combustible gases, such as marsh-gas, carbon monoxide, and vapour of ether; all were supposed to contain the same inflammable principle, *phlogiston*, modified by variable amounts of other substances.

Macquer and De la Metherie first observed, in 1766, that water was produced by burning hydrogen, but it was then thought that other products than water were produced at the same time, and Lavoisier made many experiments with the object of detecting the presence of an acid which he imagined should be among the products of combustion, as was the case in the combustion of such bodies as sulphur, carbon, phosphorus, &c. Cavendish, however, in 1781, proved conclusively that water was the only product of combustion when hydrogen burns in air or oxygen, and that if a mixture of hydrogen and oxygen in the proportion of two volumes of the former to one of the latter were burnt, the whole of the gases were converted into water.

Sources. Hydrogen occurs free in nature in the gaseous mixtures evolved from certain volcanos (Bunsen, Ann. Chim. Phys. 1853, [iii.] 38, 215; Deville, Compt. rend. 1862, 55, 75). The gases evolved from Mte. Pelée in Martinique during the eruptions of 1902 contained 22·3 p.c. of hydrogen by volume (Moissan, Compt. rend. 1902, 135, 1085). It also occurs in the jets of steam, known as *fumerolles*, which occur in Tuscany and other places. The gases issuing from the salt beds of Stassfurt (Reichardt, Arch. Pharm. 1860, [ii.] 103, 347; Precht, Ber. 1880, 13, 2326), and Wieliczka (Rose, Pogg. Ann. 48, 353) contain hydrogen, and it also occurs in the gases given off by the oil-wells of Pennsylvania (Engler, Ber. 1888, 21, 1816). Hydrogen has been found occluded in certain meteorites (Graham, Proc. Roy. Soc. 1867, 15, 502; Mallet, *ibid.* 1872, 20, 365), and in a large number of minerals (Ramsay and Travers, Proc. Roy. Soc. 1897, 60, 442; Tilden, *ibid.* 1897, 60, 453). To a very slight extent, hydrogen occurs free in the atmosphere (Gautier, Ann. Chim. Phys. 1901, [vii.] 22, 5; Liveing and Dewar, *ibid.* 1901, 22, 482; Rayleigh, Phil. Mag. 1902, [vi.] 3, 416; Leduc, Compt. rend. 1902, 135, 860, 1332). According to Claude (Compt. rend. 1909, 148, 1454), there is less than 1 part of hydrogen in one million parts of air. Hydrogen is also produced in the decay of various organic bodies, being found in the intestinal gases of many animals (Tappeiner, Ber. 1881, 14, 2375).

Spectroscopic observations have shown that hydrogen completely surrounds the sun, forming an envelope which has received the name of the *chromosphere*. Hydrogen also occurs in certain stars and nebulæ.

In a state of combination, hydrogen forms one-ninth the weight of water and one-fourth the weight of marsh-gas. It also occurs in smaller quantities in combination with phosphorus, sulphur, iodine, bromine, carbon, and nitrogen. It is an essential constituent of all acids; most animal and vegetable substances contain it, and it is a constituent of many minerals. It exists in the air in small quantities in combination with nitrogen as ammonia; and in certain mineral and volcanic springs it is found in combination with sulphur and chlorine as sulphuretted hydrogen and hydrochloric acid respectively.

Preparation. (1) *Electrolysis of certain aqueous solutions.*—Pure hydrogen is readily prepared by the electrolysis of a mixture of 1 part of sulphuric acid and 10 parts of water, between platinum electrodes. The potential difference between the terminals must exceed 1·7 volts. The hydrogen is evolved at the cathode, and suitable provision must be made to prevent oxygen from the anode diffusing into the hydrogen. A convenient method consists in immersing the anode in a mass of liquid zinc-amalgam, which absorbs the oxygen completely, forming zinc oxide and eventually zinc sulphate. The current from three or four Bunsen elements is sufficient to work such an electrolytic cell for laboratory use. A suitable piece of apparatus is described in Amer. Chem. J. 1897, 19, 810. A 30 p.c. solution of sodium hydroxide may also be employed; plate nickel electrodes are most convenient, and a useful piece of apparatus for this purpose is described by Vèzes and Labatut (Zeitsch. anorg. Chem. 1902, 32, 464). Hydrogen prepared from sodium hydroxide solution always contains a little organic matter, owing to the presence of carbonate in solution (Morley); it can be obtained quite pure by electrolysing a solution of pure recrystallised baryta (Baker, Chem. Soc. Trans. 1902, 81, 400).

These electrolytic methods are employed on a commercial scale, dilute sulphuric acid being electrolysed between lead electrodes, or sodium hydroxide between iron electrodes. The chief difficulty encountered is that of preventing diffusion between the hydrogen and the oxygen simultaneously produced. The introduction of diaphragms increases the resistance of the cell, and is therefore to be avoided if possible. Various patterns of cell have been devised, and are described in J. Soc. Chem. Ind. 1900, 19, 1120; 1901, 20, 258; Eng. Pats. 2820, 1902, and 27249, 1903; Fr. Pats. 355652, 1905, and 397319, 1908; D. R. P. 198626, 1906.

(2) *Chemical decomposition of water.*—Hydrogen may be prepared by decomposing water; a large number of readily oxidisable substances can be employed for this purpose.

The alkali metals and the metals of the alkaline earths decompose water at ordinary temperatures, liberating hydrogen and producing the corresponding metallic hydroxide. The action is very violent, particularly with potassium, rubidium, and cæsium. The reactions can be readily controlled, however, by employing the amalgams of these metals. The action of steam on pure sodium has been used for the preparation of pure hydrogen (Scott, Phil. Trans. 1893, 184, 548; Mellor and Russell, Chem. Soc. Trans. 1902, 81, 1279), and the use of sodium, mixed with oil, aluminium, and infusorial earth, for the preparation of hydrogen on a commercial scale has been patented (U.S. Pats. 883531, 1908; 909536, 1909).

Magnesium decomposes water at temperatures above 70° (Ditte, Compt. rend. 1871, 73, 108), and burns vigorously when heated in steam. Magnesium amalgam decomposes cold water (Fleck and Basset, J. Amer. Chem. Soc. 1895, 17, 789).

Aluminium does not decompose water unless some means is afforded of removing the oxide from the surface of the metal. This is easily effected by amalgamating it with $\frac{1}{15}$ its weight of mercury, when the amalgam produced readily decomposes water and can be employed as a source of pure hydrogen (Baille and Féry, Ann. Chim. Phys. 1889, [vi.] 17, 248; Wislicenus and Kauffmann, Ber. 1895, 28, 1323). Hydrogen is readily obtained pure by slowly adding water to a mixture of fine aluminium filings containing 1 to 2 p.c. of mercuric chloride and 0·5 p.c. of potassium cyanide, keeping the temperature at 70° (Mauricheau-Beaupré, Compt. rend. 1908, 147, 310; Fr. Pat. 392725, 1908). One kilo. of this mixture yields 1300 litres of hydrogen.

At a red heat, water vapour is easily decomposed by iron, hydrogen and triferric tetroxide being produced (Lavoisier, Œuvres, 2, 360). This method is employed on a large scale and has been the subject of numerous patents (Eng. Pats. 7518, 1887; 20752, 1890; 4134, 1891; 28721, 1896; 10356, 1903; 21479, 1908; Fr. Pats. 373271, 1907; 386991, 1908; 395132, 1908; U.S. Pat. 971206, 1908; D. R. P. 226453, 1909). The oxide produced is reduced to metal by heating with coal or by some other process, and used again.

Steam is readily decomposed by passing it over red-hot coke, when a mixture consisting essentially of carbon monoxide and hydrogen in approximtaely equal volumes, is produced, known as *water-gas* (*v.* GAS, WATER). Numerous methods have been proposed for the purpose of preparing hydrogen commercially from this mixture. In one process (Frank, Fr. Pat. 371814, 1906), the dried mixture is passed over calcium carbide at a temperature above 300°; carbon monoxide and dioxide are removed as calcium oxide, calcium carbonate, and carbon, while the nitrogen present is converted into calcium cyanamide. The oxides of carbon may be partially removed by a preliminary cooling process, whereby the monoxide is liquefied and the dioxide solidified. Jouve and Gautier (Fr. Pat. 372045, 1906) propose to pass the gas through a porous partition in order to separate the hydrogen by reason of its rapid power of diffusion. It is said that by one such operation the percentage of carbon monoxide may be reduced from 45 to 8 p.c. In other processes, the carbon monoxide is removed by chemical means; for this purpose it is decomposed by heating to bright redness with excess of steam, when the monoxide is replaced by an equal volume of hydrogen, carbon dioxide being produced, which may be removed by solution in water or by absorbing it in milk of lime (Henry and Hembert, Compt. rend. 1885, 101, 797; D. R. P. 224862, 1907).

The oxidation of carbon monoxide by steam with the liberation of hydrogen can be effected at 400°–500° in the presence of reduced iron or nickel (Fr. Pats. 355324, 1905; 375164, 1906; *cf.* Mond and Langer, Eng. Pat. 12608, 1888, and Fr. Pat. 361429, 1905).

Hydrogen free from compounds of carbon and oxygen, can be prepared by heating coke, impregnated with 10 p.c. potassium carbonate and mixed with five times its weight of burnt lime, in a current of steam at 550°–750° (Eng. Pat. 8734, 1910).

The decomposition of steam may also be effected by passing it over red-hot barium sulphide, which becomes oxidised to sulphate, with the simultaneous formation of hydrogen (Fr. Pat. 361866, 1905). The sulphate is reduced with coal or producer gas to sulphide, and used again.

(3) *Action of metals on acids.*—The commonest method of preparing hydrogen for laboratory purposes consists in acting upon granulated zinc with either dilute hydrochloric acid (1 of acid to 2 of water), or sulphuric acid (1 of acid to 8 of water), when hydrogen is evolved and zinc chloride or sulphate left in solution. Very pure hydrogen is obtained from pure zinc and pure diluted acid, but the action is extremely slow. A regular stream of the gas may be obtained, however, by adding a little platinic chloride solution. Platinum is deposited over the surface of the zinc, and the liberated hydrogen escapes freely from the surface of the platinum, leaving the zinc surface free from bubbles of gas (Gourdon, Compt. rend. 1873, 76, 1250). A similar effect is produced by adding a small quantity of a salt of copper, silver, gold, tin, antimony, bismuth, nickel, or cobalt.

Other metals, *e.g.* aluminium, magnesium, and iron, may be used instead of zinc for generating hydrogen from acids. Pure hydrogen is readily prepared by acting upon aluminium with mercuric chloride solution slightly acidified with hydrochloric acid (Bodenstein, Zeitsch. physikal. Chem. 1897, 22, 3). The use of zinc, and more particularly of iron and sulphuric acid upon a commercial scale is very common (*v.* Eng. Pats. 15509, 1897; 16277, 1896; 17515, 1898; 25084, 1897).

(4) *Action of metals and non-metals on alkalis.*—The metals, zinc, aluminium, and tin, readily dissolve in warm concentrated alkali hydroxide solutions, liberating hydrogen and forming alkali zincate, aluminate, and stannate respectively. Very pure hydrogen is thus produced from aluminium free from carbon. The non-metallic element, silicon, similarly dissolves, and considerable quantities of hydrogen are now prepared by heating powdered silicon with sodium hydroxide solution and milk of lime (D. R. P. 216768, 1908; Eng. Pat. 21032, 1909) (*v. infra, Hydrogen for Balloons*).

Hydrogen may be prepared by heating slaked lime with either zinc dust (Schwarz, Ber. 1886, 19, 1141) or coal. The resulting calcium carbonate in the latter process may be reconverted into slaked lime by heating in steam (Bloxam).

(5) *Decomposition of metallic hydrides.*—The hydrides of the alkali metals and those of the alkaline earths readily decompose water at ordinary temperatures, liberating hydrogen and forming the corresponding metallic hydroxide. The use of calcium hydride for preparing hydrogen is very convenient, since the hydride is readily portable, and each gram of the substance yields more than 1 litre of hydrogen when decomposed by water. The hydrogen liberated is twice that which is absorbed by the metallic calcium in the preparation of the hydride (Fr. Pat. 327878, 1902); (*v. infra, Hydrogen for Balloons*).

Palladium foil is capable of directly absorbing large quantities of hydrogen; from the substance thus produced, pure hydrogen is readily obtained by heating it under reduced pressure (*v. infra*, p. 65).

Purification.—The electrolysis of either dilute sulphuric acid or a solution of pure baryta, yields practically pure hydrogen, as also does the action of steam on pure sodium. Most methods of preparation, however, yield hydrogen containing more or less of a number of impurities, nearly all of which may be removed by treating the gas with reagents capable of absorbing them. The precise nature of most of the impurities depends upon the method of preparation employed, but one in particular, viz. atmospheric air, is common to nearly all methods. Its presence in the gas is due partly to its presence in the liquids employed in the preparation of the gas, a source of error which may be diminished by previously boiling the solution, partly to the difficulty of completely expelling air from the apparatus, and partly owing to leakage into the apparatus through cork or rubber joints, which should therefore be reduced to a minimum. The oxygen thus introduced may be removed by passing the gas over red-hot copper or spongy platinum or through chromous chloride solution, but the nitrogen cannot be similarly removed.

A convenient but expensive method of obtaining pure hydrogen consists in passing the dried, approximately pure gas over palladium, the metal having been previously strongly heated, introduced into a tube fitted with a stopcock and the tube evacuated. The metal is allowed to cool during the absorption of the gas. The gas left in the apparatus is finally pumped out. From the palladium-hydrogen, pure hydrogen is readily obtained by attaching the palladium tube to the apparatus into which the gas is to be introduced, and gently warming the metal.

Hydrogen prepared from acid and ordinary iron, which contains a certain amount of carbide, invariably contains gaseous hydrocarbons which give the gas a most unpleasant odour, and this method of preparation is never used for laboratory purposes. The hydrocarbons may be removed by passing the gas through alcohol, or a tube filled with pieces of wood-charcoal or paraffin (Stenhouse, Annalen, 1858, 106, 125; Varenne and Hèbré, Bull. Soc. chim. 1877, [ii.] 28, 523).

According to Morley, the purest redistilled zinc always contains a little occluded oxides of carbon, which find their way into hydrogen prepared from the metal and acid. The commercial metal may also contain, besides a little lead, traces of sulphur, arsenic, antimony, carbon, silicon, and even phosphorus, which cause the hydrogen generated from the metal by means of acid to contain the corresponding gaseous hydrides. Sulphuric acid may contain sulphur dioxide, which will be partly evolved with the hydrogen and partly reduced to hydrogen sulphide (Kolbe, Annalen, 1861, 119, 174), and also nitrogen compounds, which lead to the formation of nitrogen and nitrous oxide in the hydrogen. Frequently sulphuric acid contains arsenic and selenium, which lead to the formation of the corresponding hydrides. Hydrochloric acid prepared from sulphuric acid may contain the same impurities.

Sulphur dioxide, the hydrides of sulphur, selenium, silicon, and hydrogen chloride carried over by the hydrogen may be absorbed in a solution of potassium hydroxide. The hydrides of phosphorus, arsenic, and antimony may be absorbed by solutions of various metallic salts, *e.g.* mercuric chloride, lead nitrate, or silver sulphate (Dumas, Ann. Chim. Phys. 1843, [iii.] 8, 189).

All the above impurities are decomposed when the hydrogen is passed over red-hot copper turnings. The small quantity of nitrogen that may be introduced by the decomposition of oxides of nitrogen is usually not inconvenient.

For laboratory purposes, hydrogen is best purified from phosphine, arsine, and stibine, by passing it through saturated permanganate solution and then through 5–10 p.c. silver nitrate. After washing hydrogen with concentrated permanganate solution, however, the gas contains traces of oxygen. For removing traces of arsine from large quantities of hydrogen, bromine is the best absorbent; on a technical scale potassium hypochlorite or bleaching powder may be substituted (Reckleben and Lockemann, Zeitsch. angew. Chem. 1908, 21, 433).

Arsine is said to be completely removed from hydrogen by bubbling the gas through petroleum spirit cooled by liquid air to −110°, and the process has been recommended for technical use (Compt. rend. 1903, 136, 1317).

An elaborate method for purifying hydrogen by freezing out the impurities is described by Kamerlingh Onnes (Proc. K. Akad. Wetensch. Amsterdam, 1909, 11, 883); using 25 litres of liquid air, 10,000 litres of hydrogen can be purified in 8 hours.

Hydrogen may be dried for ordinary purposes by passing it over anhydrous calcium chloride or through concentrated sulphuric acid. The latter process, however, slightly contaminates the gas with sulphur dioxide (Dittmar and Henderson, Proc. Roy. Soc. Glasgow, 1891, 22, 33; Berthelot, Compt. rend. 1897, 125, 743; Milbauer, Zeitsch. physikal. Chem. 1907, 57, 649). The use of phosphoric anhydride, free from lower oxides, is to be preferred.

Properties.—Hydrogen is a colourless, odourless, tasteless gas. It is the lightest gas known, 1 litre of hydrogen at N.T.P. and at sea-level in lat. 45°, weighing 0·089873±0·0000027 grams (Morley, Zeitsch. physikal. Chem. 1896, 20, 242; *cf.* Regnault, Relation des Expér. 2, 121; Leduc, Compt. rend. 1891, 113, 186; Thomsen, Zeitsch. anorg. Chem. 1896, 12, 1). The density of hydrogen compared with air is therefore 0·0694. The coefficient of expansion at constant pressure is 0·003661 (Regnault), and at constant volume the pressure coefficient is 0·0036624 (Chappuis). The thermal conductivity of hydrogen is seven times that of air (Stefan). Between 0° and 200° the molecular specific heat at constant pressure is 6·81 and at constant volume is 4·81 calories. The specific heat increases with rise of temperature. According to Mallard and le Chatelier (Compt. rend. 1887, 104, 1780), the mean molecular specific heat of hydrogen at constant pressure between 0° and t° is 6·5+0·0006 (t+273); the value at constant volume is

4·700+0·00045t (Pier. Zeitsch. Elektrochem. 1909, 15, 536). The ratio of the specific heats is 1·405 (Röntgen). Hydrogen is diamagnetic.

Hydrogen is very slightly soluble in water, its absorption-coefficient between 0° and 25° being given by the formula

$$0{\cdot}021528-0{\cdot}00019216t+0{\cdot}000001728t^2$$

(Timofejeff, Zeitsch. physikal. Chem. 1890, 6, 141; *cf.* Winkler, Ber. 1891, 24, 89; Bohr and Bock, Wied. Ann. 1891, 44, 316; Geffken, Zeitsch. physikal. Chem. 1904, 49, 257). For its solubility in alcohol, *v.* Timofejeff. *l.c.*, and in various aqueous salt solutions, *v.* Geffken, *l.c.*

The liquefaction of hydrogen for many years presented the most difficult problem to experimenters on the liquefaction of gases. In 1877, Cailletet submitted hydrogen to the same process as he had successfully used in the liquefaction of oxygen and nitrogen, and observed the formation of a fine mist when hydrogen was subjected to a pressure of 280 atmos. and then suddenly released. In 1884 Wroblewski (Compt. rend. 1884, 100, 979) liquefied hydrogen by cooling the gas, under a pressure of 190 atmos., by means of boiling nitrogen, and then quickly releasing the pressure. By a similar method, Olszewski (Compt. rend. 1884, 99, 133; 1885, 101, 238) succeeded in obtaining colourless drops of liquid hydrogen. Dewar (Chem. Soc. Proc. 1895, 229; Chem. Soc. Trans. 1898, 528; Proc. Roy. Soc. 1901, 68, 360) was the first to succeed in preparing liquid hydrogen in sufficient quantity to show a definite meniscus by applying the regenerative process to the compressed gas after first cooling it to −205°. Travers (Phil. Mag. 1901, [vi.] 1, 411), Olszewski (Ann. Chim. Phys. 1903, [vii.] 29, 289), and Nernst and Pollitzer (Zeitsch. Elektrochem. 1911, 17, 735) have since described processes whereby liquid hydrogen may be prepared in quantity.

Liquid hydrogen forms a clear, colourless liquid, boiling at −252·5° (Dewar, Proc. Roy. Soc. 1898, 63, 256; Travers, Phil. Mag. 1902, [vi.] 3, 535). The vapour pressures of the liquid at various temperatures have been measured by Travers and Jacquerod (Zeitsch. physikal. Chem. 1904, 46, 447). At its boiling point the density of the liquid is only 0·07. Liquid hydrogen has the greatest specific heat of any liquid, namely 6·4 (Dewar). When cooled by rapid evaporation under diminished pressure, the liquid solidifies to a transparent solid, melting at −257° (Dewar) or −258·9° (Travers, Proc. Roy. Soc. 1902, 70, 484), and having a sp.gr. at −259·9° of 0·0763 (*ibid.* 1904, 73, 251). The critical pressure of hydrogen is 15 atmos. and its critical temperature is −243° to −241° (Dewar).

The spectrum of hydrogen consists essentially of four bright lines—one in the red, corresponding with Fraunhofer's dark line C, and one in the greenish-blue, coincident with the dark line F. Their wave-lengths are (Angström) C=6562, F=4861, blue = 4340, indigo=4101 in ten-millionths of a millimetre.

Hydrogen is an inflammable gas, burning in air or oxygen with an extremely hot, almost colourless flame, and producing water. Even with pure hydrogen, however, the centre of the flame is coloured green, while the external portions are of a violet-blue colour. On reducing the pressure, the blue colour is transformed to green, and from that successively to yellow, orange, and red. Under increased pressure, hydrogen burns with a luminous flame.

The combination of hydrogen and oxygen proceeds slowly at ordinary temperatures in the presence of sunlight (Baker, Chem. Soc. Trans. 1902, 81, 400). The rate of combination is slow at 180° (Gautier and Hélier, Bull. Soc. chim. 1896, [iii.] 15, 468), but with rise of temperature it becomes quicker and quicker, and explosion occurs at about 550° (Gautier and Hélier, *l.c.*; Berthelot, Compt. rend. 1897, 125, 271; Ann. Chim. Phys. 1898, [vii.] 13, 30; Meyer and Raum, Ber. 1895, 28, 204; Bone and Wheeler, Phil. Trans. 1906, A, 206, 1; Rowe, Zeitsch. physikal. Chem. 1907, 59, 41). Mixtures of the two gases, if perfectly pure and dry, may be heated to the melting-point of silver without combination occurring (Baker, *l.c.*). The ignition-points of various mixtures of oxygen and hydrogen, from $3H_2+O_2$ to H_2+4O_2, vary between 557° and 507° when fired by adiabatic compression, electrolytic gas having an ignition-point of 536° (Dixon, Chem. Soc. Trans. 1910, 97, 661; *cf.* Falk, J. Amer. Chem. Soc. 1906, 28, 1517; 1907, 29, 1536). The union of hydrogen and oxygen proceeds quickly at ordinary temperatures in the presence of finely divided palladium, platinum, iridium, osmium, or gold.

Hydrogen unites at 250° with sulphur and selenium, and at 400° with tellurium. It can be made to unite directly with nitrogen under the influence of the silent discharge (Chabrier, Compt. rend. 1872, 75, 489; Donkin, Proc. Roy. Soc. 1881, 31, 281) or of electric sparks (Berthelot, Ann. Chim. Phys. 1880, [v.] 21, 385); compounds of hydrogen with arsenic, phosphorus, antimony, boron, and silicon, can be prepared indirectly.

Hydrogen unites with pure carbon directly when heated to 1150°, methane being produced (Bone and Jerdan, Chem. Soc. Trans. 1897, 71, 41; Bone and Coward, 1908, 93, 1975; 1910, 97, 1219). By passing an electric arc between carbon poles in an atmosphere of hydrogen, acetylene is produced, accompanied by a little methane and ethane (Berthelot, Compt. rend. 1862, 54, 640; Bone and Jerdan, Chem. Soc. Trans. 1901, 79, 1062).

Gaseous hydrogen combines with fluorine even in the dark and at ordinary temperatures, with explosive violence, hydrofluoric acid being produced (Moissan, Ann. Chim. Phys. 1891, [vi.] 24, 224). With liquid fluorine at −210°, explosion also occurs, and a similar result follows on mixing solid fluorine and liquid hydrogen (Moissan and Dewar, Bull. Soc. chim. 1897, [iii.] 17, 932; Compt. rend. 1903, 136, 641).

Chlorine does not combine appreciably with hydrogen at ordinary temperatures in the dark, but only when heated above 400° or exposed to light. In diffused light, combination occurs slowly, and there is usually an initial *period of induction* (Bunsen and Roscoe, Phil. Trans. 1857, ii. 378) during which the rate of combination slowly increases to its maximum value and afterwards remains constant. This period of induction is due to the presence of traces of volatile impurities (Burgess and Chapman, Chem. Soc. Trans. 1906, 89, 1399). Under the direct action of actinic rays, mixtures of hydrogen and chlorine explode.

Hydrogen combines directly with bromine above 400°, and slowly even at 100° in the presence of light (Kastle and Beatty, Amer. Chem. J. 1898, 20, 159). With iodine, the rate of combination becomes measurable above 200°.

The alkali metals, when heated to 360° in hydrogen, directly absorb the gas, forming white solid hydrides of the type MH (Guntz, Compt. rend. 1896, 122, 244; Moissan, Bull. Soc. chim. 1902, 27, 1141; Ann. Chim. Phys. 1905, [viii.] 6, 289, 323; Holt, Chem. Soc. Abstr. 1909, ii. 807). The alkaline-earth metals similarly combine with hydrogen, yielding solid hydrides of the type RH_2 (Moissan, Bull. Soc. chim. 1899, [iii.] 21, 876; Guntz, Compt. rend. 1901, 133, 1209). According to Winkler (Ber. 1891, 24, 884), hydrogen combines directly with various finely divided metals, *e.g.* cerium, yttrium, lanthanum, obtained by reducing their oxides with magnesium powder.

Hydrogen is a reducing agent, and readily displaces a large number of metals from their compounds with oxygen, sulphur, chlorine, &c. Thus the oxides of copper, lead, iron, antimony, &c., are easily reduced to the metallic state, with the formation of water, when heated in a current of hydrogen to a more or less elevated temperature. Silver oxide is slowly reduced at ordinary temperatures, and rapidly and completely at 100° (Colson, Compt. rend. 1900, 130, 330), a reaction which may be used to determine hydrogen in gaseous mixtures. Palladous oxide is reduced in the cold by hydrogen (Wöhler, Annalen, 1874, 174, 60), as also is the corresponding chloride, either in the anhydrous state or in solution (Phillips, Amer. Chem. J. 1894, 16, 255; Campbell and Hart, *ibid.* 1896, 18, 294).

When hydrogen is passed through a solution of silver nitrate, sulphate or acetate, metallic silver is precipitated; the amount of metal thus separated is small compared with that left in solution. The reaction is carried further by raising the temperature, and the precipitated metal is very pure. Palladium, platinum, and gold are similarly precipitated. Under great pressures, such reductions are much more complete. Thus silver and mercury are quantitatively precipitated from solutions of their salts at ordinary temperatures under 200 atmos. pressure. At higher temperatures, nickel, cobalt, lead, and bismuth are similarly precipitated, the deposition of nickel being complete at 200° and 180 atmos. (Ipatieff and Werchowsky, Ber. 1909, 42, 2078).

Occluded hydrogen (*v. infra*, p. 65) is capable of bringing about a great number of chemical changes that the free gas is unable to effect. Thus hydrogen occluded in palladium will unite with chlorine, iodine, and oxygen, even in the dark, at ordinary temperatures (Böttger, Ber. 1873, 6, 1396). It also reduces chlorates to chlorides; nitrates to nitrites, and even to ammonia; mercuric chloride to mercurous chloride; ferric salts to ferrous salts; ferricyanides to ferrocyanides; and indigo-blue to indigo-white (Gladstone and Tribe, Chem. News, 1878, 37, 68). A number of these reactions can be utilised in quantitative analysis (Chapman, Analyst, 1904, 29, 346). Hydrogen occluded in platinum or copper produces similar changes.

Hydrogen also becomes much more chemically active in contact with various finely divided metals, such as platinum black and nickel, cobalt, iron and copper reduced from their oxides. Thus, hydrogen and oxygen combine rapidly, at ordinary temperatures, in the presence of platinum black. The union of the gases is started by the heat evolved as they are occluded, and, once started, combination proceeds quickly, the metal being heated so much that it becomes incandescent. Similarly, at 400° hydrogen and iodine vapour rapidly unite in the presence of platinum black.

A very general method of reduction and hydrogenation has been based upon the fact that hydrogen becomes intensely chemically active in the presence of finely divided nickel that has been just previously reduced from its oxide. By passing the vapours of a large number of substances, mixed with hydrogen, over reduced nickel at quite moderate temperatures, reductions are easily effected; thus nitrous oxide produces nitrogen and water, nitric oxide and nitrogen peroxide are reduced to ammonia, and the oxides of carbon are converted into methane. Organic nitro compounds, fatty or aromatic, are reduced to amines. Unsaturated fatty hydrocarbons are transformed into paraffins, while benzene and numerous derivatives are easily converted into hexahydrobenzene and its substitution-products. Aldehydes and ketones are reduced to alcohols with remarkable ease. The nickel is not altered, and permits of hydrogenation being carried on indefinitely (Sabatier and Senderens, Compt. rend. 1897, 124, 1358; 1899, 128, 1173; 1900, 130, 1559, 1628, 1761; 131, 140; 1901, 132, 210, 566, 1254; 133, 321; 1902, 134, 514, 689, 1127; 135, 87, 225; 1903, 136, 738, 921, 983; 137, 301, 1025; 1904, 138, 457, 1257; 1905, 140, 482; Bull. Soc. chim. 1905, [iii.] 33, 263; Ann. Chim. Phys. 1905, [viii.] 4, 319, 433; Sabatier and Mailhe, Compt. rend. 1903, 137, 240; 1904, 138, 407, 245; 1905, 140, 350; 1906, 142, 553; 1907, 144, 824, 955, 784, 1086; 145, 18, 1126; 1908, 146, 457, 1193; Ann. Chim. Phys. 1909, [viii.] 16, 70).

Certain chemical systems which lead to the liberation of hydrogen are capable of acting as reducing agents when another substance is added to them that is capable of being reduced. Thus a solution of potassium chlorate remains unaffected when hydrogen is passed through it, but reduction to chloride readily occurs if zinc and sulphuric acid are added to the solution. Other systems are furnished by the alkali metals or their amalgams in contact with water, which are capable, among other things, of reducing aldehydes and ketones to alcohols; and zinc, iron, or tin, with either hydrochloric, sulphuric, or acetic acid, systems which are capable of reducing nitro compounds to amines, &c. Hydrogen evolved from such systems therefore appears to possess an activity superior to that of the ordinary gas; it is termed *nascent* hydrogen.

The superior activity possessed by hydrogen at the moment of its liberation is supposed by some chemists to be due to the fact that the gas is liberated in the atomic state, and is therefore more capable of entering into chemical reactions than after it has assumed the molecular state, since the combination of atoms to form molecules is accompanied by the degrading of a certain amount of energy. That this cannot be a full explanation is seen, however, by the fact that a reduction effected by one system evolving nascent hydrogen is not necessarily effected by another system, *e.g.* the system zinc and dilute sulphuric acid will reduce chlorates to chlorides, but the system sodium-amalgam and water will not.

Adsorption of hydrogen by metals. In 1863, Deville and Troost (Compt. rend. 1863, 57, 894) observed that red-hot platinum and iron were permeable to hydrogen. Upon further investigating this subject, Graham (Proc. Roy. Soc. 1867, 15, 223; 1868, 16, 422; 1869, 17, 212, 500) found that palladium possessed this property in a much higher degree, and, further, he showed that there was no need to assume a porosity in the structure of these metals to account for this phenomenon, but that it was due to the fact that such metals absorb hydrogen, yielding substances which still retain metallic lustre and characteristic metallic properties, but which readily evolve the absorbed gas under altered conditions. To this property, Graham gave the name *occlusion.* It may be studied by placing the metal within a porcelain tube, glazed inside and out, evacuating it by means of a mercury pump and heating to redness. Hydrogen is then admitted and allowed to flow over the metal while it cools. The tube is then evacuated again and the contents heated to redness once more, by which means the occluded hydrogen is expelled from the metal, and may be pumped off and measured.

The amount of hydrogen adsorbed depends to some extent on the physical condition of the metal. In one experiment, a palladium wire was found by Graham to absorb 935 times its own volume of hydrogen. Mond, Ramsay, and Shields (Phil. Trans. 1895, A, 186, 657; 1897, A, 190, 129; 1898, A, 191, 105) have shown that palladium black adsorbs at the ordinary temperature 873 to 889 volumes of hydrogen and that palladium wire and sponge adsorb a similar amount. Palladium-hydrogen readily evolves hydrogen in a vacuum, that prepared from the 'black' at the ordinary temperature, while the substance obtained from the foil requires warming to 100°. In all cases, however, a red heat is required to drive off the last traces of gas. Even at a red heat, however, palladium still adsorbs large quantities of hydrogen if the pressure is sufficiently increased (Dewar, Chem. Soc. Proc. 1897, 192).

Palladium readily adsorbs 935 vols. of hydrogen if it is employed as negative electrode in a water voltameter. Should the electrolysis be continued beyond this point, the metal becomes supersaturated with gas; the excess is, however, evolved as soon as the current ceases (Thoma, Zeitsch. physikal. Chem. 1889, 3, 69).

Colloidal palladium and platinum solutions adsorb hydrogen very readily and in large amounts (Kernot and Niguesa, Rend. accad. Sci. Fis. Mat. Napoli, 1909, [iii.] 15, 168). Various other metals, *e.g.* iron, nickel, cobalt, gold, and copper, also adsorb small quantities of hydrogen.

The process of occlusion is accompanied by an evolution of heat, 4370 calories being evolved per gram of hydrogen occluded; the thermal effect is the same for each successive fraction of gas absorbed (Favre, Compt. rend. 1869, 68, 1306; Mond, Ramsay, and Shields, *l.c.*).

The nature of the substances formed when hydrogen is occluded by metals has not yet been determined with certainty. The metals are unaltered in appearance, and such physical properties as thermal and electrical conductivity, sp.gr., and tenacity are only slightly diminished. Graham was of opinion that no chemical union occurs, but that the hydrogen assumes the solid form and acts as a quasi-metal. This adsorbed form of hydrogen he proposed to call *hydrogenium.*

From the expansion of alloys of palladium with platinum, gold, and silver, when charged with hydrogen, Graham calculated the sp.gr. of hydrogen to be 0·733; subsequent determinations by Dewar gave the figure 0·620, a figure which does not compare at all with the actual sp.gr. of solid hydrogen.

Troost and Hautefeuille (Compt. rend. 1874, 78, 686) believed that their experiments indicated the existence of a definite compound, Pd_2H, whilst Dewar (Chem. News, 1897, 76, 274) suggested the existence of Pd_3H_2. The fact that when fully charged with hydrogen, the composition of palladium-hydrogen approximates closely to this latter formula is, however, almost the only evidence that can be adduced in support of the existence of this compound (Mond, Ramsay, and Shields, *l.c.*). The experiments of Hoitsema (Zeitsch. physikal. Chem. 1895, 17, 1) have shown that between 20° and 200° no definite compounds of palladium and hydrogen exist; at constant temperature the relationship between the vapour tension of the system palladium-hydrogen and the percentage of hydrogen in the solid phase is such, however, as would be expected if two partially-miscible solid solutions of hydrogen in the metal are formed, the miscibility of which increases with rise of temperature.

The meteoric iron of Lenarto, containing 91 p.c. of iron, yields 2·85 times its volume of occluded gas, mainly hydrogen (Graham, Proc. Roy. Soc. 1867, 15, 502). Since under ordinary pressure iron absorbs only half its volume of hydrogen, this would seem to show that the meteorite has come from an atmosphere containing hydrogen under a pressure much greater than that of our own atmosphere, thus affording a confirmation of the conclusions drawn from spectroscopic observations regarding the existence of dense and heated hydrogen atmospheres in the sun and fixed stars.

Atomic weight of hydrogen. This has been determined by measuring the ratio of the combining weights of oxygen and hydrogen. Since this ratio is of fundamental importance, a very considerable amount of attention has been directed towards its accurate measurement. The methods used may be grouped under two headings: (*a*) synthesis of water; and (*b*) determinations of the relative densities of hydrogen and oxygen.

(*a*) The classical method, first employed by Dulong and Berzelius (1820), and used later by Dumas (Ann. Chim. Phys. 1843, [iii.] 8, 189) in his elaborate series of determinations, consists in reducing heated cupric oxide in a stream of pure, dry hydrogen, and estimating the water produced and the loss in weight experienced by the cupric oxide. The result obtained by Dumas, viz. H : O :: 1 : 15·9607, corroborated as it was by the experiments of Erdmann and Marchand (J. pr. Chem. 1842, 26, 461) was for many years accepted as the true value; but subsequent work has shown that this result deviates considerably from the truth, and has disclosed numerous sources of error in the older determinations. The method of Dumas, with various modifications, has been used by Cooke and Richards (Amer. Chem. J. 1888, 10, 81, 191); Keiser (*ibid.* 1888, 10, 249); Noyes (*ibid.* 1889, 11, 155; 1890, 12, 441); Dittmar and Henderson (Proc. Roy. Soc. Glasgow, 1891, 22, 33), and Leduc (Compt. rend. 1892, 115, 41); their results are given in the table below.

The synthesis of water has been effected by other methods than the above. In 1889, Rayleigh (Proc. Roy. Soc. 45, 425) weighed pure hydrogen and oxygen in glass globes, mixed them and then gradually exploded the mixture in a eudiometer. The residual gas was then analysed, and hence the ratio of hydrogen to oxygen determined. The first complete quantitative syntheses of water, in which both gases were weighed separately, and afterwards in combination, are due to Morley (Smithsonian Contributions to Knowledge, 1895, 29). The hydrogen was weighed in palladium (a method due to Keiser) and the oxygen in compensated globes, after the manner of Regnault. After weighing, the gases were burned by means of electric sparks in a suitable apparatus, from which the unburned residue could be withdrawn for examination. Finally, the apparatus containing the water produced was closed by fusion and weighed.

The syntheses of water by Keiser (Amer. Chem. J. 1898, 20, 733) were effected by the direct oxidation of hydrogen occluded in palladium; the hydrogen, oxygen, and water were all determined. The experiments recorded in the elaborate investigation by Noyes (J. Amer. Chem. Soc. 1907, 29, 1718) were performed partly by this method and partly by the method employed in his earlier work (*v. supra*). A novel, but indirect method for measuring the ratio of oxygen to hydrogen has been employed by Thomsen (Zeitsch. anorg. Chem. 1895, 11, 14).

The results of these experiments are collected in the following table :—

Experimenter	Date	Ratio O/H	At.wt. of Hyd. (O=16)
Dumas . . .	1842	15·9607	1·00246
Erdmann & Marchand	1842	15·9750	1·00156
Cooke & Richards .	1888	15·8690	1·00825
Keiser . . .	1888	15·9514	1·00305
Noyes . . .	1889	15·8966	1·00650
Dittmar & Henderson	1891	15·8677	1·00834
Leduc . . .	1892	15·8810	1·00750
Rayleigh . . .	1889	15·8900	1·00692
Morley . . .	1895	15·8790	1·00762
Keiser . . .	1898	15·8799	1·00756
Noyes . . .	1907	15·8745	1·00783
Thomsen . . .	1895	15·8690	1·00825

The weighted mean of these results is H=1·00769 according to Clarke (A Recalculation of the Atomic Weights, 3rd edit. 1910, 29).

(*b*) The ratio of the densities of oxygen and hydrogen is, subject to a correction to be mentioned later, equal to the ratio of their atomic weights. The first accurate measurements of these densities were made by Dumas and Boussingault in 1841 (Compt. rend. 12, 1005); the results obtained four years later by Regnault (*ibid.* 20, 975) were adopted as standard values for many years, and gave for the ratio a value of 15·9611. The remarkable agreement of this figure with that deduced from Dumas' synthesis of water is only, however, accidental, for in 1885, Agamennone, and independently, Rayleigh in 1888 (Proc. Roy. Soc. 43, 356) pointed out a serious error in all previous determinations of gaseous densities, owing to the fact that the glass globes in which the gases are weighed are elastic, and shrink to a measurable extent when evacuated. The effect of neglecting to correct for this shrinkage is that the apparent weight of gas is slightly lower than its true value. The corrected value for the density ratio from Regnault's experiments is 15·9105 (Crafts, Compt. rend. 1888, 106, 1662).

In recent years, the densities of hydrogen and oxygen have been frequently determined with the utmost care; *v.* Rayleigh (Proc. Roy. Soc. 1892, 50, 448; Cooke, Amer. Chem. J. 1889, 11, 509); Leduc (Compt. rend. 1891, 113, 186); Thomsen (Zeitsch. anorg. Chem. 1896, 12, 4) and especially Morley (Smithsonian Contributions, 1895). The table below summarises the results obtained :—

Experimenter	Date	Density ratio O/H
Dumas & Boussingault .	1841	15·9015
Regnault . . .	1845	15·9105
Rayleigh . . .	1888	15·8840
Rayleigh . . .	1892	15·8820
Cooke	1889	15·8900
Leduc	1891	15·9060
Morley . . .	1895	15·8955
Thomsen . . .	1896	15·8878

The weighted mean is 15·8948 (Clarke. *l.c.*).

This result is subject to a slight correction for the fact that hydrogen and oxygen do not combine together by volume exactly in the ratio of two to one; according to Morley (*l.c.*), the exact ratio is 2·00274 (*cf.* Scott, Phil. Trans. 1893, 184, 543; Leduc, Compt. rend. 1892, 175, 311; Rayleigh, Proc. Roy. Soc. 1904, 73, 153). Correcting the above mean value for the density ratio in accordance with this result, the figure 15·8726 is obtained, which leads to the value 1·00803 for the atomic weight of hydrogen on the oxygen scale.

According to Clarke (*l.c.*), the probable mean derived from the results of methods (*a*) and (*b*) combined, is H=1·00772. The value at present adopted is H=1·008.

Applications of hydrogen. Hydrogen is used in conjunction with oxygen for the production of the Drummond or oxy-hydrogen lime light. For this purpose, the gases are compressed in iron bottles furnished with taps and jets, so that they can be allowed to escape, and burned as required. They are allowed to impinge on a cylinder of lime which is thereby heated to whiteness, and gives a light almost equal to the electric arc.

For the autogenous welding of metals, the working of platinum, and the manufacture of laboratory utensils and mercury vapour lamps from fused quartz, hydrogen in the form of the oxyhydrogen blowpipe flame is used in large quantities, although it has here to meet the competition of acetylene, which is cheaper and readily obtainable as required from calcium carbide.

Autogenous soldering.—This process is much used for uniting the edges of the sheets of lead which are employed in making vessels for the purpose of holding acids. Joints made in this way are much more durable than those made with solder. The apparatus for this purpose is made so that hydrogen can be generated at pleasure, and when not in use the pressure of gas inside the apparatus lifts the acid out of contact with the zinc. The hydrogen generator consists of a cylindrical copper vessel lined with lead; there is an upper and lower chamber connected by a pipe, and they are filled with arrangements which admit of easy renewal of acid or zinc and the removal of the zinc sulphate formed. The apparatus gives a very constant flame, which may be used with advantage in soldering lead in the way which is practised in the construction of sulphuric acid chambers. The hydrogen is delivered from a platinum-tipped nozzle through which a jet of air also issues from a foot bellows; this is effected by attaching the nozzle by means of india-rubber tubing to a tube which branches out V-shaped into two limbs each provided with a stopcock; each of these limbs is provided with an india-rubber tube, one of which is attached to the bellows and the other to the delivery tube of the hydrogen generator. The operator can, therefore, carry the nozzle in his hand and direct the flame where he pleases, and by means of the stopcock he can readily regulate the supply of air or hydrogen.

Tungsten lamps.—The manufacture of tungsten filament lamps requires a regular supply of hydrogen to prepare the inert atmosphere in which the filaments are heated to a high temperature during the final treatment. It is almost the universal custom to employ a mixture of equal volumes of hydrogen and nitrogen when the filaments are electrically heated to whiteness. Since incandescent tungsten filaments are very sensitive to oxidation, it is of great importance that the hydrogen employed should be of a high degree of purity. The process devised by Lane (*v. infra*) is frequently adopted for obtaining the gas, since besides preparing hydrogen, it also admits of nitrogen being collected.

Hydrogen for balloons.—Soon after Cavendish published his researches on 'inflammable air,' Charles, in 1783, suggested the application of hydrogen for the inflation of balloons. Montgolfier had, during the same year invented the balloon which he inflated with rarefied air. In hydrogen, however, Charles recognised a much more suitable means of inflation, although the cost was very considerable, 500 lbs. of sulphuric acid and twice that amount of iron being consumed in the inflation of a balloon about 13 feet in diameter.

The first balloon sent up from English soil, on Nov. 25, 1793, was inflated with hydrogen. In the following year, the French Government instituted a series of experiments at Meudon under Guyton de Morveau, Contelle, and Comté with the view of perfecting the balloon for reconnoitring, signalling, and other warlike purposes. For the preparation of the hydrogen, Guyton de Morveau suggested a method invented by Lavoisier, that of passing steam over red-hot iron, and a furnace was accordingly built, which after many trials, was capable of producing sufficient gas to fill a balloon, 27 feet in diameter, in 4 hours. This balloon, with one filling, remained in use for a month.

Balloons inflated with hydrogen were used in the American Civil War in 1861. The gas was generated from old scrap iron and sulphuric acid in wooden tanks lined with lead: the apparatus was carried from place to place on two carts.

In 1878, Giffard made a gigantic captive balloon for the Paris Exhibition. It was spherical in form, 118 feet in diameter, and had a capacity of 882,902 cb. feet. To fill this great aerial ship with hydrogen gas, 190 tons of sulphuric acid and 80 tons of iron were consumed (Jour. United Service Inst. 27, 735–756).

Hydrogen was also used in the Soudan War for inflating balloons. For this purpose, the gas was compressed in strong iron cylinders, 12 feet long by 1 foot in diameter; these were for a reserve supply, and weighed half a ton each. A gas factory and pumping station were put up. To meet first requirements about 100 lighter cylinders, 9 feet long, and containing 120 feet of gas in a compressed condition, were taken out; these were so constructed as to be easily carried by men. One waggon containing a ton of stores was sufficient for a balloon ascent; a volume of gas occupying 4,150 feet was sufficient to lift a man 1,000 yards (Illus. Nav. and Mil. Gaz. 11, 172).

At the present time it is highly important for the maintenance of large dirigible balloons to be assured of a regular supply of pure hydrogen gas. The chief drawback to the use of hydrogen is its high rate of diffusion, a drawback which is being minimised by improvements in the manufacture of balloon fabrics.

Most of the hydrogen now used for inflating the gas bags of dirigible airships is produced either electrolytically or by the action of steam on red-hot iron. The former method has been largely developed in Germany, and depends for success upon a cheap supply of electrical energy. It yields pure hydrogen and the plant requires very little attention.

The other method is now used in this country as described by Lane (Eng. Pat. 17591, 1909); iron is heated to redness in a current of steam, and the oxide produced is reduced by heating in a current of water gas, the resulting metal being used again. By carrying on the reduction process in a number of the retorts and the preparation of hydrogen simultaneously in the others, it is possible to make the production of hydrogen more or less continuous.

The need for rapid convenient methods for preparing hydrogen for military purposes has led to the introduction of the '*hydrolith*' and '*hydrogenite*' processes for its preparation, which are employed by the French army. In the former process, 'hydrolith,' a white crystalline powder consisting of calcium hydride (90 p.c. pure, the remainder being oxide and nitride), is decomposed by water. One kilo. of the solid yields about 1 cubic metre of hydrogen. The portable apparatus used by the French army can fill an army dirigible in 4 hours. For speed, convenience, and reliability, hydrolith is unexcelled, but its high cost renders its use almost prohibitive for private aeronautics. 'Hydrogenite' is a compressible powder, consisting of ferrosilicon (90–95 p.c. Si) 25 pts., sodium hydroxide 60 pts., and slaked lime 20 pts. (Sander, Chem. Zeit., 1911, 35, 1273); when ignited by a suitable 'match,' it reacts spontaneously, much as do thermit mixtures, with the evolution of hydrogen and the production of sodium and calcium silicates. The material is hygroscopic, and is sold in a compressed cake in metal cartridges. One kilo. of substance yields from 270 to 370 litres of hydrogen. (For the method of using the substance for filling balloons, *v.* Jaubert, Rev. gén. chim. 13, 341, 357; and *cf.* D. R. P. 218257, 1908.)

HYDROGENIUM *v.* HYDROGEN.

HYDROGEN PEROXIDE. Symbol H_2O_2. This compound was discovered in 1818 by Thenard. It occurs at times in small quantities in the atmosphere, in dew, in rain, and in snow (Schöne, Ber. 1874, 7, 1695; *ibid.* 1893, 26, 3011; *ibid.* 1894, 27, 1233; Zeitsch. anal. Chem. 1894, 33, 137); but Ilosva (Ber. 1894, 27, 920) maintains that the tests used for detecting it in these media would also be given by the oxides of nitrogen, which are always present. It is said to be contained in many green plants (Bach, Compt. rend. 1894, 119, 1218; Chodat and Bach, Ber. 1902, 35, 1275, 3943; 1903, 36, 1756; 1904, 37, 36). It is also contained in solution in the water produced by the combustion of hydrogen in oxygen (Schuller and Bach, Compt. rend. 1897, 124, 951; Keiser and McMaster, Amer. Chem. J. 1908, 39, 96), and in the flames of alcohol, coal gas, ether, and carbon disulphide (Engler, Ber. 1900, 33, 1109).

Hydrogen peroxide is formed in small quantities in the electrolysis of aqueous solutions (Richarz, Zeitsch. anorg. Chem. 1903, 37, 75; Ber. 1909, 42, 4674; Riesenfeld and Reinhold, *ibid.* 2977); when a Tesla brush discharge, or the silent electric discharge is passed through water vapour (Findlay, Zeitsch. Elektrochem. 1906, 12, 129; Nernst, *ibid.* 1905, 11, 710; Löb, Ber. 1908, 41, 1517; Ringe and Fischer, *ibid.* 945); during the slow oxidation of many metals, particularly their amalgams, in the presence of water (Traube, Ber. 1893, 36, 1471; Smith, Chem. Soc. Trans. 1906, 481; Barnes and Shearer, J. Phys. Chem. 1908, 12, 155, 468; Rankin, Proc. Roy. Soc. 1910, B, 82, 78); with zinc amalgam and in the presence of an alkaline earth a better yield is said to be obtained (D. R. P. 48542; J. Soc. Chem. Ind. 1890, 213).

Hydrogen peroxide is also formed under several other circumstances, as, *e.g.*, when freshly-ignited bone black is moistened with as much water as it will take up, and exposed to light and air. Even in a few minutes a perceptible amount of hydrogen peroxide is formed (Dingl. poly. J. 256–519). A carbonic oxide flame (when the gas has been previously passed through water) is said to produce it in quantity, or if burnt in contact with the surface of water the same effect is produced (J. Soc. Chem. Ind. 1884, 496).

When turpentine oil or any other hydrocarbon containing a terpene is oxidised by air or ozone in the presence of water, hydrogen peroxide is formed and passes into solution in the water. In this way it is possible to prepare a solution of two volumes strength, that is to say, of such a strength that when fully decomposed it is capable of yielding twice its own volume of oxygen gas (Kingzett, Eng. Pat. 12274; J. Soc. Chem. Ind. 1898, 691).

It is also said to be produced by the oxidation of a number of organic compounds, such as urine, ether, &c., in direct sunlight (Richardson, Chem. Soc. Trans. 1893, 1110; *ibid.* 1896, 1349).

Preparation.—1. By passing a copious stream of well-washed carbon dioxide through cooled distilled water to which is added very gradually pure barium peroxide, finely powdered and suspended in water. The cautious addition of the barium peroxide is necessary, as an excess of it would cause the decomposition of any hydrogen peroxide formed, with evolution of oxygen and formation of water. After allowing the gas to pass some considerable time, the barium carbonate is filtered off, and the solution evaporated *in vacuô* over sulphuric acid until it acquires a syrupy consistency;

$$BaO_2+CO_2+H_2O=H_2O_2+BaCO_3$$

(D. R. P. 179771, 179826; J. Soc. Chem. Ind. 1906, 117).

2. The preparation is also effected by the decomposition of barium peroxide with hydrofluoric, silicofluoric, phosphoric, sulphuric, borofluoric, or hydrochloric acid, of which the last is to be preferred, owing to its cheapness, whilst the purest peroxide is obtained with phosphoric or borofluoric acids. The barium peroxide, which must be of the purest quality and very finely ground, is made into a thin paste with water, and introduced very gradually into the acid solution, the temperature of which must never exceed 10°–15°, and must be constantly agitated. When the solution is nearly neutralised, the liquid is decanted from the precipitate, and freed from iron and aluminium oxides by treatment with sodium phosphate solution, then with sufficient barium peroxide or waste barium oxide to make the liquid neutral, lastly with ammonia, after which it is rapidly pumped through a filter press. It is then freed from dissolved baryta by the addition of sodium sulphate. The most stable peroxide is that prepared with phosphoric acid, and contains a small amount of that acid in the free state (Chem. Zeit. 9, 949 and 976; Bourgougnon, J. Amer. Chem. Soc. 12, 64; Fawsitt, J. Soc. Chem. Ind. 1902, 229; *see* also Eng. Pats. 10476, 3628, 21333; J. Soc. Chem. Ind. 1891, 482; *ibid.* 1892, 707; *ibid.* 1900, 70). Nitric acid has also been employed (Fr. Pat. 359523; J. Soc. Chem. Ind. 1906, 374).

3. Hydrogen peroxide has also been conveniently, but not so cheaply, prepared by treating sodium peroxide with hydrofluoric or hydrochloric acids (U.S. Pat. 692139; J. Soc. Chem. Ind. 1902, 364; Forcrand, Compt. rend.

1899, 129, 1246; Merck, Chem. Zentr. 1904, ii. 67); and by treating persulphates, percarbonates, and perborates, obtained by electrolysis of the ordinary acids with dilute acids (Jaubert, Chem. Zentr. 1905, ii. 99; D. R. PP. 217538, 217539, 195351, 199958, 179826; J. Soc. Chem. Ind. 1905, 379; *ibid.* 1906, 321, 379; *ibid.* 1908, 448, 856; *ibid.* 1910, 489).

Pure concentrated solutions of hydrogen peroxide have been prepared by the action of alcohol and dilute sulphuric acid on sodium peroxide in earthenware, glass, or lead vessels at −10°. The alcohol is then removed by distillation *in vacuô* (Dony-Hénault, Fr. Pat. 403294; J. Soc. Chem. Ind. 1909, 1314). A mixture of a perborate with an equivalent amount of a dry solid organic or inorganic acid, or of a solid acid salt has been prepared, which, on treatment with water, yields hydrogen peroxide (Fr. Pat. 401911; J. Soc. Chem. Ind. 1909, 1198).

Hydrogen peroxide has also been prepared by blowing superheated steam against a heated body (Eng. Pat. 20868, 1907; Fr. Pat. 382189, 1907; D. R. P. 205262, 1908; J. Soc. Chem. Ind. 1906, 808; *ibid.* 1908, 123, 226; *ibid.* 1909, 140; Fischer and Ringe, Ber. 1908, 41, 945), and by blowing moist air against a spark or arc discharge (D. R. PP. 197023; 228425; J. Soc. Chem. Ind. 1910, 1462).

(For other methods *see* D. R. P. 185597; Bornemann, Zeitsch. anorg. Chem. 34, 1; Fr. Pat. 371043; Scheuer and Vernet, Bull. Soc. Ind. Mulhouse, 1907, 77, 336; *ibid.* 1908, 78, 184, 187; J. Soc. Chem. Ind. 1910, 1306; Fr. Pat. 415361.)

Commercial hydrogen peroxide is liable to contain hydrochloric, sulphuric, phosphoric, and hydrofluoric acids, alumina, lime, magnesia, potash, and soda, derived from water or other materials used in its manufacture, whilst baryta and traces of iron, copper, lead, and manganese are sometimes found if it has been carelessly made.

When these last are present, the product is tolerably stable only if it be sufficiently acid, though even then it is less stable than in the absence of these impurities.

The commercial liquid of so-called 10 volume or about 3 p.c. strength may be purified by the addition of about $\frac{1}{4}$ p.c. of concentrated phosphoric acid (preferably pure) to precipitate iron, copper, lead, and manganese, and prevent the subsequent formation of their peroxides which would otherwise take place. Saturated baryta water (hot or cold) is then added very gradually, until neutrality is reached. No excess must be used or hydrated BaO_2 will be precipitated, which will induce decomposition of a portion of the hydrogen peroxide.

The clear liquid is now drawn off, and is poured into an excess of cold saturated baryta water, when hydrated BaO_2 is thrown down, and is then washed until no metal except barium can be detected in the washings.

The BaO_2 is then suspended in water and added drop by drop to a solution consisting of 90 parts of distilled water to 10 parts of pure concentrated sulphuric acid until only traces of acid remain free; these are best removed by weak baryta water, for an accidental excess of BaO_2 will induce decomposition of some of the already formed hydrogen peroxide, whilst an excess of BaO will have no such effect. The barium sulphate is allowed to settle, and the clear liquid drawn off, if found free from both barium and sulphuric acid. The resulting product is about 3 p.c. strength, fairly stable and of great purity (Mann, Chem. Zeit. 12, 857; J. Soc. Chem. Ind. 1889, 640).

The commercial solutions can be concentrated to 95–99 p.c. by evaporating in air at 75° to 20 p.c. strength, then *in vacuô* to 50–55 p.c., after which it is treated with ether, in which the peroxide is readily soluble. The ethereal extract is then carefully distilled and fractionated *in vacuô* (Wolffenstein, Ber. 1894, 27, 3307; Staedel, Zeitsch. angew. Chem. 1902, 15, 642; Tyrer, *l.c.*; Merck, *l.c.*); also by distilling the solutions at a temperature below 85° in a powerful current of an inert gas (D. R. P. 219154).

The concentrated solution remains liquid at −20°, but when immersed in a mixture of ether and carbon dioxide, it crystallises to a solid mass, consisting of the anhydrous peroxide. Clear colourless crystals of the latter can also be obtained by introducing a fragment of the solid into a freshly prepared 90-80 p.c. solution at −8° (Staedel, *l.c.*). Hydrogen peroxide should be kept in paraffin or paraffin-lined vessels.

A number of substances have been proposed as suitable for increasing the stability of hydrogen peroxide, such as sulphuric or phosphoric acids (Tyrer, Pharm. J. 63, 100); sodium pyrophosphate (Eng. Pat. 23676; J. Soc. Chem. Ind. 1910, 152); organic substances such as alcohol, ether, glycerol, &c. (Sanders, Bull. Soc. Ind. Mulhouse, 1897, 95; Freyes, *ibid.* 97 Eng. Pat. 15993); 1 gram pure crystalline naphthalene to 1 litre of solution (Zinno, Bull. Soc. Ind. Mulhouse, 1895, 78); gallic acid or pyrogallol (Arndt, D. R. P. 196370); uric or barbituric acids (D. R. PP. 216263, 203019, J. Soc. Chem. Ind. 1908, 1204; *ibid.* 1909, 1314); phenacetin or an amide or imide or acetyl derivative of an aromatic base (J. Soc. Chem. Ind. 1906, 1219); oxalic acid (Fischer, Pharm. Zentr. 1907, 48, 57, 79).

According to Allain (J. Pharm. Chim. 1906, 24, 162) sodium or calcium chloride in the proportion of 1 p.c. are more efficient preservatives for medicinal hydrogen peroxide than sulphuric or phosphoric acids. They are also less objectionable than the latter, from a therapeutic point of view. *See* also Kingzett (J. Soc. Chem. Ind. 1890, 3).

The amount of hydrogen peroxide in an aqueous solution may be conveniently determined by titration with a solution of potassium permanganate containing 7·9 grams $KMnO_4$ per litre. 2 c.c. of hydrogen peroxide solution are introduced into a graduated tube of 35 c.c. capacity, 5 or 6 drops of hydrochloric acid are added, and then the solution of permanganate is gradually introduced with constant agitation until the contents of the tube are of a red or brownish colour; the quantity of solution is then read off, 5 c.c. representing 1 p.c. of hydrogen peroxide. The results are accurate to within 0·1 p.c. and can be obtained in a few minutes[1] (Chem. Zeit. 9, 940 and 976).

---

[1] The reaction between hydrogen peroxide and potassium permanganate in acid solution may be utilised for preparing oxygen gas. In this way a good stream of tolerably pure oxygen may be readily

In the presence of persulphates, however, accurate results can only be obtained by using a minimum volume of solution, a large excess of sulphuric acid and performing the titration very rapidly; for this purpose an excess of permanganate is added, and the latter is then titrated back with sodium thiosulphate (Friend, Chem. Soc. Trans. 1904, 597, 1533; *ibid.* 1905, 1367; Skrabal and Vacek, Chem. Zeit. 1910, 34; Rep. 121).

If oxalic acid is present, this must first be removed (Sisley, J. Soc. Chem. Ind. 1901, 1028; *ibid.* 1904, 685; Roche, *ibid.* 1902, 190).

Another and more accurate method is to strongly acidify the solution of hydrogen peroxide with sulphuric or hydrochloric acid, then add a solution of potassium iodide free from iodate, and determine the iodine liberated by means of a standard solution of sodium thiosulphate (Kingzett, Chem. Soc. Trans. December, 1880, and The Analyst, 1888, 13, 62; Rupp, Arch. Pharm. 238, 156; Planés, J. Pharm. Chim. 1904, 20, 538).

Hydrogen peroxide can also be estimated by titrating against ferrous ammonium sulphate in presence of ammonium sulphate and phosphoric acid (Mathewson and Calvin, Amer. Chem. J. 1906, 36, 113); and by estimating the quantity of arsenious acid it will oxidise to arsenic acid (Grützner, Arch. Pharm. 237, 705).

According to Dehn the most rapid, convenient, and accurate method of estimating hydrogen peroxide is to measure the volume of oxygen evolved when a known quantity of the solution is treated with sodium hypobromite in a special apparatus described by him (J. Amer. Chem. Soc. 1907, 29, 1315). The following reaction takes place $H_2O_2+NaBrO=NaBr+H_2O+O_2$. By this method the presence of preservatives may be neglected. (For the estimation of the peroxide retained by fabrics, *see* Scheuer and Vernet, *l.c.*)

To determine the quantity of acid present in commercial hydrogen peroxide, the best method is by direct titration in the cold, with N/10 sodium hydroxide solution, using phenolphthalein as indicator (Brown, J. Ind. Eng. Chem. 1910, 377; Endemann, Zeitsch. angew. Chem. 1909, 22, 673; Lüning, *ibid.* 1549).

Properties.—Pure anhydrous hydrogen peroxide forms colourless prismatic crystals; m.p. −2°, b.p. 84°–85°/68 mm., 69·2°/26 mm. It forms a syrupy transparent acid liquid, which is colourless in thin layers, but bluish-green when viewed in bulk (Spring, Chem. Zentr. 1895, i. 1105). It has sp.gr. 1·4584 at 0° (Brühl, Ber. 1895, 28, 2854). It forms hydrates H_2O_2,H_2O, $H_2O_2.2H_2O$ (Wolffenstein, *l.c.* 3311).

When heated to the boiling-point of water it decomposes with explosive violence into oxygen and water, but when the peroxide or its solutions are quite pure it is not so readily decomposed by heat; the vapours of hydrogen peroxide are said to be quite stable (Wolffenstein, Ber. 1894, 27, 3307; Nernst, Zeitsch. physikal. Chem. 1904, 46, 720).

The liquid evaporates slowly *in vacuô* without the residue undergoing any change (Thenard). It bleaches organic colouring matters, but not so quickly as chlorine; when brought in contact with the skin it forms a white blister, which, after a time, produces an irritable, itching sensation (Wolffenstein, *l.c.*).

One volume of the concentrated solution yields at 14° and 760 mm. pressure, 475 volumes of oxygen, the theoretical amount being 501·8 volumes (Thenard). The compound is most stable in dilute aqueous solution; when the solution is subjected to great cold, part of the water freezes out.

Hydrogen peroxide is a remarkable oxidising agent. It converts arsenious into arsenic acid, and sulphurous acid into sulphuric acid; lead and other sulphides into the corresponding sulphate; manganese monoxide into dioxide and monoxides of iron and cobalt into the sesquioxides. The monoxides of barium, strontium, and calcium are converted by it into their respective peroxides. The concentrated solution of hydrogen peroxide acts with violence on selenium, arsenic, molybdenum, and chromium, converting them at once into their oxides.

It decomposes alkaline copper, silver, and bismuth nitrate solution with evolution of oxygen and formation of the metallic oxide, or in the last case the hydroxide (Berthelot, Compt. rend. 1901, 132, 897; Moser, Zeitsch. anorg. Chem. 1906, 50, 33; Gutbier and Bünz. Chem. Zentr. 1909, i. 732).

Hydrogen peroxide oxidises organic sulphides into sulphoxides (Gazdar and Smiles, Chem. Soc. Trans. 1908, 1833). It also reacts with benzene in presence of ferrous sulphate, forming phenol (Young, Chem. Soc. Proc. 1899, 131), and with α-diketones, and generally with substances possessing a quinonoid structure, and can therefore be employed for oxidising phenolic substances like brazilein and aurin, without having to protect the hydroxyl group by methylation (Perkin, Chem. Soc. Proc. 1907, 166). Hydrogen peroxide reacts with a number of opium alkaloids forming new crystalline bases (Freund and Speyer, Pharm. Zeit. 1907, 52, 115). According to Schaer (Arch. Pharm. 1910, 248, 458), it may be used as a test for other alkaloids. A few milligrams of the alkaloid to be tested are added to a cooled mixture of the peroxide and sulphuric acid. Quinine gives a lemon or canary yellow colour; berberine a cherry red; hydrastine a chocolate; emetine a dark orange, and nicotine a blood-red colour.

In presence of ferrous sulphate hydrogen peroxide also reacts with a number of sugars, forming osones (Cross, Bevan, and Smith, Chem. Soc. Trans. 1898, 403; Morell and Bellars, *ibid.* 1905, 280; Chem. Soc. Proc. 1902, 55; Chem. News, 1904, 90, 158). It also reacts with other organic compounds (Cross, Bevan, and Heiberg, Chem. Soc. Proc. 1899, 130; Harden, *ibid.* 158; Wolffenstein, Ber. 1895, 28, 1459; Bevan and Heiberg *ibid.* 1900, 33, 2015; Clover and Haughton, Amer. Chem. J. 1904, 32, 43).

Pure hydrogen peroxide reacts with potassium cyanide thus:

$$KCN+H_2O_2=KCNO+H_2O$$
$$KCNO+2H_2O=K(NH_4)CO_3.$$

Potassium formate and ammonia are also produced, but if the peroxide contains acid, then oxamide is formed (Masson, Chem. Soc. Trans. 1907, 1449).

---

prepared. Crystals of the $KMnO_4$ should be placed in a Woulff's bottle containing 1 : 9 sulphuric acid, and the 3 p.c. solution of H_2O_2 allowed to drop regularly into the solution from a suitable reservoir.

With potassium persulphate it reacts thus:

$$H_2O_2+K_2S_2O_8=2KHSO_4+O_2$$

an unstable intermediate compound is also formed (Friend, Chem. Soc. Trans. 1906, 1092).

With sodium thiosulphate it gives the reaction:

$$Na_2S_2O_3+4H_2O_2=Na_2S_3O_6+2NaOH+3H_2O$$
$$Na_2S_2O_3+2NaOH+4H_2O_2=2Na_2SO_4+5H_2O$$

(Willstätter, Ber. 1903, 36, 1831).

In presence of certain solid substances, especially when finely divided, hydrogen peroxide undergoes violent decomposition, the substances themselves remaining unchanged (Fillippi, Chem. Zentr. 1907, ii. 1890; Antropoff, Zeitsch. physikal. Chem. 1908, 62, 513; Bredig Wilkie, Biochem. Zeitsch. 1908, ii. 67). This is the case with carbon, many metals, and oxides, and iodine (Walton, Zeitsch. physikal. Chem. 1904, 47, 185; Abel, Zeitsch. Elektrochem. 1908, 14, 589). Gold, platinum, and particularly silver, act most violently and evolve great heat. The presence of acids retards this decomposition, whilst the presence of alkalis facilitates it.

This decomposition is still more readily brought about by these metals when in the colloidal state (Bredig and Reinders, Chem. Zentr. 1901, ii. 87; Bredig, Zeitsch. physikal. Chem. 1899, 31, 258; *ibid.* 1901, 37, 323; *ibid.* 38, 122; Price and Denning, *ibid.* 1903, 46, 89; Brossa, *ibid.* 1909, 66, 162; Spear, J. Amer. Chem. Soc. 1908, 30, 195; *see* also Kastel and Loevenhart, Amer. Chem. J. 1903, 29, 563; Liebermann, Ber. 1904, 37, 1519; Bredig, *ibid.* 798; Poppada, Gazz. chim. ital. 1907, 37, ii. 172).

Hydrogen peroxide is also decomposed by *catalases*, a class of organic ferments which are widely distributed in the animal and vegetable kingdoms (Senter, Proc. Roy. Soc. 1904, 74, 201; Wender, Chem. Zeit. 1904, 28, 300, 322; Euler, Chem. Zentr. 1905, i. 941; Bach, Ber. 1904, 37, 3785; *ibid.* 1905, 38, 1878; Laer, Bull. Soc. chim. Belg. 1906, 19, 337; J. Inst. Brewing, 1906, 12, 313; Rywosch, Centr. Bakt. Par. 1907, i. 44, 295).

Hydrogen peroxide also acts as a deoxidising agent; thus silver oxide when brought in contact with it causes a mutual decomposition of the two compounds $Ag_2O+H_2O_2=H_2O+O_2+Ag_2$, an atom of oxygen is liberated from each compound, and a molecule of free oxygen is thus obtained. A similar reaction occurs when hydrogen peroxide and ozone are brought together, $H_2O_2+O_3=H_2O+2O_2$ (Mulder, Rec. trav. chim. 1903, 22, 388; Baeyer and Villiger, Ber. 1902, 34, 749; 2769; Inglis, Chem. Soc. Trans. 1903, 1013).

Hydrogen peroxide is reduced by manganese dioxide and peroxide of lead in presence of an acid, $H_2O_2+MnO_2=MnO+O_2+H_2O$.

Alkaline mercury salts are reduced to the metallic state by hydrogen peroxide (Kolk, Chem. Zeit. 1901, 25, 21). Direct sunlight accelerates the decomposition of hydrogen peroxide. The effect of hydrogen peroxide on a photographic plate is similar to that of light, and is probably due to the hydrogen peroxide vapour itself, and not to a radiation from it (Russell, J. Soc. Chem. Ind. 1899, 516; Otsuki, *ibid.* 1905, 575; Precht and Otsuki, *ibid.* 290; Dony-Hénault, *ibid.* 1904, 138; Graetz, Chem. Zentr. 1904, ii. 1561; Dony-Hénault, *ibid.* 1906, ii. 203; Bull. Soc. chim. Belg. 1908, 22, 224; Soeland, Ann. Physik. 1908, [iv.] 26, 899).

Hydrogen peroxide forms molecular compounds with certain inorganic and organic salts in which it appears to play the same part as water of crystallisation (Tanatar, Chem. Zeit. 1901, 25; Rep. 326; J. Russ. Phys. Chem. Soc. 1908, 40, 376; Staedel, *l.c.*; Jones and Carroll, Amer. Chem. J. 1902, 28, 284; Willstätter, Ber. 1903, 36, 1828; De Forcrand, Compt. rend. 1902, 134, 601).

An acidified solution of potassium dichromate in presence of hydrogen peroxide gives rise to an unstable combination of chromic acid and the dioxide; this, on mixing with ether, can be extracted from the aqueous solution, imparting to it a beautiful and characteristic blue colour.

A solution of guaiacum mixed with a small amount of blood gives a blue colouration on addition of hydrogen peroxide. This is a delicate test for the compound, and serves also as a test for blood.

Hydrogen peroxide gives a blue-green colouration with an alcoholic solution of guaiacol and sulphuric acid, and an intense yellow colour with a solution of quinine sulphate in concentrated sulphuric acid (Denigès, Pharm. J. 1909, July 31st).

In the presence of hydrogen peroxide, chlorates, bromates, iodates, phosphates, sulphates, and alkali hypohalites, also salts of organic acids, give a yellow-green colouration with 1 p.c. guaiacol solution. On addition of hydrochloric or sulphuric acid the colour changes to red (Baudran, Compt. rend. 1905, 141, 891). Solutions of vanadic and titanic acids are turned brown or red by the peroxide and with a mixture of potassium chlorate and aniline in the presence of acid a violet colour is formed after a short time (Bach, Compt. rend. 1894, 119, 1218); if dimethylaniline is used instead of aniline, a yellow colour is formed. By the latter reaction 1 part of peroxide in 5,000,000 can be detected.

When hydrogen peroxide is added to a solution of potassium iodide, even in presence of ferrous sulphate or copper sulphate, iodine is set free, which may be shown by the colouration of starch. Hydrogen peroxide is the only compound known which can liberate iodine in presence of ferrous sulphate (*cf.* Traube, Ber. 1884, 17, 1062), 1 part in 25,000,000 can thus be detected.

A very delicate reagent for hydrogen peroxide has been suggested by Charitschkoff (Chem. Zeit. 1910, 34, 50). It consists of the pinkish-red cobalt salts of the naphthenic acids obtained from the waste liquors from the refining of petroleum with alkali. A strip of filter paper is dipped into a petroleum solution of the cobalt salt, and, after drying, is moistened with the liquid to be tested. If the peroxide is present the colour changes immediately to olive-green. Ozone does not give this reaction.

For other tests *see* Denigès (Bull. Soc. chim. 1890, 797); Aloy (*ibid.* 1902, 27, 734); Precht and Otsuki (Zeitsch. physikal. Chem. 1905, 52, 236).

Technical applications.—Moistened lead sulphide in contact with hydrogen peroxide is quickly oxidised to lead sulphate. This fact has led to the employment of hydrogen peroxide as a *picture restorer.* The painting darkened by age or by exposure to air containing sulphuretted hydrogen, owing to the white lead employed as body colour being partially converted into lead sulphide, after careful treatment with an aqueous solution of the peroxide is found to be greatly improved in colour from the oxidation of the sulphide to the white sulphate.

Dilute solutions of hydrogen peroxide mixed occasionally with nitric acid, are also used as 'auricome,' 'golden hair water,' &c., for imparting a light colour to the hair (Schrötter, Ber. 1874, 7, 980; Lange, Dingl. poly. J. 1886, 259, 196).

It is also employed for removing the last traces of chlorine from vegetable fibres which have been bleached with the latter, and to remove the last traces of sulphur dioxide from bleached wool and silk.

Hydrogen peroxide may be used for bleaching in many cases where other agents, such as bleaching powder, sulphurous acid, chlorine, would be injurious. It is particularly valuable for bleaching ostrich feathers, bones, ivory, silk, wood, cotton, the teeth, &c.

The advantages of using hydrogen peroxide as a bleaching agent, particularly for wool, are claimed to be the following: a purer white can be obtained; the fibres are not tendered by it to the same extent as by the sulphur bleach; the wool, after bleaching, does not turn yellow, does not emit an unpleasant odour when in contact with perspiration, and purer tones and more even colours can be obtained on dyeing the bleached wool. It is also stated to be more convenient to use, more pleasant for the workpeople, and less corrosive on the machinery. With care, the process, moreover, need not be much more expensive than with the older bleaches, and it is now used very extensively and with good results, both in England and on the Continent (Wachtel, Färber-Zeit. 1900, 11, 268; Russell, Proc. Roy. Soc. 1899, 64, 409).

In the case of wool the scoured article is first soaked thoroughly in a dilute solution of sodium silicate (2 lbs. to 10 gallons). After saturation the wool is wrung out and placed in the peroxide bath, which is prepared by adding 3½ gallons of 10 volume peroxide to 6½ gallons of water in which ½ lb. of sodium silicate has been dissolved. The wool is kept in the bath for about 24 hours (or a shorter or longer interval depending on the quality of the wool and on the whiteness desired) at 80°F. Occasionally the wool is turned over, and the solution tested whether it is alkaline, which it must be for satisfactory results. It is then pressed through a wringing machine and dried at a temperature of 15°–17°C., and preferably in the sunlight. When quite dry the wool is well washed and redried (Fawsitt, J. Soc. Chem. Ind. 1902, 229; Luttringhaus, Färber-Zeit. 1901, 12, 328; Dommergne, Rev. Chim. Ind. 1896, 7, 73).

With slight modifications this process is also applicable to cotton, straw and silk, but for the two last, the peroxide solution is made up of 1 part 10 volumes peroxide to 2 of water, and for every 10 volumes of peroxide, 4 ozs. of sodium silicate is employed (Fawsitt, *l.c.*; Koechlin, J. Soc. Chem. Ind. 1899, 1119). In the case of silk the bath may be made strongly alkaline with caustic soda from the beginning of the process.

Bone and ivory are first cleansed by treatment with light petroleum, ammonia or other solvent; they are then immersed in a bath containing 1 of 10 volumes peroxide to 2 of water made slightly alkaline with ammonia. Feathers are bleached similarly, but are washed after bleaching with a dilute solution of sulphuric acid.

On a small scale lace can be bleached conveniently in the following way: The material, after being moistened with water, is immersed in a solution of potassium permanganate for a few minutes. It is then rinsed and treated for about 10 minutes with a very dilute solution of hydrogen peroxide, after which it is treated with acid to remove the manganous oxide formed in the previous operation (Thomas, J. Soc. Chem. Ind. 1900, 734).

For bleaching delicate materials the hydrogen peroxide should not be too strong; a solution of 1 in 10 is strong enough, and a bleaching vat of this solution may be used for a long time if the strength be kept up by fresh additions of hydrogen peroxide. In bleaching dead hair, it is first digested for 12 hours in a solution of 3 parts of ammonium carbonate in 100 of water at a temperature of 30°C., rinsed, then washed with soap and treated with ammonium carbonate until all fatty matter is removed. Thus prepared it is treated in a bath of hydrogen peroxide and water as in the first case.

Hydrogen peroxide has been used for tanning leather, also to disinfect hides that have been long stored, and to preserve extracts of tanning materials (Göhring, J. Soc. Chem. Ind. 1890, 84). It has also been recommended for use in photographic processes (Smith, J. 1873, 1131; Gros, D. R. PP. 147131; 153769; 158368; Otsuki, *l.c.*; Lüppo Cramer, Chem. Zeit. 1902, 26, Rep. 292, 336; Ebert, *ibid.* 27, Rep. 152).

Medicinal and surgical applications.—As an antiseptic and disinfectant it has the advantage of (1) being odourless; (2) yielding oxygen without leaving any residuum but pure water; (3) absence of injurious influence on the organism.

The antiseptic properties of hydrogen peroxide solution were first brought into notice by Richardson in 1860. They were also studied by Kingzett, and subsequently by Paul Bert and Regnard (Compt. rend. 1882, 94, 1383).

It is used in the treatment of syphilitic and scrofulous sores, alveolar abscesses, and purulent discharges. It is also of great value in cases of purulent discharge from the conjunctiva, and it is particularly efficient for destroying diphtheritic membranes.

Its behaviour is that of a powerful oxidising agent, but on healthy skin its action is slow. In contact with fistulous wounds or pus it is rapidly decomposed with effervescence, which continues till the wound is cleansed or the diseased secretion is destroyed (Kingzett, J. Soc. Chem. Ind. 1890, 3; Paneth, Chem. Zentr. 1890, 174; Schmidt, *ibid.* 1906, ii. 145; Jaubert, *ibid.* 1905, ii. 99).

Hydrogen peroxide may be used to bleach discoloured teeth. In cases where the teeth are covered with coloured matter (*Lichen dentalis*, &c.) peroxide of hydrogen in conjunction with finely levigated pumice-stone may be employed in place of water. A suitable liquid for cleansing the teeth and mouth is prepared by mixing 1 part of 3 p.c. peroxide of hydrogen with 9 parts of water (Chem. News, 45, 71; and Ch. Trade J. April 14, 1888).

It has been proposed to use mixtures of hydrogen peroxide containing starch, cooked or in viscid solution, with anhydrous calcium sulphate as dentrifices, the starch preventing loss of oxygen from the oxide and the latter preserving the starch from putrefaction (Queissier, Fr. Pat. 381924, 1907; J. Soc. Chem. Ind. 1908, 226).

Hydrogen peroxide has the power of freeing water from living organisms, a property which has been utilised in brewing. It also destroys the acid and mould ferments in the wort. In stronger doses it destroys the alcoholic ferment and stops fermentation (G. Reisenbichler, Chem. News, 56, 219; Miquel, Monit. Scient. 1884, [3] 14, 170; Chodat and Bach, Ber. 1902, 35, 1275; Loew, *ibid.* 2487; Bonjean, Compt. rend. 1905, 140, 50; Laer, J. Inst. Brewing, 1909, 15, 553).

Altenhöfer has recommended hydrogen peroxide as a disinfectant for drinking water (Zentr. Bakteriol and Parasitenkde, 1890, 129; Küster, Chem. Zentr. 1889, i. 411; 1891, ii. 272; 1895, i. 948; but see also Gourmont, Nagier, and Rochaix, Compt. rend. 1910, 150, 1453).

Hydrogen peroxide is one of the chief constituents of 'sanitas,' which is a solution of the products of oxidation of terpentine oil in the presence of water and air (Kingzett).

It has been tried with success in the preservation of beer; after a month the taste and aroma of the beer remained good (Weingartner, Bied. Zentr. 1884, 428).

Hydrogen peroxide has been suggested as a useful and harmless preservative of milk (Jablin and Gounet, Ann. Chim. anal. 1901, 6, 129; J. Soc. Chem. Ind. 1902, 420; *ibid.* 1905, 1184; Fr. Pat. 355547; Amberg, J. Biol. Chem. New York, 1906, i. 219).

To test milk for hydrogen peroxide, 10 drops of a 2 p.c. alcoholic solution of benzidine and a few drops of acetic acid are added to 10 c.c. of the milk. If hydrogen peroxide is present a blue colouration appears. The peroxide can be detected in this way in other liquids if a little milk serum is added (Wilkinson and Peters, Zeitsch. Nahr. Genussm. 1908, 16, 172, 515, 589; for other tests, *see* Feder, *ibid.* 15, 234; Arnold and Mentzel, *ibid.* 1903, 6, 305).

Hydrogen peroxide is used in the laboratory in the valuation of bleaching-powder, the principle depending upon the fact that hypochlorites, when mixed with hydrogen peroxide, instantly evolve all their oxygen, at the same time liberating the oxygen of the peroxide (J. Soc. Chem. Ind. 1887, 391). It is also employed in estimating the amount of active oxygen in potassium permanganate and in manganese dioxide (Schlossberg, Zeitsch. anal. Chem. 1902, 41, 735; Carnot, Compt. rend. 1893, 116, 1295). The amount of sulphur in sulphides is also determined by first oxidising the sulphate and then proceeding as usual (G. Lunge, Ber. 18, 1872; *see* also Baumann, Zeitsch. angew. Chem. 1890, 72; Talbot and Moody, J. Soc. Chem. Ind. 1893, 780).

Hydrogen peroxide has been employed in the separation of a number of metals from one another (Rose, Ber. 1894, 27, 2227; Lesinsky, *ibid.* 1893, 26, 1496, 2331, 2908; Jannasch and Röttgen, Zeitsch. anorg. Chem. 1895, 8, 202; Friedheim and Brühl, Zeitsch. anal. Chem. 1899, 38, 681). Also for the separation of the halogens (Jannasch and Zimmermann, Ber. 1906, 39, 196, 3655), and for separating vanadium from ores and slags (Fr. Pat. 357397; J. Soc. Chem. Ind. 1906, 72).

Hydrogen peroxide has also been used as a solvent for Indian gum (Bull. Soc. Ind. Mulhouse, 1894, 36), but its use in the estimation of the quantity of flour in a mixture of the latter with bran, is considered to be untrustworthy by Bremer (Zeitsch. Nahr. Genussm. 1906, 11, 569).

Hydrogen peroxide has been employed with success in determining the amount of sulphur in coal gas. The solution used for this purpose consists of the commercial product diluted to a 1 p.c. solution. This solution is run into the Referees' 'apparatus,' through which the coal gas passes at a measurable rate, and the sulphurous acid gas in it is oxidised to sulphuric acid $SO_2+H_2O_2=SO_4H_2$. The amount of sulphur is then determined by titration or precipitation (J. Soc. Chem. Ind. 1887, 285).

Higher oxides of hydrogen.—The oxides H_2O_4 and H_2O_3 have been described (Bach, Ber. 1900, 33, 1506, 3111; *ibid.* 1902, 35, 158; Berthelot, Compt. rend. 1900, 131, 637), but it is doubtful whether they really exist (Armstrong, Chem. Soc. Proc. 1900, 134; Ramsay, Chem. Soc. Trans. 1901, 1324; *see* also Baeyer and Villiger, 1900, 33, 2488; Clover, Amer. Chem. J. 1903, 24, 463; Brühl, Chem. Zentr. 1896, i. 86; Nagel, Pharm. Zeit. 1898, 43, 556). Kastner (J. 1820, 472) described a *suboxide*, but its existence has not been confirmed.

HYDROGEN SULPHIDES *v.* SULPHUR.

HYDROLITES *v.* AGATE.

HYDROLYSIS. The term hydrolysis (or hydrolytic dissociation) is given to a number of different chemical reactions, all of which consist in the addition of water to a complex, and the subsequent resolution of the product into simpler substances.

Some of the best-known types of hydrolysis are those of metallic salts, esters, acid chlorides, amides, &c., or generally acyl derivatives, complex carbohydrates, and glucosides, and finally, polypeptides and proteins.

1. **Hydrolysis of salts.** The hydrolysis of a salt by water may be represented by means of an equation of the type:

$$KCN+H{\cdot}OH \leftrightarrows HCN+KOH.$$

The reaction is a balanced one, and may be regarded as due to the incomplete neutralisation of the acid and base from which the salt is derived; in terms of the ionic theory the acid in question (HCN) does not yield sufficient hydrions to combine with the hydroxyl ions of an equivalent quantity of the strong base (KOH). When equivalent quantities of a strong acid and a strong base are brought together in aqueous solution complete neutralisation takes place, and a normal salt with a neutral reaction towards common indicators is formed. (Basis of methods of acidimetry and alkalimetry.) In the cases of such salts appreciable hydrolysis would not be expected even in dilute solution. The following are the common types of salts which are hydrolysed by water: (1) salts derived from feeble acids and strong bases; (2) salts from strong acids and feeble bases; (3) salts from feeble acids and feeble bases. As examples of the first type we have potassium cyanide and sodium phosphate.

$$KCN+H{\cdot}OH \rightleftarrows HCN+KOH$$

$$Na_3PO_4+H{\cdot}OH \rightleftarrows Na_2HPO_4+NaOH$$

and even

$$Na_2HPO_4+H{\cdot}OH \rightleftarrows NaH_2PO_4+NaOH$$

Solutions of such salts invariably have an alkaline reaction towards common indicators, *e.g.* litmus, phenolphthalein. The water may be regarded as a feeble acid, which, like any other feeble acid, liberates a certain amount of acid from the salt with which it is brought into contact. In many cases acid salts are first formed, *e.g.* sodium phosphate, sodium carbonate, but free acid and free base may be liberated. The alkaline reaction of the solution can be accounted for by the fact that the feeble acid, or the acid salt formed, is ionised to a slight extent only, whereas with moderately dilute solutions the strong base is almost completely ionised, and thus there is a great excess of hydroxyl ions over hydrions. As examples of the second type we have ferric chloride and cupric sulphate, which are derived respectively from the feeble bases, ferric hydroxide and cupric hydroxide. The aqueous solutions of such salts invariably give an acid reaction. The hydrolysis may be represented by means of the equations:

$$FeCl_3+H{\cdot}OH \leftrightarrows FeCl_2{\cdot}OH+HCl$$

or even $FeCl_3+3H{\cdot}OH \leftrightarrows Fe(OH)_3+3HCl$

and $CuSO_4+2H{\cdot}OH \leftrightarrows Cu(OH)_2+H_2SO_4$.

With moderately concentrated solutions basic salts, *e.g.* $FeCl_2{\cdot}OH$ are almost certainly formed, and it is only in very dilute solution that the hydrolysis will proceed to the formation of the metallic hydroxide, and even when this is formed it is not precipitated, but remains in solution in the form of a colloid. A group of salts which belongs to this type is that of the salts dervied from feeble organic bases such as aniline, and from the strong mineral acids, *e.g.*

$$\underset{\text{Aniline hydrochloride.}}{C_6H_5{\cdot}NH_3Cl}+H{\cdot}OH \rightleftarrows \underset{\text{Aniline hydroxide.}}{C_6H_5{\cdot}NH_3{\cdot}OH}+HCl$$

$$\rightleftarrows C_6H_5NH_2+H_2O+HCl.$$

As examples of the third type we have ferric phosphate, aluminium carbonate and sulphide, and aniline acetate. The hydrolysis in the first case is readily shown by washing finely divided ferric phosphate with distilled water, when it is found that the filtrate is always distinctly acid, owing to the free phosphoric acid which has been washed away by the water, and if the operation is continued nearly pure ferric hydroxide remains on the filter. In the case of the two aluminium salts, they are so readily hydrolysed that when brought into contact with water they yield the corresponding metallic hydroxide, and the free acids, carbonic acid and hydrogen sulphide, which escape and thus destroy the equilibrium.

In the case of salt formation we may regard the water as capable of acting as either a feeble base or a feeble acid. When in contact with equivalents of a strong acid and a feeble base the water competes with the base for the acid, and hence neutralisation is not complete, or, in other words, hydrolyis of the salt occurs and the feebler the base the greater the degree of hydrolysis. The mechanism of salt hydrolysis according to the ionic theory is as follows: In aqueous solution the given salt, *e.g.* potassium cyanide is ionised in the ordinary manner into $\overset{+}{K}$ and $\overset{-}{CN}$ ions, but water itself is ionised to a certain extent, $H_2O \rightleftarrows \overset{+}{H}+\overset{-}{OH}$, and as hydrogen cyanide is a very feeble acid, and therefore ionised to only a very slight extent in aqueous solution, there is a tendency for the $\overset{+}{H}$ ions of the water to combine with the $\overset{-}{CN}$ ions from the cyanide, yielding undissociated HCN, the result is that the equilibrium $H_2O \rightleftarrows \overset{+}{H}+\overset{-}{OH}$ is destroyed and more molecules of water are ionised, but this results in further combination between $\overset{+}{H}$ and $\overset{-}{CN}$ ions, and by this means an excess of $\overset{-}{OH}$ over $\overset{+}{H}$ ions is produced, and thus the alkaline reaction. The changes continue until ultimately an equilibrium is established between the KCN, $\overset{-}{CN}$, $\overset{+}{K}$, $\overset{+}{H}$, $\overset{-}{OH}$, HCN, and H_2O present. The degree of hydrolysis, *i.e.* the fraction of the salt hydrolysed, cannot be determined by direct titration of the free acid or free base present in the solution; the addition of standard acid to the solution of potassium cyanide would immediately destroy the equilibrium which previously existed, and more salt would be hydrolysed in order to restore the equilibrium, and the point of neutrality would not be reached until acid sufficient to decompose the salt completely had been added. The methods commonly adopted for determining the degree of hydrolysis are (*cf.* Farmer, B. A. Report 1901, 240): 1. Determination of the concentration of the free acid or free alkali present in the solution of the salt by its catalytic effect on the hydrolysis of an aqueous solution of ethyl acetate or on the inversion of a solution of cane sugar, and then determining the amount of pure acid or alkali required to produce the same effect (for acid, *cf.* Walker, Zeitsch. physikal. Chem. 1889, 4, 319; for alkali, *cf.* Shields, *ibid.* 1893, 12, 167; also Bruner, *ibid.* 1900, 32, 133; Ley, *ibid.* 1899, 30, 216; Walker and Aston, Chem. Soc. Trans. 1895, 67, 576). 2. Determination of the electrical conductivity of the solution (Walker, Zeitsch. physikal. Chem. 1889, 4, 333; Bredig, *ibid.* 1894, 13, 313; Denham, Chem. Soc. Trans. 1908, 93, 41). The molecular conductivity of a hydrolysed salt of the type aniline hydrochloride is made up of two quantities: (*a*) conductivity due to the non-hydrolysed salt; (*b*) conductivity due to the free acid formed on hydrolysis—since the free base (aniline) is not an electrolyte. $M=(1-x)u_1+xu_{HCl}$, where M = molecular conductivity, x=degree of hydrolysis, u_1=molecular conductivity of non-hydrolysed salt. The various quantities in the equation with the exception of x can be determined and then x calculated. 3. By determining the partition coefficient (Farmer, Chem. Soc. Trans. 1901, 79, 863). In the case of aniline hydrochloride the hydrolysis of the salt leads to the formation of free aniline and hydrochloric acid, and the concentration of the free base is determined by shaking the aqueous solution at a given temperature with a known volume of benzene, and finding the concentration of the aniline in the benzene layer. Since C_B/C_{Aq} is always constant (C_B=concentration of aniline in benzene and C_{Aq}=concentration of aniline in water) for a given temperature the concentration of free aniline in the aqueous layer can be calculated directly, and thus the degree of hydrolysis determined. The assumption is made that the salt present does not effect the partition coefficient to an appreciable extent. 4. By the change in colour produced by a solution of the hydrochloride of an organic base on a solution of methyl orange of known concentration, and a comparison of this change with that produced by the addition of known quantities of hydrochloric acid (Veley, Chem. Soc. Trans. 1908, 93, 652, 2114, 2122; 1909, 95, 758; Trans. Far. Soc. 1908, 4, 19).

Most of the methods give only rough approximations (*cp.* Beveridge, Proc. Roy. Soc. Edin. 1909, 29, 648). A few of the results obtained are as follows:—

Salt	Temp.	P.c. of salt hydrolysed in 0·1 N solution	Method
Glycine hydrochloride	25°	19·00	Hydrolysis of ester
Acetoxime ,,	25	36·00	,, ,,
Urea ,,	25	90·00	,, ,,
Urea ,,	60	81·00	Inversion of sugar
Sodium cyanide .	25	1·10	Saponification of ester
,, acetate .	25	0·008	,, ,,
,, carbonate .	25	3·17	,, ,,
,, phenate .	25	3·05	,, ,,
Aniline hydrochloride	60	2·60	Inversion of sugar
,, ,,	25	1·50	Conductivity
Zinc chloride . .	100	0·10	Inversion of sugar
Aluminium chloride .	100	6·10	,, ,,
,, ,, .	25	0·50	Conductivity
Ferric chloride . .	40	10·00	Inversion of sugar
Lead ,, . .	25	0·50	Conductivity

The whole question becomes more complicated when the acid or base formed by hydrolysis is unstable and is transformed into an isomeride (pseudo-acid or pseudo-base).

The influence of concentration on hydrolysis is given by Guldberg and Waage's law of mass action. According to this $\frac{C_S}{C_A \times C_B}$=constant, where C_S represents the concentration (molar) of the non-hydrolysed salt, C_A that of the acid formed by hydrolysis, and C_B that of the base. If originally 1 gram mol. of salt was dissolved in v litres of solution and x gram mols. were hydrolysed, then

$$\frac{1-x}{v}\bigg/\frac{x}{v}\cdot\frac{x}{v}=\text{constant, or}\frac{v(1-x)}{x^2}=\text{constant.}$$

It is obvious that as v increases, *i.e.* as the concentration is diminished, x, *i.e.* the degree of hydrolysis, must increase in order to keep the whole expression constant.

The relationships are not quite the same in the case of a salt derived from a feeble base and a feeble acid, *e.g.* aniline acetate.

$$C_6H_5{\cdot}NH_3{\cdot}O{\cdot}CO{\cdot}CH_3+H_2O \rightleftarrows C_6H_5{\cdot}NH_3{\cdot}OH+CH_3{\cdot}CO{\cdot}OH.$$

If the reaction is represented as taking place between the ions of the salt and the water, and the salt is practically completely ionised, and the base and acid not appreciably, then $C_{Cat}{\cdot}C_{An}/C_A{\cdot}C_B$=constant, where C_{Cat}=concentration of the cation and C_{An}=concentration of the anion. But $C_{Cat}=C_{An}=C_{Salt}$.

$$\therefore\ C^2_{Salt}/C_A{\cdot}C_B=\text{constant, or}\left(\frac{s}{v}\right)^2\bigg/\frac{a}{v}\cdot\frac{b}{v}=\text{constant}$$

where s, a, b are the gram mols. respectively of salt, acid, and base in v litres of solution. But this expression is independent of v, and hence dilution does not affect the degree of hydrolysis.

Another factor which affects the degree of hydrolysis is the addition to the solution of one of the products of hydrolysis, *e.g.* free acid or free base. Thus the hydrolysis of aniline hydrochloride in aqueous solution can be stopped completely by the addition of hydrochloric acid or of aniline. This follows again directly from the equation $C_S/C_A{\cdot}C_B$=constant. If C_A, *i.e.* the concentration of the acid is increased it is necessary, in order that the whole expression may remain constant, that either C_B should diminish or C_S increase or both, and the only way in which this can be affected is by a diminution in the degree of hydrolysis.

The velocity of salt hydrolysis has been determined in a few cases, *e.g.* ferric chloride (Goodwin, Zeitsch. physikal. Chem. 1896, 21, 1); potassium ruthenium chloride K_2RuCl_5 (Lind and Bliss, J. Amer. Chem. Soc. 1909, 31, 868).

A type of hydrolysis analogous to salt hydrolysis is that of the chlorides of certain non-metals, *e.g.* $PCl_3+3H_2O=3HCl+P(OH)_3$. This reaction proceeds to completion in the presence of an excess of water, and, as a rule, the chlorides of non-metals are hydrolysed more readily than those of metals. Nitrogen trichloride and carbon tetrachloride are, however, stable in the presence of water and many metallic chlorides derived from feeble electropositive metals are appreciably hydrolysed, *e.g.* $FeCl_3$, $BiCl_3$, &c.

2. **Hydrolysis of esters.** The hydrolysis of an ester may be brought about by water alone, by solutions of neutral metallic salts, by aqueous solutions of strong alkalis or acids, by water in the presence of finely divided solids, such as charcoal, and also by means of enzymes.

The reaction with water may be represented by an equation of the type:

$$CH_3{\cdot}CO{\cdot}OC_2H_5+H{\cdot}OH \rightleftarrows CH_3{\cdot}CO{\cdot}OH+C_2H_5OH$$

The reaction is the reverse of esterification, and is hence a balanced bimolecular reaction; in dilute solutions, however, the mass of the water may be regarded as remaining constant, and the reaction becomes practically non-reversible. The course of the reaction can be followed by estimating the amount of free acid in the solution after given intervals of time; this is accomplished by removing an aliquot part of the solution at the given time and titrating the free acid by means of standard alkali solution. In most cases it is necessary to use a feeble alkali for titration, *e.g.* ammonium hydroxide using litmus as indicator, as nearly all esters which are hydrolysed appreciably by water are decomposed very readily by strong alkalis, and it becomes impossible to tell the end point of the titration when sodium or barium hydroxide solutions are used. Comparatively few esters are hydrolysed to any appreciable extent by water at the ordinary temperature, the few that have been investigated are esters derived from comparatively strong acids, *e.g.* ethyl nitrate, ethyl formate, ethyl trichloroacetate, and ethyl pyruvate. In these cases the velocity of the reaction does not correspond with that of a simple unimolecular reaction, the values for K calculated by means of the usual equation $K=1/t \log a/a-x$, increase as t increases, and the probable reason is that the acid formed during the hydrolysis reacts catalytically on the reaction (*see* under hydrolysis by acids). Hydrolysis of natural glyceryl esters by means of superheated steam is used as a commercial method for the production of stearic acid for the manufacture of candles.

The hydrolysis of esters by means of dilute mineral acids is slow and readily lends itself to study as a time reaction. The velocity is directly proportional to the concentration of the mineral acid, *i.e.* probably to the hydrions which act as a catalyst, and the reaction may be represented by the differential equation

$$dx/dt=K{\cdot}C_{\text{Ester}}{\cdot}C_{H_2O}{\cdot}C_{\overset{+}{H}}.$$

In dilute solution, and most esters are somewhat sparingly soluble in water, C_{H_2O} can be regarded as not changing, and $C_{\overset{+}{H}}$ is also constant, since the catalyst is not used up during the reaction. The process thus becomes a typical unimolecular reaction, and the velocity constant can be determined with the aid of the usual formula $K=1/t \log_e a/a-x$.

The concentration of the organic acid at any given time is obtained by titrating a portion of the solution with standard barium hydroxide solution and phenolphthalein (unless the ester is derived from a strong acid when ammonia and litmus are used) and subtracting from the total alkali used the amount required by the mineral acid. The following relative values have been obtained at 25°, using 0·1 N-hydrochloric acid as catalyst working with the methyl, ethyl, and propyl esters of acetic, propionic, and butyric acids:

K methyl ester : K ethyl ester=0·97
and K ethyl ester : K propyl ester=1·01.
K acetate ester : K propionate ester=1·07
K propionate ester : K butyrate ester=1·75
K butyrate ester : K valerate ester=2·93.

From these values it is clear that in the hydrolysis of an ester R·CO·OR′ by means of a strong mineral acid the acyl group R·CO has a much greater influence than the alkyl group R′ on the velocity of hydrolysis (Hemptinne, Zeitsch. physikal. Chem. 1894, 13, 562). Lowenherz (*ibid.* 1894, 15, 389) working at a temperature of 40° found that ethyl formate is hydrolysed much more readily than ethyl acetate (ratio 20 : 1); that methyl and ethyl monachloroacetates are hydrolysed at much the same rates, ratio 1·01 : 1, that the ratio K ethyl acetate : K ethyl monochloroacetate=1·7 and that K ethyl dichloroacetate : K ethyl monochloroacetate =1·6, and that ethyl benzoate is hydrolysed extremely slowly.

The majority of chemists are of opinion that the process of hydrolysis consists first of all in the formation of an additive compound between the ester and the water, *e.g.*  $\mathrm{R{\cdot}C}\begin{cases}\mathrm{OH}\\ \mathrm{OH}\\ \mathrm{OEt}\end{cases}$ (*cp.* esterification), and the subsequent breaking up of this into acid and alcohol. The manner in which the complex dissociates, *e.g.* into water and ester, or into alcohol and acid, will depend largely on the relative amounts of water and alcohol present. A view put forward by Stieglitz, and supported by many chemists (*cp.* Acree and Johnson, Amer. Chem. J. 1907, 38, 335), is that the ester, being a feeble base, combines with the strong mineral acid used as catalyst, forming a salt, *e.g.* $R{\cdot}CO_2Et,HCl$, only small amounts of such salts would be formed, as the base is an extremely feeble one. The salt would be ionised in the usual manner into $\overset{-}{Cl}$ ions and complex cations $R{\cdot}C\overset{+}{O_2}Et,H$. It is these complex cations which then react with the water and undergo hydrolysis

$$R{\cdot}CO_2\overset{+}{E}t,H+H_2O=R{\cdot}CO_2H+EtOH+\overset{+}{H}$$

and the assumption has to be made that the hydrolysis of the complex cations proceeds more rapidly than the hydrolysis of the ester molecules. The view that it is the complex cation and not the unionised salt (ester hydrochloride) which reacts with the water is supported by the fact that the rate of hydrolysis is directly proportional to the concentration of the mineral acid, *i.e.* to the concentration of the hydrion and not to the square of the concentration of the hydrion.

The hydrolysis of an ester by means of an alkali hydroxide can be represented by an equation of the type:

$$\mathrm{R{\cdot}C}\begin{cases}\mathrm{O}\\ \mathrm{OEt}\end{cases}\!\!+KOH=\mathrm{R{\cdot}C}\begin{cases}\mathrm{O}\\ \mathrm{OK}\end{cases}\!\!+EtOH.$$

The reaction is non-reversible, as the alkali salt cannot react directly with the alcohol, and as both ester and alkali are used up as the hydrolysis proceeds the reaction should be bimolecular. Hydrolysis by alkalis proceeds more rapidly than that by mineral acids (*cp.* Van Dikjen, Rec. trav. chim. 1895, 14, 106), and is the common method used in the laboratory. The ester is boiled for some time with an excess of sodium (or potassium) hydroxide solution in a flask fitted with a reflux condenser. If the ester is an oil only sparingly soluble in water, the completion of the reaction is denoted by the disappearance of the oily layer, unless the alcohol formed is also insoluble in water. If, however, the ester itself is soluble in water, but has a characteristic odour, the disappearance of the odour indicates complete hydrolysis. In order to separate the acid and alcohol formed, the mixture is (*a*) boiled, when the alcohol passes over together with water, provided the alcohol is a comparatively simple monohydric one; (*b*) extracted with ether if the alcohol is complex and is not readily volatile. To obtain the acid the alkaline solute left after treatment (*a*) or (*b*) is acidified with hydrochloric acid, when the organic acid is directly precipitated if it is sparingly soluble in water, or can be extracted with ether if soluble in water.

An alcoholic solution of potassium hydroxide is sometimes used for hydrolysing purposes, especially when the ester is practically insoluble in water.

The decomposition of esters by alkaline hydroxide solutions is the basis for the usual methods for the manufacture of hard and soft soaps (*see* SOAP; SAPONIFICATION), and hence a common name for the process is '*saponification.*' The common fats are glyceryl esters of monobasic acids of high molecular weight, more especially of palmitic, stearic, and oleic acids, and on saponification yield the trihydric alcohol glycerol and the sodium or potassium salts of the acids, *e.g.*

$$C_3H_5(O{\cdot}CO{\cdot}C_{17}H_{35})_3+3NaOH$$
$$=C_3H_5(OH)_3+3C_{17}H_{35}{\cdot}COONa.$$

Reicher (Annalen, 1885, 228, 257) was one of the first to determine the velocity of saponification under varying conditions. When the alkali and ester are not used in equivalent quantities the differential equation is of the type

$$dx/dt=K(a-x)(b-x)$$

where a and b are the original concentrations, and $a-x$ and $b-x$ the concentrations at the time t. When integrated this gives an equation

$$K=\frac{1}{t(a-b)}\log_e\frac{b(a-x)}{a(b-x)}$$

for calculating K. The concentration of the alkali at any given time is determined by titration with standard acid and the concentration of the ester calculated from that of the alkali, as with an ester of the type of ethyl acetate, the disappearance of each gram molecule of alkali entails the disappearance of a gram molecule of ester (*cf.* Warder, Amer. Chem. J. 1882, 3, 340; Ber. 1881, 14, 1311). The velocity constant K can be calculated by means of the equation

$$K=\frac{1}{C_\infty t}\log_e\frac{C_t(C-C_\infty)}{C(C_t-C_\infty)}$$

where C, C_t, and C_∞ denote the concentration of the alkali just after mixing, the concentration after time t and the concentration after complete hydrolysis (24–48 hours).

Reicher's experiments were carried out at 9·4°, and show that the velocity is practically the same whether sodium, potassium, or calcium hydroxide is used as saponifying agent. With strontium or barium hydroxide the velocity constants are somewhat smaller and with a feeble alkali, such as ammonium hydroxide, the value for K is much less, *e.g.*

$$K_{NaOH}:K_{NH_4OH}=200:1.$$

The results obtained by using different esters show that the alkyl group R′ in the ester  $R{\cdot}C\begin{smallmatrix}\nearrow O\\ \searrow OR'\end{smallmatrix}$ influences the rate of hydrolysis to a greater extent than it does when mineral acids are used for hydrolysing; thus the values for K using sodium hydroxide at 9·4° are: methyl acetate 3·49, ethyl acetate 2·31, propyl acetate 1·92, *iso*butyl acetate 1·62, and *iso*amyl acetate 1·64. The influence of the acyl group R·CO is also marked, as shown by the following values for K at 14·4°, using sodium hydroxide and ethyl esters: acetate 3·2, propionate 2·8, butyrate 1·7, *iso*butyrate 1·73, *iso*valerate 0·62, and benzoate 0·83. Later experiments by Sudborough and Feilmann (Chem. Soc. Proc. 1897, 13, 243) prove that the introduction of methyl groups into the ethyl acetate molecule retards hydrolysis by means of alcoholic potassium hydroxide, whereas the introduction of chlorine atoms facilitates the decomposition. The investigations of Gyr (Ber. 1908, 41, 4308) show that two or three phenyl groups in the ethyl acetate molecule also retard hydrolysis, whereas the ethyl ester of phenylacetic acid is hydrolysed more readily than ethyl acetate itself. The results obtained by Hjelt (Ber. 1896, 29, 1864) with substituted derivatives of ethyl malonate also show that the introduction of an alkyl group into the ethyl malonate molecule retards hydrolysis, and that when two such groups are present the effect is still more noticeable. The influence of the strength of the acid from which the ester is derived also appears to be a determining factor. The investigations of Kellas (Zeitsch. physikal. Chem. 1897, 24, 243) on the hydrolysis of ethyl esters of substituted benzoic acids show that the esters of many substituted benzoic acids are hydrolysed by alcoholic potash more readily than ethyl benzoate itself. This appears to be true of all esters derived from acids much stronger than benzoic acid, *e.g.* the bromo-, chloro-, and nitro-benzoic acids, but does not hold good when the esters are derived from acids with small dissociation constants, *e.g.* the toluic acids. Kellas's results also show that when the rates of hydrolysis of a group of three isomeric esters are compared the ortho-compounds are invariably hydrolysed more slowly than the isomeric, meta-, and para- compounds, even when the ortho- acid is a much stronger acid than the isomers.

Findlay and Turner (Chem. Soc. Trans. 1905, 87, 747) and Findlay and Hickmans (*ibid.* 1909, 95, 1004) show that an *a*-hydroxyl group increases the readiness with which the ester is hydrolysed by alkalis. The ratio K ethyl glycollate : K ethyl acetate=11·5; and K ethyl lactate : K ethyl propionate=11·9, and K methyl mandelate : K methyl phenylacetate =5·7. The introduction of a phenyl group in the *a*-position does not necessarily increase the rate of hydrolysis. The ratio K ethyl phenylacetate : K ethyl acetate=1·9, but K ethyl mandelate : K ethyl glycollate=0·88. It is shown that there is no direct proportionality between the affinity constant of the acid and the saponification constant of its ester, although in any given series of compounds the two constants follow the same order. The results obtained by different authorities point to the general conclusion that two factors at least determine the rate of hydrolysis of ethyl esters by alkalis or acids. (*a*) The complexity of the acyl group, especially as regards the presence of substituents in close proximity to the carbonyl group, *e.g.* in the *a*-position in aliphatic, the ortho- position in aromatic, and probably the cis- position in unsaturated esters. (*b*) The strength of the acid from which the ester is derived. When mineral acids are used as hydrolysing agents the rate of hydrolysis appears to be determined largely by the first factor, although the second factor also has an effect, as shown by the fact that ethyl trichloroacetate is hydrolysed more readily than the dichloroacetate. When alkalis are used and also probably when water alone is used, the second factor has a much more marked effect than when acids are used; the effect is so marked in certain cases that the influence of the first factor is almost completely obscured, *e.g.* with the esters of the chloroacetic acids, of the α-hydroxy acids and of nitro substituted benzoic acids.

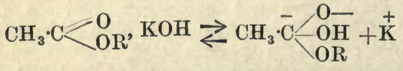
The generalisation drawn by V. Meyer (Ber. 1895, 28, 1263; *cp.* Wegscheider, *ibid.* 2536) viz. that there is a simple relationship between the rate of hydrolysis of an ester by alkalis and its rate of formation by the catalytic method of esterification does not hold. It is highly probable that there may be a relationship between the rate of esterification of an acid by the direct method and the rate of saponification of the ester, and also a relationship between the rate of hydrolysis of the ester by acids and the rate of esterification by the catalytic method. No relationship between the rate of saponification or by hydrolysis by acids and the constitution of the alkyl group R′ in the ester $R{\cdot}C\begin{array}{l}\diagup O\\ \diagdown OR'\end{array}$, can be deduced as the data available are not sufficiently numerous.

Since sodium, potassium, and calcium hydroxides as saponifying agents have practically the same effect when solutions of equivalent strengths are used, the conclusion has been drawn that the hydrolysis is due to the hydroxyl ions present. The reaction cannot be a simple addition of the alkali to the ester followed by the elimination of alcohol, as then the reaction with calcium hydroxide would be termolecular

$$2R{\cdot}CO_2Et+Ca(OH)_2=(R{\cdot}CO_2)_2Ca+2EtOH$$

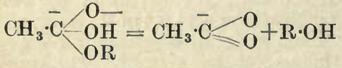
whereas it can be shown to be bimolecular.

It is possible that the reaction consists in the addition of water (not alkali) to the ester and the subsequent resolution of this complex into acid and alcohol. The alkali in this case would act first as a catalyst, and secondly as a base for neutralising the acid formed. According to Acree (Amer. Chem. J. 1907, 38, 344) the ester can function as a feeble acid and form small amounts of salts with the alkali, *e.g.*



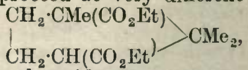
$$CH_3{\cdot}C\begin{array}{l}\diagup O\\ \diagdown OR'\end{array}, KOH \rightleftarrows CH_3{\cdot}\overset{-}{C}\begin{array}{l}\diagup O—\\ —OH\\ \diagdown OR\end{array}+\overset{+}{K}$$

and it is the complex anion which reacts with the water yielding the anion of the acid and alcohol



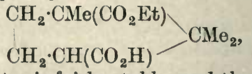
$$CH_3{\cdot}\overset{-}{C}\begin{array}{l}\diagup O—\\ —OH\\ \diagdown OR\end{array}=CH_3{\cdot}\overset{-}{C}\begin{array}{l}\diagup O\\ \diagdown O\end{array}+R{\cdot}OH$$

Esters of dibasic acids. J. Meyer (Zeitsch. physikal. Chem. 1909, 66, 81, and 67, 257) by the study of the hydrolysis of esters of dibasic acids (tartaric, succinic, and camphoric) with hydrochloric acid as catalyst, has been able to prove that the reaction proceeds in two distinct stages: (*a*) normal ester+water⟶acid ester +alcohol; (*b*) acid ester+water⟶acid+alcohol. With the ethyl esters of symmetrical dibasic acids, *e.g.* tartaric and succinic, the whole reaction appears to be unimolecular as the velocity constant for the first stage is almost exactly double that for the second stage, and the whole is pseudo-unimolecular. In the case of ethyl camphorate, the ester of an unsymmetrical acid, the two stages proceed at very different rates, the normal ester



$$\left.\begin{array}{l}CH_2{\cdot}CMe(CO_2Et)\\ |\\ CH_2{\cdot}CH(CO_2Et)\end{array}\right\rangle CMe_2,$$

is rapidly hydrolysed to the acid ester,



$$\left.\begin{array}{l}CH_2{\cdot}CMe(CO_2Et)\\ |\\ CH_2{\cdot}CH(CO_2H)\end{array}\right\rangle CMe_2,$$

but this latter is fairly stable, and the method is a convenient one for the preparation of the acid ester. For different esters of the same acid the influence of the alcoholic group on the rate of esterification is scarcely noticeable, whereas the constitution of the acyl group has a marked effect. Experiments carried out with the same esters using alkali hydroxide as hydrolysing agent show that here also the reaction proceeds in two distinct stages, but the relationship between the velocity constants of the two is not so simple as when hydrochloric acid is used. With ethyl malonate the first stage proceeds about 100 times as quickly as the second, but with ethyl succinate the ratio is about 10 : 1, and in neither case can the whole process be represented as a simple bimolecular reaction. With the esters derived from symmetrical dihydric alcohols, *e.g.* glycol diacetate $C_2H_4(OAc)_2$, although the saponification proceeds in two distinct stages the velocity constants of the two stages bear a simple relationship to one another, *e.g.* 2 : 1, and hence the whole appears to be a bimolecular reaction. The same holds good for the hydrolysis of glyceryl triacetate, where the three distinct stages proceed at the relative rates 3 : 2 : 1.

Esters of sulphonic acids. Esters of sulphonic acids can also be hydrolysed by water, mineral acids, or alkalis, and since most of the sulphonic acids are very strong acids, their esters are hydrolysed quite readily by water alone. The esters are also converted into the corresponding acids when heated with alcohol (Krafft and Roos, Ber. 1892, 25, 2225; Kastle and Murrill, Amer. Chem. J. 1895, 17, 290), a reaction in which an alkyl ether is also formed

$$R{\cdot}SO_2{\cdot}OEt+EtOH=R{\cdot}SO_2{\cdot}OH+Et_2O$$

This decomposition proceeds slowly at the ordinary temperature, and is brought about more readily by methyl than by ethyl alcohol.

Kastle, Murrill, and Frazer (Amer. Chem. J. 1897, 19, 894) have shown that 0·1 N-solutions of sulphuric and acetic acids have no effect on the hydrolysis of esters of sulphonic acids by water. Hydrochloric and hydrobromic acids, on the other hand, have an apparent retarding effect, but this is due to the fact that the halogen hydracids can react with the ester according to the equation:

$$R{\cdot}SO_2{\cdot}OEt+HCl \rightleftarrows R{\cdot}SO_2{\cdot}OH+EtCl$$

a reaction which does not affect the total acidity of the solution. A more detailed investigation has proved that this second reaction proceeds more rapidly and to a greater extent than the hydrolysis of the ester by water. The hydrolysis of a sulphonic ester by means of a large excess of water or alcohol in acetone solution gives concordant values for K when the equation for a monomolecular reaction is used. Alkalis are much more efficient hydrolysing agents than water for sulphonic esters; this may be due to the alkali acting independently of the water or to the alkali catalytically affecting the hydrolysis by water. The constants at 25° for methyl benzenesulphonate, using water and N-potassium hydroxide solution, are 1 : 90 (Wegscheider and Furcht, Monatsh. 1902, 23, 1903). When the neutral ester of a mixed carboxylic sulphonic acid is hydrolysed, *e.g.* $OEt\cdot SO_2\cdot C_6H_4\cdot CO_2Et$, the $\cdot SO_2\cdot OEt$ group is hydrolysed much more readily than the $\cdot CO_2Et$ group, and an acid ester of the type $OH\cdot SO_2\cdot C_6H_4\cdot CO_2Et$ is formed.

Esters can also be hydrolysed by water with finely divided metals as catalysts, *e.g.* Neilson (Amer. J. physiol. 1903, 10, 191) has shown that platinum black accelerates the hydrolysis of ethyl butyrate by water. The reaction is, however, very slow, and increases with the amount of platinum present. The maximum effect is obtained at 50°, and the activity of the catalyst is readily destroyed by various 'poisons.' The reaction is reversible as platinum black can also accelerate the esterification of butyric acid in ethyl alcoholic solution.

Sabatier and Maihle (Compt. rend. 1911, 152, 494) have shown that titanium dioxide is a good catalyst for the conversion of acids and alcohols into esters. The method adopted is to allow a mixture of molecular quantities of the vapours of the two compounds to pass over a column of the dioxide kept at 280°–300°. The yield of ester is much the same as in Berthelot and Menschutkin's experiments, but the process is extremely rapid. The reaction is reversible, and using equivalent quantities of acid and alcohol an approximately 70 p.c. yield of ester was obtained in most cases examined. A similar method may also be used for hydrolysis of esters. It consists in allowing a mixture of the vapour of the ester with an excess of steam to pass over the titanium dioxide at 280°–300°.

Similar results can be obtained with thorium oxide as catalyst provided aromatic acids of the type of benzoic are used (*ibid.* 358).

Certain neutral metallic salts also act catalytically on the hydrolysis of esters by water (Kellog, J. Amer. Chem. Soc. 1909, 31, 403, 886). The salts which have been investigated are potassium chloride, bromide, and iodide. The catalytic effects are comparatively small when compared with those of strong acids, the chloride has the greatest effect and the iodide the least, and when the concentration of the salt reaches a certain value the catalytic effect is negative. No simple explanation of the results can be given.

Hydrolysis of halogen derivatives. The hydrolysis of chloroacetic acid $CH_2Cl\cdot CO_2H$ and of its sodium salt to glycollic acid $OH\cdot CH_2\cdot CO_2H$ has been studied. With water at high temperatures the reaction is unimolecular and non-reversible, and when salts of the acid are used the velocity appears to be independent of the base with which the chloroacetic acid is combined. The velocity coefficients of N-, 0·3 N-, and 0·1 N-solutions of salts of monochloro- and monobromoacetic acids are inversely proportional to the affinity constants of the two acids. The rate diminishes with dilution and reaches a minimum at about 0·1 N, and from that point to $v=1000$ the velocity of decomposition is practically constant (Kastle and Keiser, Amer. Chem. J. 1893, 15, 471).

Senter (Chem. Soc. Trans. 1907, 91, 460) has shown that N solutions of hydrochloric acid and neutral salts have but little effect, and that the hydrolysis of the monochloroacetic acid is directly proportional to the concentration of the acid within wide limits. At 102° it is shown that the reaction is strictly unimolecular in dilute solution, but that slight deviations are met with in more concentrated solutions. The reaction is presumably between unionised water and unionised acid, and when the sodium salt is used the reaction is between unionised water and both unionised salt and the anion. When sodium hydroxide is used for hydrolysis at 102° the reaction is bimolecular in dilute solutions, although deviations are met with in more concentrated solution, and the reaction with the alkali proceeds some 10 times as fast as with water alone. For comparison of rates of various α-bromo acids and sodium salts, *cp.* Chem. Soc. Trans. 1909, 95, 1835. The velocity reaction between the sodium salt of the acid and water is appreciably increased by the introduction of methyl and ethyl groups into the acid molecule, whereas the reaction between the sodium salt and sodium hydroxide is retarded by the presence of alkyl substituents.

The *esters of imino acids* can be hydrolysed in two different ways:

(1) 
$$R\cdot C{<}^{NH}_{OR'}+H_2O \rightarrow R\cdot C{<}^{O}_{OR'}+NH_3$$

(2) 
$$R\cdot C{<}^{NH}_{OR'} \rightarrow R\cdot C{:}N+R'\cdot OH$$

The former reaction is enormously accelerated by acids and the latter by alkalis. According to Steiglitz (Amer. Chem. J. 1908, 39, 29, 166) the former reaction consists in the hydrolysis of the complex cation $(R\cdot C(:NH)\cdot OR',\overset{+}{H})$, and the latter in the decomposition of the anion $R\cdot C(:N)\cdot OR'$. The effect of alkalis is much more pronounced than that of acids. When water alone is used it is the non-ionised ester which is decomposed.

3. **Hydrolysis of acyl derivatives.** The chlorides, amides, anilides, and anhydrides of organic acids can be hydrolysed in much the same manner as esters, *e.g.*

$$R\cdot CO\cdot Cl+H\cdot OH=R\cdot CO\cdot OH+HCl;$$
$$R\cdot CO\cdot NHPh+K\cdot OH=R\cdot CO\cdot OK+NH_2Ph.$$

As a rule the derivatives of aliphatic acids are hydrolysed more readily than those derived from aromatic acids, *e.g.* acetamide more readily than benzamide. The hydrolysis is usually effected by boiling with alkali hydroxide, but the presence of ortho- substituents in derivatives of benzoic acid retards hydrolysis to an appreciable extent (V. Meyer, Ber. 1894, 27, 2153; Sudborough, Chem. Soc. Trans. 1894, 65, 1030; 1895, 67, 587; 1897, 71, 229; Reed, Amer. Chem. J. 1899, 21, 281). When two such substituents are present the amide cannot be hydrolysed by boiling with potassium hydroxide solution, but the hydrolysis may be accomplished by heating with concentrated hydrochloric or hydrobromic acid under pressure in sealed tubes. One of the most convenient methods for converting a diortho- substituted benzonitrile into the corresponding acid is to hydrolyse to the amide $R\cdot CN+H_2O=R\cdot CO\cdot NH_2$ by heating at 120°–130° with 90 p.c. sulphuric acid, and when cold to replace the amino group by hydroxyl by the addition of sodium nitrite solution (Bouveault, Bull. Soc. chim. 1892, [iii.] 9, 368; Sudborough, Chem. Soc. Trans. 1895, 67, 602).

The hydrolysis of acetamide by hydrochloric acid has been studied by Acree and Nirdlinger (Amer. Chem. J. 1907, 38, 489). The amount of hydrolysis after given intervals of time was determined by introducing known volumes of the reaction mixture into a Lunge nitrometer containing sodium hypobromite solution and measuring the nitrogen evolved. Their results show that at 65° the reaction is practically unimolecular when dilute solutions are used, but that the values for K tend to increase with the time, probably owing to a slight catalytic effect of the ammonium chloride formed on hydrolysis. These chemists conclude that the hydrolysis of an acid amide by mineral acids is analogous to the hydrolysis of an ester or the inversion of cane sugar by acids, and that the first stage consists in the formation of a small amount of salt between the acid and the amide, the final stage consisting in the hydrolysis of the complex cation derived from the salt.

$$
\begin{aligned}
&CH_3{\cdot}CO{\cdot}NH_2+\overset{+}{H}+\overset{-}{Cl}+H_2O\\
&\qquad\rightleftharpoons CH_3{\cdot}\overset{+}{CO}{\cdot}NH_3+H_2O+\overset{-}{Cl}\\
&\qquad\qquad\rightarrow CH_3{\cdot}CO_2H+\overset{+}{NH_4}+\overset{-}{Cl}.
\end{aligned}
$$

Croker and Lowe (Chem. Soc. Trans. 1907, 91, 593, 952) have studied the hydrolysis of the amides of the simple aliphatic acids with hydrochloric acid, and also with sodium hydroxide solution, using the electrical conductivity method in order to determine the amount of amide hydrolysed. The order of the amides when hydrochloric acid is used is formamide, propionamide, acetamide, *iso*butyramide, capronamide, butyramide, and valeramide; but with sodium hydroxide the order is formamide, acetamide, propionamide, capronamide, butyramide, *iso*butyramide, and valeramide, in both cases formamide is the amide most readily hydrolysed, and in every case the hydrolysis with alkali proceeds more rapidly than that with hydrochloric acid under similar conditions.

E. Fischer (Ber. 1898, 31, 3266) has pointed out that uric acid and similar cyclic nitrogen derivatives are less readily hydrolysed by dilute alkalis than their alkylated derivates, *e.g.* 1:3:9-trimethyl uric acid. Similarly the amide and methyl ester of the methyl ether of salicylic acid are more readily hydrolysed than the corresponding derivatives of salicylic acid itself, and in all such cases the compounds most resistant to the hydrolysing agent are those which can form metallic salts with the alkalis.

These facts support Stieglitz's view that in hydrolysis by alkalis a salt of the alkali and amide (or ester) is formed and that the complex anion of this salt undergoes hydrolysis. When the amide or ester contains a replaceable hydrogen atom, salt formation of a different type occurs, and the characteristic complex anion is not formed.

Most compounds of the type of alkylated acid amides, *e.g.* compounds containing the grouping  $\vdots C{\cdot}C\genfrac{}{}{0pt}{}{\diagup NH{\cdot}C\vdots}{\diagdown\!\!\diagdown O}$, can be hydrolysed. Thus hippuric acid (benzoylglycine)

$$C_6H_5{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}CO_2H$$

is hydrolysed to benzoic acid and glycine hydrochloride when boiled with concentrated hydrochloric acid. The hydrolysis of naturally occurring protein derivatives by means of acids or alkalis consists in the addition of water to such groups and the subsequent resolution into simpler cleavage products, ultimately into amino acids (*see* PROTEINS). (For hydrolysis of sulphonic acids, *cp.* Crafts, Bull. Soc. chim. 1907, [iv.] 1, 917.)

4. **Hydrolysis of di- and poly-saccharoses.** As a rule compounds of the ether type, *i.e.* compounds containing two alkyl or substituted alkyl groups attached to oxygen, are not readily hydrolysed when boiled with alkali or acid solutions.

All the carbohydrates of the di- or poly-saccharose type take up water when warmed with dilute mineral acid and are resolved into mono-saccharoses. The best known examples are:

sucrose (cane sugar)+water
=glucose (dextrose)+fructose (lævulose)
malt sugar+water=dextrose
lactose (milk sugar)+water
=dextrose+galactose.

All these reactions can be represented by the equation:

$$C_{12}H_{22}O_{11}+H_2O=C_6H_{12}O_6+C_6H_{12}O_6.$$

Starch is also hydrolysed by dilute mineral acids yielding as final product dextrose:

$$(C_6H_{10}O_5)n+n(H_2O)=n(C_6H_{12}O_6).$$

The hydrolysis of cane sugar (sucrose) by means of dilute mineral acid has been examined in detail; it is usually referred to as the inversion of sucrose, as the optical rotatory power changes from + to − during the reaction. The investigations of Wilhelmy (Pogg. Ann. 1850, 81, 413, 499) proved that in dilute solution the amount of sugar inverted is proportional to the amount present, or, in other words, the reaction is unimolecular. The method of determining the concentration of the sucrose at any given time is based on polarimetric readings. If the original rotation of the sucrose solution be $+x°$, and after complete inversion be $-y°$, then the total change is $x+y°$. If after an interval of time t the rotatory power of the solution is $+z°$, then the fraction of sucrose which has undergone inversion is $\frac{x-z}{x+y}$, and the velocity constant can be determined by substituting the values for t, C_o, and C_t in the equation

$$K=1/t \log_e C_o/C_t$$

where C_o represents the concentration of the sucrose at the beginning and can be expressed by $x+y$, C_t represents the concentration at time t, and is equal to $x-z$. The velocity of inversion is directly proportional to the concentration of the hydrochloric acid, and increases with rise in temperature. J. Meyer (Zeitsch. physikal. Chem. 1908, 62, 59) states that the reaction between sucrose and dilute mineral acid is not a simple unimolecular reaction, but is complicated by the mutarotation of the glucose and fructose.

Hudson (J. Amer. Chem. Soc. 1908, 30, 1165), on the other hand, claims that the reaction is typically unimolecular, and that the question of mutarotation does not arise, as both the α-glucose and α-fructose first formed undergo mutarotation immediately in the presence of the acid giving the usual rotatory values for invert sugar. Even in the earlier readings deviations from the unimolecular reaction are not encountered.

The hydrolysis of other di-saccharoses, and even of glucosides by dilute mineral acids, also follows Wilhelmy's Law, but the relative rates are very different; the following values have been obtained for *N*-sulphuric acid at 20°: lactose 1, maltose 1·27, sucrose 1240; or again α-methylglucoside 100, and β-methylglucoside 179. The hydrolysis of carbohydrates by means of dilute mineral acids is the basis of certain commercial methods for the manufacture of glucose. Large quantities of this carbohydrate are manufactured by boiling starch (*e.g.* potato or maize starch) with dilute sulphuric acid, removing the acid by precipitating as calcium sulphate and evaporating the clear solution under reduced pressure.

Neutral salt action. The investigations of Ostwald (J. pr. Chem. 1883, [ii.] 28, 460), Spohr (*ibid.* 1886, [ii.] 33, 265), and Arrhenius (Zeitsch. physikal. Chem. 1889, 4, 234; 1899, 31, 207) prove that the addition of a substance which is largely ionised in aqueous solution accelerates the hydrolysis of esters or of carbohydrates by aqueous solutions of strong acids. This has been proved by the addition of metallic chlorides to mixtures in which hydrogen chloride is the catalyst, the addition of bromides to hydrogen bromide, and of nitrates to nitric acid. The majority of chlorides have much the same effect if readily ionised, whereas a salt such as mercuric chloride, which is only partially ionised, has a much feebler action. Non-electrolytes, such as methyl and ethyl alcohols have but little effect on the hydrolytic activity of hydrogen ions. The neutral salt action has been shown to be independent of the concentration of the compound hydrolysed, and is stated to be proportionately greater the more dilute the acid solution, but Lunden (Med. Nobel Institut. 1910, 2) disputes this statement.

Caldwell (Proc. Roy. Soc. 1906, A, 78, 272), working with weight normal solutions, shows that the presence of metallic chlorides increases the catalytic activity of hydrogen chloride on the inversion of cane sugar, and that calcium chloride has the most pronounced effect. Similar effects on the activity of nitric acid are produced by nitrates (Whymper, *ibid.* 1907, A, 79, 576). Salts also tend to increase the activity of hydrogen chloride when used as a catalyst in the hydrolysis of methyl acetate (Armstrong and Watson, *ibid.* 1907, A, 79, 579), but their effect is not so marked as in the case of the inversion of sucrose (*cp.* Armstrong, *ibid.* 1908, A, 81, 90; Armstrong and Crothers, *ibid.* 102). According to Armstrong and Caldwell the salts act by removing part of the water in the form of definite hydrated compound, and in this manner increase the concentration of the reacting substance. Senter (Chem. Soc. Trans. 1907, 91, 462) is of opinion that this view cannot be correct, as the relative neutral salt action of different salts is not that of their ordinary degree of hydration (*cf.* chlorides and nitrates), and as in equivalent solutions the effect is practically independent of the nature of the salt (*cp.* Jones, Zeitsch. physikal. Chem. 1906, 55, 355, 429). A further argument used by Senter is that whereas rise of temperature affects hydration to an appreciable extent, alteration of temperature has but little effect on neutral salt action. It is concluded that probably the earlier suggestion of Arrhenius is correct, namely, that the ions of the neutral salt have some action on the hydrions or hydroxyl ions of the catalyst.

Reed (Amer. Chem. J. 1899, 21, 342) states that neutral salts retard the hydrolysis of acid amides by alkalis; and Arrhenius (Zeitsch. physikal. Chem. 1887, 1, 110) and Spohr (*ibid.* 1888, 2, 1194) claim that the same effect is produced by salts on the rate of hydrolysis of esters by alkalis. Senter, on the other hand (*l.c.* 473), shows that they accelerate the hydrolysis of sodium chloroacetate by sodium hydroxide. Since neutral salts have no effect on the decomposition of sodium chloroacetate by water, it is claimed that the effect of the salts cannot be due to their action on the reacting substance (the chloroacetate), and probably is due to their action on the hydroxyl ions (*cf.* Zeitsch. physikal. Chem. 1910, 70, 517).

5. Hydrolysis by enzymes. Many of the hydrolytic processes induced by aqueous solutions of acids or alkalis can also be brought about by certain complex organic substances found in animal and plant tissues. Such substances are termed unorganised ferments or *enzymes*; they act not merely as catalysts in processes of hydrolysis, but certain of them induce processes of oxidation—the oxidases—and others can effect complex decompositions as exemplified by the decomposition of glucose into ethyl alcohol and carbon dioxide under the influence of zymase. The enzymes are somewhat unstable, nitrogenous, organic compounds of colloidal nature, but not necessarily proteins; they act as catalysts, in the majority of cases as positive, but in a few as negative catalysts. The catalytic nature is shown by the fact that the rate of reaction is directly proportional to the concentration of the catalyst, but that the total decomposition is the same whatever the amount of catalyst used, provided sufficient time is allowed, and provided the enzyme does not undergo decomposition owing to secondary reactions. One of the most characteristic proofs of their catalytic nature is that due to Henri, who showed that when sugar was added after given intervals of time to a solution in which cane sugar was undergoing hydrolysis by invertase, the added sugar in each case began to be inverted by the enzyme at a rate irrespective of the amount already decomposed. Unlike most organic ferments the enzymes are sensitive to high temperatures; thus when heated to just below 100° their activity is completely destroyed; they are, however, resistant towards certain antiseptics which destroy protoplasm and kill fermenting organisms. A colloidal solution of an enzyme can often be prepared free from living organisms by treatment with a mild antiseptic, *e.g.* toluene, and filtration through a porous clay filter. Strong antiseptics such as formaldehyde are to be avoided, as they tend to destroy the enzyme also. A study of enzyme action is often complicated by the fact that it is impossible to isolate, in a state of purity, the particular enzyme required, and it may be accompanied by another enzyme capable of causing the destruction (autolysis) of the first, and thus bringing the reaction to an end long before all the substrate is decomposed.

The name given to a particular hydrolysing enzyme usually indicates the substance it is capable of hydrolysing and in all cases the termination *ase* is used. Thus maltase is the enzyme which hydrolyses maltose, amylase the enzyme which hydrolyses starch; but in some cases older names which were in use before this scheme was adopted, are still retained, *e.g.* sucrase, the enzyme which inverts sucrose (cane sugar), is still called invertase or even invertin, the common digestive enzymes are termed trypsin and pepsin. The substance which is decomposed by the enzyme is usually termed the substrate.

Although the processes of hydrolysis by acids and by enzymes are frequently compared it should be borne in mind that the rate at which a given substance is hydrolysed by the two different types of catalysts is frequently quite different, *e.g.* sucrose is hydrolysed by invertase much more readily than by a N-solution of hydrochloric acid; in fact, with a concentrated solution of invertase at 0° the inversion is practically instantaneous. It is not essential that the products obtained by the two processes should be identical. Thus in the case of the inversion of cane sugar by invertase the products are α-glucose and α-fructose, whereas when mineral acids are used the products are equilibrium mixtures of α- and β-glucose and α- and β-fructose, as the α-glucose and the α-fructose undergo immediate mutarotation in the presence of the mineral acid. Another example of a similar type is met with in the tri-saccharose, raffinose; when hydrolysed by acids this yields galactose, fructose, and glucose, the same sugar with raffinase yields melibiose and fructose, and with emulsin it yields galactose and sucrose, Similarly natural products of protein character yield comparatively simple amino acids when hydrolysed with acids or alkalis, whereas with enzymes more complex intermediate products are formed.

An important point of difference between hydrolysis by means of acids or alkalis and hydrolysis under the influence of enzymes is that any particular enzyme has a very restricted use as a catalyst or the action of enzymes is essentially selective. Thus lipase can hydrolyse esters and not carbohydrates; maltase can hydrolyse maltose but not sucrose. That a slight difference in the configuration of two isomeric compounds is sufficient to affect their reactivities with a particular enzyme is shown in the case of the two stereoisomeric α-methylglucosides. (For further details, *see* art. FERMENTATION.) Further examples are met with among the numerous polypeptides prepared within recent years (*cp.* Fischer and Bergell, Ber. 1903, 36, 2592; 1904, 37, 3103; Fischer and Abderhalden, Zeitsch. physiol. Chem, 1905, 46, 52; 1907, 51, 264).

The behaviour of some of the natural and artificial glucosides (*see* GLUCOSIDES) towards the two enzymes maltase and emulsin has been made use of in determining their configurations. Thus maltose, which is hydrolysed by maltase but not by emulsin, is regarded as an anhydride of α-glucose having a configuration similar to that of the α-methylglucoside; most of the natural glucosides, on the other hand, are hydrolysed by emulsin, but not by maltase, and therefore are probably analogous to β-methylglucoside. As a rule a natural glucoside is accompanied in the plant tissue by the enzyme which is able to hydrolyse it. The commonest glucosidoclastic enzymes, *i.e.* enzymes capable of hydrolysing glucosides are emulsin (β-glucase), myrosin, which hydrolyses sulphur glucosides, rhamnase, and tannase.

The products formed by the hydrolysis of naturally occurring compounds by enzymes are various; thus the natural glucosides can give rise to sugars, alcohols, phenols, aldehydes, acids, mustard oils, anthracene derivatives, indigo, &c.

It has been proved in many cases that a specific enzyme can act not merely as a hydrolysing, but also as a synthesising agent. The process of hydrolysis is thus, in certain cases, a balanced reaction, but the equilibrium is mainly in the direction of analysis and not synthesis. The synthesising activity of an enzyme was first demonstrated by Croft Hill (Chem. Soc. Trans. 1898, 73, 634; 1903, 83, 578) in the case of maltase. The greater portion of the maltose is hydrolysed by the enzyme to glucose, but a certain proportion of di-saccharose is always present.

Emulsin and lipase have also been shown to possess synthesising properties; in the latter case natural fats have been synthesised by the action of lipases on mixtures of glycerol and the higher fatty acids in the absence of a large excess of water. The lipatic enzymes present in certain seeds are made use of on a commercial scale for the preparation of fatty acids from natural fats (*cp.* Welter, Zeitsch. angew. Chem. 1911, 24, 385; Pottevin, Bull. Soc. chim. 1906, [iii.] 35, 693). For details of the synthetic functions of enzymes, *see* art. FERMENTATION.

In some of these balanced actions between carbohydrates or esters and enzymes it has been shown that the equilibrium mixture is the same, whether mineral acid or enzyme is used, *e.g.* Visser's experiments using invertase and emulsin; in other cases, however, the equilibrium mixture with the enzyme is quite different from that obtained when an acid is used, *e.g.* Dietz's experiments with lipase and *iso*-amyl *n*-butyrate (Zeitsch. physiol. Chem. 1907, 52, 279).

A considerable amount of work has been done on the velocities of different reactions in which enzymes play a part. Henri (Lois general de l'action des diastases, 1903) and others claim that the rate of inversion of sucrose by invertase, unlike that by mineral acids, does not agree with the unimolecular formula. The investigations of O'Sullivan and Tompson (Chem. Soc. Trans. 1890, 57, 834) and of Hudson (J. Amer. Chem. Soc. 1908, 30, 1160, 1564; 1909, 31, 655) prove conclusively that the unimolecular formula holds for any given solution, if the birotation of the α-glucose and a-fructose first formed is taken into consideration. The complications attending the mutarotation of the glucose and fructose can be avoided by adding a small amount of alkali, *e.g.* 10 c.c. of 0·4 N-sodium carbonate solution for each

100 c.c. of sugar solution, a short time before the polarimetric reading is taken. The alkali stops the hydrolysis and rapidly brings about equilibrium between the α- and β-glucoses and α- and β-fructoses, so that the normal rotatory power of invert sugar is given. Hudson's results clearly prove that the α-modifications of glucose and fructose are first formed, and that these are stable in the presence of enzyme, but rapidly undergo mutarotation in the presence of a little alkali. Hudson's experiments also show that a trace of hydrochloric acid, *e.g.* 0·0006 *N*, accelerates the action of the invertase to an appreciable extent.

The decomposition of the cane sugar is directly proportional to the concentration of the enyzme, and in very dilute solutions (under 5 p.c.) is also proportional to the concentration of the sugar, but with more concentrated solutions it is not even approximately proportional, but decreases and becomes practically zero in the strongest solutions. According to O'Sullivan and Tompson, and to Hudson, the diminution in the velocity in concentrated solutions is due principally to the viscosity of the medium; it may also be partly due to the formation of a definite compound between the sugar and enzyme. According to A. J. Brown (Chem. Soc. Trans. 1902, 81, 373) a given quantity of invertase decomposes a nearly constant weight of sugar in unit time (*i.e.* the decomposition is independent of the sugar concentration), provided the solution is moderately concentrated; but after an appreciable amount of sugar is decomposed the further inversion is directly proportional to the concentration of the sugar. This change of velocity from a linear to a logarithmic period is in harmony with the view that the sugar unites with the enzyme, and that it is the additive compound which is hydrolysed, and that the enzyme thus liberated immediately combines with a further amount of sugar. *Cp.* the hydrolysis of milk sugar by enzymes (E. F. Armstrong, Proc. Roy. Soc. 1904, 73, 500).

The reaction between salicin and water in the presence of emulsin is also a unimolecular reaction (Hudson and Paine, J. Amer. Chem. Soc. 1909, 31, 1242), provided alkali is added to bring about mutarotation of the β-glucose, which is the primary product

$$C_{13}H_{18}O_7+H_2O=C_6H_{12}O_6+C_7H_8O_2$$

Salicyl alcohol.

The reaction between lipase and *iso*amyl butyrate or between the same enzyme and *iso*amyl alcohol and *n*-butyric acid in the presence of a large excess of alcohol is a normal unimolecular reaction, although it proceeds in a heterogeneous medium. Dietz concludes that the reaction takes place in the solid phase, and that the diffusion of the ester or acid into the colloidal enzyme takes place so rapidly when compared with the velocity of reaction that the rates of diffusion do not affect the determination of the velocity of the reaction.

The hydrolysis of ethyl butyrate by lipase (Pierce, J. Amer. Chem. Soc. 1910, 32, 1517) points to the formation of an additive compound of the ester and enzyme. In many other cases the velocity relationships are not so simple. In some of these the reaction is retarded after a certain time owing to the product or products formed combining with the enzyme, or to negative autocatalysis, or to the gradual destruction of the enzyme.

In the reaction between pepsin and albumen the amount of albumen transformed in given time by different amounts of pepsin is proportional to the square root of the pepsin concentrations. The same relationship holds good with regard to trypsin and albumen, and is due to the fact that the velocity is inversely proportional to the amount of substance transformed, and this points to the formation of a definite compound between the enzyme and one of the products.

Most decompositions by enzymes are characterised by a high temperature coefficient when compared with catalytic reactions in which acid or alkali is used. In the latter case the coefficient is about 2–3 for a rise of 10°; with emulsin, however, the coefficient is 7·14 for a rise from 60° to 70°, with trypsin 5·3 for a rise from 20° to 30°; but like most colloidal catalysts enzymes exhibit an optimum temperature, at which the activity is greatest, and then falls again with further rise of temperature. This may be due to the coagulating effects which a moderately high temperature usually has on the majority of colloids.

In certain cases it has been found possible to obtain by dialysis from a given enzyme two portions, a dialysate and a residue; neither portion alone is active, but the hydrolytic activity is restored when the dialysate is added to the dialysed residue. This residue is decomposed when boiled with water, and is the enzyme proper, whereas the dialysate is not decomposed when boiled and contains the co-enzyme (*see* art. FERMENTATION). In the case of liver lipases it has been proved that both enzyme and co-enzyme are essential for the hydrolysis of esters, and it has also been proved that the co-enzyme is a metallic salt of taurocholic acid. In living tissues a number of complex substances are present which are capable of interfering with the specific action of an enzyme. These are termed anti-enzymes; some are normally present in tissues, others appear to be formed when an enzyme is injected into the tissue.

A view generally held with regard to the mechanism of enzyme reaction is that compounds perhaps of the type of 'absorption compounds' (Bayliss) are formed between the enzyme and substrate, and that the absorbed material then reacts with water (*see* art. FERMENTATION). The fact that a specific enzyme can hydrolyse only certain particular substrates is in harmony with this view, as it is known that chemical constitution plays an important part in absorption phenomena (Zung, Arch. inter. Physiol. 1907, 5, 245; Hedin, Bio-Chem. J. 1907, 2, 112; Acree, J. Amer. Chem. Soc. 1908, 30; 1755; *cp.* also Freundlich, Zeitsch. physikal. Chem. 1907, 57, 385).

6. **Alcoholysis.** Reactions in which alcohols play much the same part as water in hydrolysis are usually grouped together under the name alcoholysis. The reaction with methyl alcohol is termed '*methanolysis*,' and that with ethyl '*ethanolysis*.'

The ethanolysis of an acid amide in the

presence of a mineral acid is analogous to the hydrolysis of the amide by dilute mineral acids as shown by the two equations :

$$R\cdot C\Big<\begin{smallmatrix}O\\ NH_2\end{smallmatrix}+H\cdot OH=R\cdot C\Big<\begin{smallmatrix}O\\ OH\end{smallmatrix}+NH_3$$

$$R\cdot C\Big<\begin{smallmatrix}O\\ NH_2\end{smallmatrix}+H\cdot OEt=R\cdot C\Big<\begin{smallmatrix}O\\ OEt\end{smallmatrix}+NH_3.$$

The latter reaction has been studied in detail by Reed (Amer. Chem. J. 1909, 41, 483). The reaction is bimolecular as the catalyst is gradually neutralised by the ammonia formed in the reaction, and proceeds at an easily measurable rate at 50° in the case of benzamide. A comparison of the values of K for *p*- and *m*-nitrobenzamide shows that this is 1·16, a value practically identical with the ratio for the hydrolysis of the two amides. The ratio of the constants for benzamide and *m*-nitrobenzamide varies considerably with the concentration of the hydrogen chloride. The presence of small amounts of water on the rate of alcoholysis is also marked, just as in the case of the esterification of an acid, and similarly ortho-substituents appear to have inhibiting effects. The general conclusion drawn is that the mechanism of alcoholysis is analogous to that of hydrolysis, and consists in the formation of salts between the amide and the mineral acid and the reaction of the complex cation with the alcohol.

Another common type of alcoholysis met with is the conversion of an ester of a given acid into another ester of the same acid by means of an alcohol, *e.g.* :

$$R\cdot CO\cdot OEt+MeOH \rightleftarrows R\cdot CO\cdot OMe+EtOH.$$

This change does not take place readily except in the presence of a catalyst, the most efficient being sodium alkyl oxide (Purdie, Chem. Soc. Trans. 1885, 47, 862 ; 1887, 51, 627 ; 1888, 53, 391 ; Claisen, Ber. 1887, 20, 646), hydrogen chloride (Patterson and Dickinson, Chem. Soc. Trans. 1901, 79, 280), sodium hydroxide (Henriques, Zeitsch. angew. Chem. 1898, 338 ; Pfannl, Monatsh. 1910, 31, 301 ; Kommenos, *ibid.* 1910, 31, 111, 687 ; 1911, 32, 77 ; Kremann, *ibid.* 1905, 26, 783 ; 1908, 29, 23) or ammonia (Leuchs and Theodorescu, Ber. 1910, 43, 1239). As a rule only a small amount of the catalyst need be used, but with the esters of aromatic acids saturation with hydrogen chloride is necessary. The reaction appears to be reversible, as it is possible to transform an ethyl into a methyl and conversely a methyl into an ethyl ester. The reaction is not limited to methyl and ethyl esters, but can be applied to more complex esters, such as benzyl and phenyl, and also to glyceryl esters (*cp.* Haller, Compt. rend. 1906, 143, 657 ; 1908, 146, 259 ; Fanto and Stritar, Monatsh. 1908, 29, 299), and is a most convenient laboratory method for the conversion of a given ester into another ester derived from the same acid. The esters of the great majority of aliphatic and aromatic acids react in this manner, but Sudborough and Edwards have shown that when the esters are derived from diortho-substituted benzoic acids the transformation cannot be affected by using either sodium alkyl oxide or saturating with hydrogen chloride and boiling for some time. Even when several substituents are present transformation occurs, provided the ortho- positions are free. This indicates that the transformation of esters under the influence of hydrogen chloride is analogous to the esterification of an acid by the same catalyst (*see* ESTERIFICATION).

Similar transformations can be brought about in the case of the alkyl ethers of carbonium bases, *e.g.*  $C_6H_4\Big<\begin{smallmatrix}CH:CH\\ \vert\\ NR\cdot CH\cdot OEt\end{smallmatrix}$ (Decker, J. pr. Chem. 1890, [ii.] 45, 182), and of the oxygen ethers of substituted thiocarbamides, *e.g.*

$$OEt\cdot CH_2\cdot NH\cdot CS\cdot NHPh \rightarrow OMe\cdot CH_2\cdot NH\cdot CS\cdot NHPh$$

(Johnson and Guest, J. Amer. Chem. Soc. 1910, 32, 1279). Comp. also Kuntze (Arch. Pharm. 1908, 246, 110). An interesting case of alcoholysis observed by Willstätter and Stoll (Annalen, 1910, 378, 18) is the conversion of amorphous chlorophyll into crystalline chlorophyll by ethyl alcohol in the presence of an enzyme 'chlorophyllase,' which accompanies chlorophyll in plant tissues. The reaction consists in the replacement of the complex phytyl group by the simpler ethyl group

$$CO_2H\cdot C_{31}H_{29}N_4Mg(CO_2Me)(CO_2C_{20}H_{39})+EtOH$$
$$=C_{20}H_{39}OH+CO_2H\cdot C_{31}H_{29}N_4Mg(CO_2Me)(CO_2Et).$$

HYDROQUINONE CARBOXYLIC ACID *v.* PROTOCATECHUIC ACID.

HYDROSOLS *v.* COLLOIDS.

HYDROSULPHITES *v.* SULPHUR.

HYDROXY ACIDS. *Oxy acids.* The organic hydroxy acids are derived from the corresponding non-hydroxylated acids by the replacement of one or more hydrogen atoms in the hydrocarbon radicle of the acid by the same number of hydroxyl groups. According as the hydroxyl group is introduced into a fatty radicle or into a benzenoid radicle, the resulting acid is an alcohol-acid or a phenol-acid.

HYDROXY ACIDS OF THE ALIPHATIC SERIES.

There are several groups of hydroxy acids of the aliphatic series and these will be discussed *seriatim.*

I. Monohydroxymonocarboxylic acids

 $C_nH_{2n}\Big<\begin{smallmatrix}OH\\ CO_2H\end{smallmatrix}$ The most important members of this group are glycollic, lactic, hydracrylic, hydroxybutyric, and hydroxystearic acids (*q.v.*). They occur naturally, *e.g.* glycollic acid in unripe grapes and in the leaves of *Ampelopsis* (*Vitis*) *hederacea* (D. C.), lactic acid in the juice of the muscles, in sour milk, in pickles and in the gastric juice.

General methods of preparation.

(i) By the careful oxidation of diprimary, primary secondary, and primary tertiary glycols with dilute nitric acid or with platinum black and air, *e.g.* lactic acid from glycol.

(ii) By the reduction of aldehyde acids, keto-acids, and dicarboxylic acids with sodium amalgam or with zinc and hydrochloric or sulphuric acids, *e.g.* lactic acid from pyroracemic acid and glycollic acid from oxalic acid.

(iii) By boiling monohalogen fatty acid

with silver oxide, alkali, or with water or by distilling them, *e.g.* glycollic acid from monochloroacetic acid; hydracrylic acid from β-chloropropionic acid; γ-butyrolactone from γ-chlorobutyric acid.

(iv) By the action of nitrous acid on amino acids of the fatty series, *e.g.* glycollic acid from glycine.

(v) By the action of hydrogen cyanide followed by hydrochloric acid on aldehydes, ketones, and glycolchlorhydrins, *e.g.* lactic acid from acetaldehyde; hydracrylic acid from glycolchlorhydrin.

(vi) By treating unsaturated acids with hydrobromic acid, or with dilute sulphuric acid or by distilling them, *e.g.* γ-valerolactone from allylacetic acid.

Properties.—These acids may be sub-divided into three groups, primary, secondary, and tertiary acids, *e.g.* hydracrylic acid,  $CH_2(OH)\cdot\overset{H}{\underset{H}{C}}\cdot CO_2H$, lactic acid,  $CH_3\cdot\overset{H}{\underset{OH}{C}}\cdot CO_2H$ and α-hydroxy*iso*butyric acid,  $CH_3\cdot\overset{CH_3}{\underset{OH}{C}}\cdot COOH$. They also exhibit differences in their properties depending on the position of the hydroxyl group in the molecule, *i.e.* whether they are α-, β- or γ-hydroxy-acids. They are more soluble in water, but less soluble in ether than the corresponding fatty acids. They are also less volatile and, as a rule, cannot be distilled unchanged.

General reactions.

(i) Like the fatty acids they yield through change in the carboxyl group normal salts, esters, amides, and nitriles.

(ii) Like the alcohols, the hydrogen of the hydroxyl group may be replaced by alkali metals or by alkyl groups; also by the action of acyl chlorides or of a mixture of concentrated nitric and sulphuric acids, acid radicles or the nitro group may be substituted for it.

(iii) Phosphorus pentachloride replaces the two hydroxyl groups by chlorine, *e.g.* glycollic acid yields chloracetylchloride.

(iv) Hydriodic acid reduces the hydroxy acids to the corresponding fatty acids, *e.g.* propionic acid from lactic acid.

In the above reactions the hydroxy acids behave similarly, but on oxidation or by the application of heat, these acids show great differences.

(v) On oxidation these acids yield different products, according as whether they are primary, secondary, or tertiary acids.

(*a*) Primary acids yield aldehyde acids and dibasic acids, *e.g.* glycollic acid yields glyoxylic and oxalic acids.

(*b*) Secondary acids yield ketonic acids; the α-ketonic acids change to aldehyde and carbon dioxide, the β-ketonic acids to ketones and carbon dioxide, *e.g.* lactic acid yields pyruvic acid, which changes into acetaldehyde and carbon dioxide.

(*c*) Tertiary α-hydroxy acids yield ketones, *e.g.* α-hydroxy*iso*butyric acid yields acetone.

(vi) By the application of heat, differences in deportment are shown by these acids, according as they are, α-, β-, or γ-hydroxy acids.

(*a*) α-Hydroxy acids lose water and become cyclic double esters—the lactides, *e.g.* lactic acid becomes lactide, two molecules of the acid condensing with the loss of two molecules of water.

(*b*) β-Hydroxy acids lose water and become unsaturated acids, *e.g.* hydracrylic acid becomes acrylic acid.

(*c*) γ- and δ-Hydroxy acids lose water at the ordinary temperature and change more or less completely into simple cyclic esters—lactones.

II. **Aldehyde acids.** Formic acid is the simplest member of this group of acids, and also of the fatty acid series. The next member is glyoxylic acid, $CHO\cdot CO_2H$. Its claim to be considered here lies in the fact that all the salts are derived from the dihydroxy formula of glyoxylic acid $(OH)_2CH\cdot CO_2H$, and thus it behaves both as an aldehyde acid and as a dihydroxy acid. For details as to this group of acids *v.* Glyoxylic acid.

III. **Monohydroxydicarboxylic acids**

$$C_nH_{2n-1}(OH)(CO_2H)_2.$$

Various groups of monohydroxydicarboxylic acids are known, corresponding to the several groups of dibasic acids (*q.v.*). The most important acids of this type are tartronic, malic, α-glutanic, and paraconic acids. They occur in nature; thus malic acid in unripe gooseberries, and in rhubarb; α-hydroxyglutaric acid in molasses. The acids in which the hydroxyl group occupy the γ position with reference to the carboxyl group, when separated from their salts, readily part with water and become lactones, *e.g.* paraconic acid. The methods of preparation are very similar to those of the monobasic acids.

IV. **Dihydroxydicarboxylic acids.** The most important acid of this group is tartaric acid (*q.v.*). Mesoxalic acid, which is ketomalonic acid, exhibits tautomerism and behaves both as a keto-acid and as a dihydroxy acid.

V. **Hydroxytricarboxylic acids.** The most important acid of this group is citric acid (*q.v.*).

Hydroxy Acids of the Aromatic Series.

If the hydroxyl group is attached to the benzene nucleus of a carboxy acid derived from benzene or its homologues, the acid thus formed is a phenol acid. Examples of this class are the three isomeric hydroxy benzoic acids, which have the formula $C_6H_4(OH)COOH$. On the other hand, in the case of carboxy acids derived from homologues of benzene, a hydroxyl group, may be introduced into a fatty lateral chain, and in such a case the resulting acid is an alcohol acid; such an acid is *mandelic acid*

$$C_6H_5\cdot CH(OH)COOH.$$

I. **Monohydroxyaromatic acids.** The most important members of this group of acids are salicylic, *m*- and *p*-hydroxybenzoic and anisic acids (*q.v.*). They occur in nature; thus salicylic acid is found in the buds of *Spiræa Ulmaria* (Linn.) and as the methyl ester in oil of winter-green.

General methods of preparation.

(i) By the action of nitrous acid on the amino-acids, *e.g.* salicylic acid from anthranilic acid.

(ii) By fusing the sulphonic acids with alkalis, *e.g.* salicylic acid from *o*-toluenesulphonic acid.

(iii) By fusing the homologous phenols with alkalis, when the methyl group attached to the benzene nucleus will be oxidised to the carboxyl group, *e.g.* salicylic acid from *o*-cresol.

(iv) By fusing the phenol aldehydes with potash, *e.g.* salicylic acid from salicylaldehyde.

(v) By the action of carbon dioxide on the dry sodium salts of the phenols at high temperatures when the carbonic acid usually enters the ring in the position ortho to the hydroxyl group, *e.g.* salicylic acid from sodium phenate.

(vi) By boiling the phenols with carbon tetrachloride and caustic potash, the carboxyl group entering the ring generally in a position para to the hydroxyl groups: *o*-acids are formed in small amounts, *e.g.* *p*-hydroxybenzoic acid from phenol, carbon tetrachloride and caustic potash.

Properties.—When these acids react with carbonates only the hydrogen of the carboxyl group is replaced by metal; but with alkaline hydroxides they behave like feeble dibasic acids, and the hydrogen of the phenolic hydroxyl is also replaced: *e.g.* in *disodium salicylate* $C_6H_4(ONa)COONa$. Carbon dioxide will convert the latter into the former. The *o*-acids, unlike the *m*- and *p*-acids, volatilise in aqueous vapour, are coloured violet by ferric chloride and dissolve in chloroform. The *m*-acids are coloured red brown when heated with concentrated sulphuric acid and are converted into hydroxyanthraquinones: they are usually more stable than the *o*- and *p*-acids. Boiling hydrochloric acid decomposes the *p*-acids into carbon dioxide and phenols. All the hydroxy acids decompose into phenol and carbon dioxide when distilled with lime.

II. **Dihydroxyaromatic acids.** The most important member of this class is protocatechuic acid (*q.v.*). These acids may be prepared by the same methods as were used for the monohydroxy acids (*v. supra*). The carboxyl group is more readily introduced into the dihydroxybenzenes than into the monohydroxybenzenes. This may be effected by heating the compounds with a solution of ammonium or sodium carbonate at 100°–130°. The dihydroxybenzoic acids break down when heated, into carbon dioxide and dihydroxybenzenes.

III. **Trihydroxyaromatic acids.** The most important members of this group are gallic and tannic acids (*q.v.*).

HYDROXYANTHRAQUINONE *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

HYDROXYBENZALDEHYDE *v.* SALICYLALDEHYDE.

HYDROXYBENZENES *v.* PHENOL AND ITS HOMOLOGUES.

HYDROXYBUTYRIC ACIDS $C_4H_8O_3$.

α-Hydroxybutyric acid

$$CH_3\cdot CH_2\cdot CH(OH)CO_2H.$$

Prepared by treating α-chloro- or α-bromo- butyric acid with baryta (Markownikow, Annalen, 153, 242) or with moist silver oxide (Naumann, Annalen, 119, 115; Friedel and Machuca, *ibid.* 120, 279); by treating the cyanhydrin of propionaldehyde with hydrochloric acid and saponifying the nitrile thus produced (Prbzibyek, J. Russ. Chem. Soc. 8, 335); by heating ethyltartronic acid at 180° (Guthzeit, Annalen, 209, 234); by boiling 100 grams of α-bromobutyric acid, 500 c.c. of water and 1 molecular proportion of potassium carbonate for 5 to 6 hours (Bischoff and Walden, *ibid.* 279, 104). Forms white crystals, m.p. 43°–44°, sublimes at 60°–70° and boils at 225°. Chromic acid oxidises it to acetic and propionic acids, whilst electrolysis of a concentrated solution of the sodium salt results in the production of propionaldehyde and formic acid (Miller and Hofer, Ber. 1894, 468). It has been resolved into its optically active components by fractional crystallisation of the brucine salts (Guye and Jordan, Compt. rend. 120, 562, 632, 1274).

β-Hydroxybutyric acid

$$CH_3\cdot CH(OH)CH_2\cdot CO_2H.$$

Prepared by the reduction of aceto-acetic ester with sodium amalgam (Wislicenus, Annalen, 149, 205); by the action of potassium cyanide on α-propylenechlorhydrin and saponification of the nitrile thus formed (Markownikow, *ibid.* 153, 237). It forms a thick syrup, which is volatile in steam and on heating decomposes into water and crotonic acid. It has been resolved into its optically active components by fractional crystallisation of the quinine salts (McKenzie, Chem. Soc. Trans. 1902, 1402). *l*-β-Hydroxybutyric acid occurs in the urine in considerable quantities in cases of *diabetes mellitus* (Laud, Chem. Zentr. 1899, ii. 63; Bergell, Zeitsch. physiol. Chem. 1901, 33, 310; Minkowski, Chem. Soc. Abstr. 1885, 413; Kulz, Zeitsch. Biol. 20, 165). (For estimation in urine *v.* Schaffer, J. Biol. Chem. 1908, 5, 211; Black, *ibid.* 207.) The liver cells contain an enzyme, *β-hydroxybutyrase*, which converts β-hydroxybutyric acid into aceto-acetic acid (Wakeman and Dakin, *ibid.* 1909, 6, 373).

γ-Hydroxybutyric acid

$$CH_2(OH)CH_2\cdot CH_2\cdot CO_2H$$

readily loses water even at the ordinary temperature passing into the cyclic ester, butyrolactone $\overline{CH_2\cdot CH_2\cdot CH_2\cdot CO\cdot O}$. Butyrolactone was discovered by Saytzeff in 1873, but he regarded it as the dialdehyde of succinic acid. He prepared it by the reduction of succinyl chloride in acetic acid with sodium amalgam (Annalen, 171, 261). It may also be prepared by the distillation of γ-chlorobutyric acid at 180°–200° (Henry, Bull. Soc. chim. [ii.] 45, 341); by the interaction of ethylene chlorhydrin and acetoacetic ester and decomposing the resulting product with baryta (Chanlaroff, Annalen, 226, 325); by treating a solution of succinic anhydride in ether with sodium amalgam and gradually adding hydrochloric acid to the product (Fichter and Herbrand, Ber. 1896, 1192); by heating γ-phenoxybutyric acid with fuming hydrobromic acid (Bentley, Haworth and Perkin, Chem. Soc. Trans. 1896, 168); by the reduction of aldehydopropionic acid with sodium amalgam (Perkin and Sprankling, *ibid.* 1899, 17). It is a colourless oil, b.p. 206° (Fittig and Roeder, Annalen, 227, 22); sp.gr. 1·1286 15°/0°; it is volatile in steam. Chromic acid oxidises it to succinic acid; heating with hydriodic acid converts it into iodobutyric acid (Saytzeff, J. pr. Chem. 25, [ii.] 70). It reacts with magnesium methyl iodide, forming δ-methylpentane-αδ-diol (Henry, Compt. rend. 1906, 143, 1221).

α-Hydroxyisobutyric acid (*Butyl-lactinic acid, Acetonic acid, Dimethyl oxalic acid*)

$$(CH_3)_2C(OH)\cdot CO_2H.$$

Prepared by treating acetone with prussic and hydrochloric acids (Staedeler, Annalen, 111, 320; Markownikow, *ibid.* 146, 339); by treating dimethyloxalic ester with zinc and methyl iodide (Frankland and Duppa, *ibid.* 135, 25); by heating acetonechloroform to 180° with water or by boiling with caustic soda (Willgerodt and Schiff, J. pr. Chem. 41, [ii.] 519; Ber. 1882, 2307); by heating α-bromo- or α-chloro*iso*butyric acid with water to 180°, with baryta, or with caustic soda (Markownikow, Annalen, 153, 228; Fittig, *ibid.* 200, 70; Ostropjatow, J. Russ. Phys. Chem. Soc. 28, 51); by treating α-amino-*iso*butyric acid with sodium nitrite (Tiemann and Friedländer, Ber. 1881, 1973); by treating *iso*butyric acid with potassium permanganate (Meyer, Annalen, 219, 240). It forms hygroscopic prisms which sublime at about 50°, and when freshly sublimed melt at 79°; b.p. 212°; volatile in steam. Oxidation with chromic acid converts it into acetic acid, acetone, and carbon dioxide; fusion with caustic soda yields acetone; heating with phosphorus pentoxide yields acetaldehyde, acetone, acetic acid, and other products (Bischoff and Walden, Annalen, 279, 111). *Acetone chloroform* (*q.v.*)

$$(CH_3)_2C(OH)CCl_3$$

is an interesting derivative of this acid.

HYDROXYLAMINE NH_2OH. Discovered by Lossen (Annalen, Suppl. 1868, 6, 220) in 1865, but until 1891 only known in the form of salts or in aqueous solution. Obtained by the reduction of nitric acid with metals under suitable conditions (Divers, Chem. Soc. Trans. 1883, 443 *et seq.*; 1885, 597 *et seq.*); by the reduction of nitrates, nitro bodies, &c., with finely divided metals (Wohl, Eng. Pat. 11216; J. Soc. Chem. Ind. 1895, 595); by the electrolytic reduction of nitric acid, nitrous acid, or their salts or other derivatives in the presence of a second acid electrolyte at a low temperature (Boehringer and Söhne, D. R. PP. 133457, 137697; Fr. Pat. 319187; J. Soc. Chem. Ind. 1902, 1458; Compagnie Parisienne de Couleurs d'Aniline, Fr. Pat. 322943; J. Soc. Chem. Ind. 1903, 425; Tafel, Zeitsch. anorg. Chem. 1902, 31, 289); by the reduction of nitrites with sodium amalgam (Divers, Chem. Soc. Trans. 1899, 89) or with sulphites (Raschig, Eng. Pat. 3028; J. Soc. Chem. Ind. 1888, 210; Eichkoff, Arch. Pharm. 27, [iii.] 713; Lidoff, J. Russ. Chem. Soc. 1884, 751; Divers and Haga, Chem. Soc. Trans. 1887, 661; 1896, 1665). It is best prepared by taking a concentrated aqueous solution of commercial sodium nitrite (2 mols.) and sodium carbonate (1 mol.) and passing in sulphur dioxide at −2° to −3° with constant stirring until it is just acid. The solution is warmed gently with a few drops of sulphuric acid and then kept at 90°–95° for two days. It is then neutralised with sodium carbonate, evaporated until the solution weighs about 10½–11 times as much as the sodium nitrite originally taken, when on cooling nearly all the sodium sulphate crystallises out. The hydroxylamine sulphate is obtained from the mother liquors and purified by recrystallisation (Divers and Haga, *l.c.*). Jouve (Compt. rend. 128, 434) has prepared hydroxylamine synthetically by the direct union of hydrogen and nitric acid in the presence of spongy platinum at 115°–120°. The anhydrous compound may be obtained by dissolving hydroxylamine hydrochloride in absolute methyl alcohol, adding a solution of sodium methoxide in the same solvent, separating the sodium chloride so formed and distilling off the greater part of the methyl alcohol under 100 mm. pressure. The residue is distilled in small portions under 20 mm. pressure with the addition of a little vaseline to prevent frothing. When the solid hydroxylamine begins to come over, the receiver is changed and cooled to 0°, care being taken that the hydroxylamine vapour does not come in contact with air at 60°–70°, as then explosions occur (Lobry de Bruyn, Rec. trav. chim. 10, 100; 11, 18; *v.* also Brühl, Ber. 1894, 1347). Crismer (Bull. Soc. chim. 6, [iii.] 793) obtains it by heating zinc dihydroxylamine chloride, and Uhlenhuth (Annalen, 311, 117) by the distillation of the phosphate under reduced pressure; the solid thus obtained may be purified by crystallisation from absolute alcohol at −18° (Ebler and Schott, J. pr. Chem. 1908, 78, [ii.] 289).

Hydroxylamine forms white inodorous scales or hard needles, sp.gr. 1·3 (*circa*), m.p. 33·05°, b.p. 58° under 22 mm. Heated to 100° it decomposes, ammonia, nitrous and hyponitrous acids being the first products of decomposition and these then interact with the formation of nitrogen and nitrous oxide. Readily soluble in water, and to a less extent in ethyl and methyl alcohols, and in boiling ether (De Bruyn, Ber. 1894, 967). When pure it is stable below 15°, but alkali decomposes it. The aqueous solution is colourless and odourless, has a strong alkaline reaction, and gives precipitates, insoluble in excess, with salts of Zn, Ni, Fe, Al, Cr, but not with those of the alkaline earths. In its general reactions resembles a solution of ammonia, although it is less basic than that substance. It acts as a strong reducing agent, *e.g.* with $CuSO_4$ solution it gives a red precipitate of Cu_2O; it reduces $HgCl_2$ to $HgCl$, and precipitates the metals from solutions of $AgNO_3$, $AuCl_3$, and $PtCl_4$. It can also act as an oxidising agent being itself reduced to ammonia (Haber, Ber. 1896, 2444; Biltz, *ibid.* 1896, 2080; Dunstan and Dymond, Chem. Soc. Trans. 1887, 646). Thus in alkaline solution it converts ferrous hydroxide into ferric hydroxide, whilst in acid solution it reduces ferric chloride to ferrous chloride. Oxidation converts hydroxylamine into nitrous oxide and nitric oxide (Arndt, Ber. 1900, 33) and caustic soda decomposes it into nitrogen, nitrous oxide, nitrous acid and water (Kolotoff, J. Russ. Phys. Chem. Soc. 25, 295).

The salts of hydroxylamine are readily soluble in water and alcohol; they crystallise well and are anhydrous.

By treating hydroxylamine sulphate in the cold with sodium nitrite and then adding silver nitrate, a yellow precipitate of silver hyponitrite is obtained (Wislicenus, Ber. 1893, 771; Tanatar, J. Russ. Phys. Chem. Soc. 25, 342; Ber. 1894, 187). By passing sulphur dioxide through a solution of the hydrochloride or sulphate, ammonium sulphate is produced (Tanatar, Ber. 1899, 241, 1016). Elber and Schott (J. pr. Chem. 1908, ii. 78, 289) have prepared metallic salts of the type $R(ONH_2)_2$, where R is any divalent metal: alkyl hydroxylamines have been prepared by the action of alkyl halides on hydroxylamine (Dunstan and Goulding, Chem. Soc. Trans.

1899, 792; *v.* also *ibid.* 1896, 839; De Bruyn, Rec. trav. chim. 15, 185).

Detection and estimation.—Hydroxylamine may be detected by its action in reducing Fehling's solution with the formation of cuprous oxide (Adams and Overman, J. Amer. Chem. Soc. 31, 637); by adding sodium nitroprusside to a neutral solution and then a little caustic soda, when a magenta red colouration is produced (Angeli, Gazz. chim. ital. 23, ii. 102); or by treating it with sodium acetate and benzoyl chloride with the formation of benzhydroxamic acid which gives a violet red colouration with ferric chloride (Bamberger, Ber. 1899, 1805). It may be estimated by titration in alkaline solution with mercury acetamide, which is reduced to metallic mercury (Forster, Chem. Soc. Trans. 1898, 785); by oxidation with vanadic sulphate, measuring the nitrogen evolved and titrating the vanadous sulphate with potassium permanganate (Hofmann and Küspert, Ber. 1896, 64); by adding excess of standard titanium trichloride and titrating back the excess with potassium permanganate (Stähler, *ibid.* 1904, 4732; *v.* also *ibid.* 1909, 2695); by titrating the solution with potassium permanganate after the addition of sodium oxalate (Simon, Compt. rend. 135, 1339); by boiling with excess of N/10 silver nitrate solution, ammonia, and caustic soda and estimating the silver nitrate unacted upon (Denigés, Ann. Chim. Phys. 7, [vi.] 427). Jones and Carpenter (Chem. Soc. Trans. 1903, 1394) add the solution containing the hydroxylamine to a hot solution of potassium copper carbonate or tartrate with stirring. The solution is boiled, filtered, the precipitate washed with hot water and dissolved in ferrous sulphate in an atmosphere of carbon dioxide. The ferrous salt is titrated back with potassium permanganate.

$$4 \text{ mols. } K_2Mn_2O_8 = 10 \text{ mols. } NH_2OH.$$

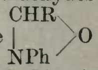
Schaeffer (Bull. Mulhouse, 1883) has applied the reducing properties of hydroxylamine in order to discharge manganese brown. The hydrochloride NH_2OH,HCl must be used. On printing this upon a manganese ground the latter is instantly reduced to manganese chloride. A very dark indigo, blue-dyed on manganese, is lowered to a lighter and brighter blue by the elimination of the MnO_2. In like manner nankin, chamois, and similar colours can be discharged white (J. Soc. Chem. Ind. 3, 166).

Hydroxylamine and its salts have been used as developers in photography, and for recovering silver from fixing bath solutions and waste liquors (Lainer, J. Soc. Chem. Ind. 1890, 890). It is a powerful antiseptic (Marpmann, Pharm. Centr. N.F. 10, 245) and has been used as a substitute for chrysarobin and pyrogallic acid, as it does not discolour the skin or bandages and has a strong reducing action (Schwarz, Pharm. Zeit. 33, 659).

Ethylhydroxylamines *v.* ETHYL.

β-Phenylhydroxylamine C_6H_5NHOH. Prepared by the reduction of nitrobenzene (1) in water with zinc (Bamberger, Ber. 1894, 27, 1348, 1548; Wohl, *ibid.* 1432); (2) in alcohol with zinc (Wohl, *ibid.* 1434; D. R. P. 84138; Frdl. iv. 44), or the zinc-copper couple (Wohl, D. R. P. 84891; *ibid.* 46) in the presence of anhydrous calcium chloride; (3) in aqueous alcohol with zinc amalgam in the presence of aluminium sulphate (Bamberger and Knecht, Ber. 1896, 29, 864); (4) in ether with zinc in the presence of anhydrous calcium chloride (Goldschmidt, *ibid.* 2307); (5) in aqueous ether with aluminium amalgam (Wislicenus, *ibid.* 494; J. pr. Chem. [ii.] 54, 57); (6) in ammonium chloride with zinc (Kalle & Co. D. R. P. 89978; Frdl. iv. 47); (7) electrolytically in acetic acid (Haber, Zeitsch. Elektrochem. 1898, 5, 77) or in alcoholic ammonia (Schmidt, Zeitsch. physikal. Chem. 32, 272); by the oxidation of aniline in ethereal solution with Caro's acid (Bamberger and Tschirner, Ber. 1899, 32, 343).

β-Phenylhydroxylamine forms colourless needles, m.p. 81°–82°; soluble in 10 parts of hot and 50 of cold water, readily soluble in alcohol, ether, carbon disulphide, and chloroform, sparingly so in petroleum. It dissolves in sulphuric acid with a deep blue colour. By heating at 100° azobenzene together with aniline, azoxybenzene, and other products are formed. Oxidation with potassium permanganate gives first nitrosobenzene, then nitrogen and azoxybenzene (Bamberger and Tschirner, Ber. 1899, 32, 342); in dilute neutral solution hydrogen peroxide yields azoxybenzene, in alkaline solution azoxybenzene and nitrobenzene (Bamberger, *ibid.* 1900, 33, 119). In the presence of hydroxylamine and air it is partly oxidised to azoxybenzene and partly reduced to aniline, phenylazoimide, and benzeneazohydroxyanilide also being formed (Bamberger, *ibid.* 1902, 35, 3893). It dissolves in sodium hydroxide forming a sodium salt which in the absence of air yields azoxybenzene, and in the presence of air azoxybenzene and nitrobenzene; alcoholic potash yields azobenzene (Bamberger and Brady, *ibid.* 1900, 33, 271). Mineral acids yield *p*-aminophenol and azoxybenzene; alcoholic sulphuric acid gives azoxybenzene, *o*- and *p*-phenetidine, *o*- and *p*-aminophenols, aniline and other compounds (Bamberger and Lagutt, *ibid.* 1898, 31, 1501). With aromatic aldehydes it yields phenylaldoximes of the type



$$\left.\begin{matrix} CHR \\ | \\ NPh \end{matrix}\right\rangle O$$

(Plancher and Piccinini, Atti. R. Acad. Lincei. 1905, [v.] 14, ii. 36). (For constitution, *v.* Brühl, Zeitsch. physikal. Chem. 1898, 26, 47.)

Nitrosophenylhydroxylamine $C_6H_5N(NO)OH$. Prepared by the action of sodium nitrite and dilute sulphuric acid on β-phenylhydroxylamine (Wohl, Ber. 1894, 27, 1435; Bamberger, *ibid.* 1553); or by the interaction of hydroxylamine and nitrobenzene in alcoholic solution in the presence of sodium ethoxide (Angeli, *ibid.* 1896, 29, 1885; Angelico, Atti. R. Accad. Lincei, [v.] 8, ii. 28).

It crystallises from petroleum in colourless needles, melting at 58°–59° and decomposing at 75°; sparingly soluble in water, readily so in most organic solvents. On heating it decomposes into nitrosobenzene and other substances (Bamberger, Ber. 1898, 31, 574, 1507). Alcoholic or ethereal solutions give a brownish-red colouration with a few drops of dilute ferric chloride (Bamberger and Ekecrantz, *ibid.* 1896, 29, 2412). Reduction with sodium amalgam yields phenylhydrazine; oxidation with potassium permanganate or sodium hypochlorite, nitrosobenzene. By heating with dilute mineral acids nitrosobenzene is formed, whilst nitrous acid yields benzenediazonium nitrite.

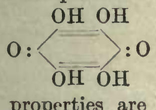
Cupferron, *Ammonium nitrosophenylhydroxylamine,* is prepared by dissolving β-phenylhydroxylamine in ether at 0°, passing in dry ammonia and adding excess of amyl nitrite, when a snow-white crystalline mass of ammonium nitrosophenylhydroxylamine is formed (Baudisch and King, J. Ind. Eng. Chem. 1911, 3, 629).

Cupferron is used in quantitative analysis for separating copper and iron from most of the metals. The iron and copper are precipitated in strongly acid solution with cupferron, the precipitate filtered, washed with water, and finally with ammonium hydroxide. The latter dissolves the copper, but not the ferric salt. The ferric salt is soluble in chloroform, ether, acetone, &c., and may be dissolved and separated from other salts, such as those of lead, silver, or tin, which may have been precipitated with it (Baudisch, Chem. Zeit. 1909, 33, 1298; Biltz and Hödtke, Zeitsch. anorg. Chem. 1910, 66, 426; Hanuš and Soukup, *ibid.* 68, 52; Fresenius, Zeitsch. anal. Chem. 1911, 50, 35). The use of cupferron as an analytical reagent is limited by virtue of its explosive properties.

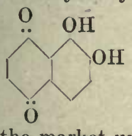
HYDROXYQUINOL *v.* PHENOL AND ITS HOMOLOGUES.

HYDROXYQUINOLINE *v.* QUINOLINE.

HYDROXYQUINONE COLOURING MATTERS. The hydroxyquinones form an important group of mordant colouring matters which are characterised by containing at least one hydroxyl group adjacent (ortho- or peri-) to an oxygen atom of a quinone, but usually two hydroxyl groups in the ortho- position with respect to one another. They possess the property of forming insoluble, coloured salts with certain metallic oxides, and therefore, when dyed on a fabric impregnated (mordanted) with such oxides, for example, the oxides of aluminium, chromium, and iron, lakes are formed which are extremely fast. The simplest compound possessing the above requirements is tetrahydroxy-*p*-benzoquinone

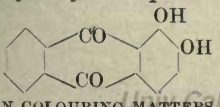


but its dyeing properties are not sufficiently intense for it to be of practical value. This desideratum is first reached in the naphthalene series in the case of dihydroxynaphthaquinone



which comes on the market under the name of Naphthazarin (*see* under NAPHTHALENE).

By far the most valuable and important hydroxyquinones are those belonging to the anthracene series, of which a large number are manufactured. The simplest and best known of these is dihydroxyanthraquinone or alizarin



(*See* ALIZARIN COLOURING MATTERS.) J. C. C.

HYDROXYSTEARIC ACIDS $C_{18}H_{36}O_3$.

α-Hydroxystearic acid

$CH_3[CH_2]_{15}CH(OH)CO_2H.$

Prepared by treating α-bromostearic acid with aqueous potash. Separates from a mixture of benzene and petroleum as a crystalline powder, m.p. 91°–92° (Hell and Sadomsky, Ber. 1891, 2391; Le Sueur, Chem. Soc. Trans. 1904, 827). By heating it to 270°, it yields margaric aldehyde $C_{16}H_{33}{\cdot}CHO$, a lactide $C_{36}H_{68}O_4$, formic acid, water and carbon dioxide.

β-Hydroxystearic acid

$CH_3[CH_2]_{14}CH(OH)CH_2{\cdot}CO_2H.$

Prepared by treating β-bromstearic acid with aqueous potash. Crystallises from chloroform in white plates, m.p. 89° (Ponzio, Atti. R. Accad. Sci. Torino, 1905, 40, 970).

γ-Hydroxystearic acid exists only in the form of a lactone  $CH_3[CH_2]_{13}CH\left<\begin{matrix}CH_2{\cdot}CH_2{\cdot}\\ O{\cdot}CO\end{matrix}\right.$ Obtained by treating the anhydride of γ-hydroxyoleic acid with potash (Geitel, J. pr. Chem. 37 [ii.] 85). Prepared by heating oleic acid with anhydrous zinc chloride. Oxidation with chromic acid in glacial acetic acid converts it into liquid monobasic and small quantities of dibasic acids, including succinic acid and γ-ketostearic acid $CH_3[CH_2]_{13}CO[CH_2]_2CO_2H$, m.p. 97° (Shukoff and Schestakoff, J. Russ. Phys. Chem. Soc. 1903, 35, 1).

ι-Hydroxystearic acid

$CH_3[CH_2]_7{\cdot}CH(OH)[CH_2]_8CO_2H.$

This acid was formerly described as *β-hydroxstearic acid* (A C. and M. Saytzew, J. Russ. Phys. Chem. Soc. 1886, 328; 17, 426; J. pr. Chem. 35, [ii.] 369, 384; Fremy, Annalen, 19, 296; 20, 50; 33, 10; Ann. Chim. Phys. 65, [ii.] 113; Sabanejew, J. Russ. Phys. Chem. Soc. 18, 41; Geitel, J. pr. Chem. 37 [ii.] 81; Leichti and Suida, Ber. 1883, 2458). Shukoff and Schestakoff (J. Russ. Phys. Chem. Soc. 1903, 35, 1) have shown that its constitution is that of ι-hydroxystearic acid. It is prepared from the sulpho or iodo derivative of oleic acid, or best by the action of sulphuric acid on oleic acid; m.p. 83°–85°. It may also be obtained from elaidic acid by the action of sulphuric acid and subsequent treatment with alcoholic potash (Tscherbakow and Saytzew, J. pr. Chem. 57, [ii.] 27). By heating to 100° it yields an anhydride; oxidation with chromic acid in glacial acetic acid converts it into sebacic, azelaic, and traces of suberic and liquid monobasic acids and ι-ketostearic acid $CH_3[CH_2]_7CO[CH_2]_7CO_2H$, m.p. 76°. Molinari and Barosi (Ber. 1908, 2794) have obtained an acid by the decomposition of the ozonide of oleic acid and consider it to be formed by the aldol condensation of monaldehyde with nonoic acid, and hence they consider it to ι-hydroxystearic acid; it melts at 41°, and hence is either impure or a hydroxystearic acid containing the hydroxyl group in some other position.

κ-Hydroxystearic acid

$CH_3[CH_2]_6CH(OH)[CH_2]_9CO_2H.$

This acid was formerly described as *α-hydroxystearic acid* (Saytzew, J. pr. Chem. 37, [ii.] 277, 284). Shukoff and Schestakoff (J. Russ. Phys. Chem. Soc. 1903, 35, 1) have shown that its constitution is that of κ-hydroxystearic acid; m.p. 84°–85°. Prepared by the action of sulphuric acid on *iso*oleic acid. Oxidation with chromic acid in glacial acetic acid yields sebacic acid, nonylene-$\alpha\iota$-dicarboxylic acid (m.p. 124°) and κ-ketostearic acid,

$$CH_3[CH_2]_6CO[CH_2]_9CO_2H,$$

m.p. 65°.

λ-Hydroxystearic acid (12-*Hydroxystearic acid*)

$$CH_3[CH_2]_5CH(OH)[CH_2]_{10}CO_2H.$$

Prepared from the methyl ester which is obtained by the reduction of the methyl ester of ricinoleic acid; m.p. 78° (Grün and Woldenberg, J. Amer. Chem. Soc. 1909, 31, 490). Kasansky (J. Russ. Phys. Chem. Soc. 1900, 32, 149) by acetylating ricinoleic acid, followed by bromination and reduction, obtained a hydroxystearic acid (m.p. 81°–82°) which is possibly identical with the above.

HYDURILIC ACID $C_8H_6O_6N_4,H_2O$ or $2H_2O$;  $CO\left<\begin{matrix}NH\cdot CO\\NH\cdot CO\end{matrix}\right>CH\cdot CH\left<\begin{matrix}CO\cdot NH\\CO\cdot NH\end{matrix}\right>CO$, was first prepared by Schlieper (Annalen, 1845, 56, 11), who obtained the acid ammonium salt together with alloxan by the action of nitric acid (sp.gr. 1·25) on uric acid. It is also prepared (2) in the form of its ammonium salt by prolonged boiling of alloxan or alloxantin with very dilute sulphuric acid (Finch, Annalen, 1864, 132, 303); (3) by heating crystallised alloxantin in a tube at 170° when it is converted quantitatively into hydurilic acid, according to the equation

$$2C_8H_4O_7N_4+3H_2O$$
$$=C_8H_6O_6N_4+4NH_3+(COOH)_2+2CO+4CO_2$$

or alloxan is similarly decomposed (Murdoch and Doebner, Ber. 1876, 9, 1102); (4) in the form of its acid ammonium salt by heating dialuric acid with glycerol at 150°, formic acid and carbon dioxide being formed at the same time (Baeyer, Annalen, 1863, 127, 14); (5) together with glycine and carbon dioxide by heating uric acid with twice its weight of concentrated sulphuric acid (Schultzen and Filehne, Ber. 1868, 1, 150); (6) by reducing dibromobarbituric acid with hydrogen iodide (Baeyer, Annalen, 1864, 130, 133); and it is also formed to a small extent by reducing alloxantin with sulphuretted hydrogen (Murdoch and Doebner, *l.c.*); (7) by the condensation of ethyl ethanetetracarboxylate with carbamide in the presence of sodium ethoxide at 60°–70°; or by the hydrolysis of ethanetetracarbonylguanide

$$NH{:}C\left<\begin{matrix}NH\cdot CO\\NH\cdot CO\end{matrix}\right>CH\cdot CH\left<\begin{matrix}CO\cdot NH\\CO\cdot NH\end{matrix}\right>C{:}NH,H_2O$$

by means of dilute hydrochloric acid at 150° (Conrad, Annalen, 1907, 365, 24). Hydurilic acid is most conveniently purified by precipitating the sparingly soluble copper salt from a solution of the neutral ammonium salt, and decomposing this with hot hydrochloric acid, in which the hydurilic acid is only slightly soluble (Baeyer, Annalen, 1863, 127, 15).

Hydurilic acid crystallises from hot water in small four-sided prisms containing $2H_2O$, or is precipitated as a fine crystalline powder containing $1H_2O$ by the addition of hydrochloric acid to a hot aqueous solution. It is sparingly soluble in alcohol or cold water, more readily so in hot water; its heat of combustion is 658·5Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 328).

Hydurilic acid bears the same relation to dialuric and barbituric acids that alloxantin bears to alloxan and barbituric acid. Conrad (Annalen, 1907, 365, 24) has shown that its constitution is correctly represented by the formula  $CO\left<\begin{matrix}NH\cdot CO\\NH\cdot CO\end{matrix}\right>CH\cdot CH\left<\begin{matrix}CO\cdot NH\\CO\cdot NH\end{matrix}\right>CO$ by its synthesis from ethyl ethanetetracarboxylate and carbamide (*v. supra*), and also by the fact that on hydrolysis with concentrated hydrochloric acid at 200°–230° it is converted almost quantitatively into carbon dioxide, ammonia, and succinic acid; barbituric acid when similarly treated yields carbon dioxide, ammonia, and acetic acid.

Hydurilic acid is not attacked by reducing agents; it yields alloxan and dibromobarbituric acid when treated with bromine.

Fuming nitric acid oxidises it into alloxan, whilst weaker acid converts it into nitrobarbituric acid (dilituric acid), *iso*nitrosobarbituric acid (violuric acid) and violantin. Ferric chloride or silver oxide oxidises it to oxyhydurilic acid, which gives a blood-red colouration with ferric chloride. Hydurilic acid has marked acidic properties, and decomposes most metallic chlorides and acetates, yielding the corresponding hydrogen hydurilate. The heat of neutralisation of hydurilic acid with 2 mols. potassium hydroxide is 21·8Cal.; but on adding a further quantity of alkali (up to 16 mols.) there is a further evolution of 4·2Cal. of heat, thus pointing to the existence of a third very feeble acid function. The following salts have been described: the *ammonium hydrogen* salt

$$NH_4{\cdot}C_8H_5O_6N_4,$$

small octahedral sparingly soluble crystals precipitated by acetic acid from solutions of the *normal ammonium* salt $(NH_4)_2C_8H_4O_6N_4$ which crystallises in needles with $1H_2O$ or in large monoclinic crystals with $4H_2O$, $a:b:c=1{\cdot}0821:1:0{\cdot}7003$. *Sodium* salt

$$Na_2C_8H_4O_6N_4,4H_2O$$

crystallises in prisms; *potassium hydrogen* salt $KC_8H_5O_6N_4$ forms sparingly soluble microscopic needles; the *normal* salt $K_2C_8H_4O_6N_4,3H_2O$ is soluble and crystallises in prisms (Matignon). The *calcium* salts $Ca(C_8H_5O_6N_4)_2,8H_2O$ and $CaC_8H_4O_6N_4,3H_2O$ are crystalline and almost insoluble; the *barium* salt $BaC_8H_4O_6N_4,H_2O$; the *zinc* salts $Zn(C_8H_5O_6N_4)_2$ and

$$ZnC_8H_4O_6N_4,2H_2O$$

are crystalline; the *copper* salt

$$Cu(C_8H_5O_6N_4)_2,8H_2O$$

forms fine yellow needles or prisms, which become red on heating with loss of water. The *silver* salt is unstable; the *ferric* salt is a dark green precipitate, and the formation of a dark green colour with ferric chloride is a characteristic reaction of the salts of hydurilic acid; the *ferrous* salt is white becoming green; the *lead* salt is insoluble in acetic acid.

Dichlorohydurilic acid $C_8H_4Cl_2O_6N_4,2H_2O$ is obtained by the action of potassium chlorate on an intimate mixture of hydurilic and concentrated hydrochloric acids (Baeyer, Annalen, 1863, 127, 26). It is a sparingly soluble powder, soluble in concentrated sulphuric acid and precipitated therefrom by the addition of water, in small rhombic crystals containing $2H_2O$; it is readily decomposed by alkalis yielding the metallic chloride. The *potassium* salt

$$K_2C_8H_2Cl_2O_6N_4,2H_2O$$

is a sparingly crystalline soluble powder.

Tetramethylhydurilic acid (*deoxyamalic acid*) $C_{12}H_{14}O_6N_4$;

$$CO\left\langle\begin{array}{l}NMe\cdot CO\\NMe\cdot CO\end{array}\right\rangle CH\cdot CH\left\langle\begin{array}{l}CO\cdot NMe\\CO\cdot NMe\end{array}\right\rangle CO$$

is obtained by the dry distillation of amalic acid (Fischer and Reese, Annalen, 1883, 221, 339), or more conveniently by heating it in a sealed tube for 3 hours at 180°–185° (Matignon, Compt. rend. 1893, 116, 642); has also been obtained by heating dimethyl*pseudo*uric acid with fused oxalic acid at 170° (Fischer and Ach, Ber. 1895, 28, 2473). Deoxyamalic acid is crystalline, has m.p. 260°, with decomposition and can be distilled, although with partial decomposition. It is almost insoluble in hot or cold water; readily soluble in chloroform or acetic acid; its heat of combustion is 1321·8 Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 327). Its chemical properties are similar to those of hydurilic acid, it reduces ammoniacal silver nitrate solution on warming, and gives a beautiful green colouration with ferric chloride; on gentle oxidation it yields a product that gives a blood-red colouration with ferric chloride; but when oxidised by nitric acid it forms dimethylalloxan.

Deoxyamalic acid has only two acidic functions; the *potassium* $K_2C_{12}H_{12}O_6N_4$ and the *sodium* salt $Na_2C_{12}H_{12}O_6N_4$ are sparingly soluble (Matignon, *l.c.*; Fischer and Ach, *l.c.*).

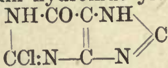
$$\begin{array}{l}N:C(OH)\cdot C\cdot NH\\ \quad\;\; | \qquad\quad \| \qquad\quad \rangle CH\\ CH:N\text{—}C\text{—}N\end{array}\quad\text{or}\quad\begin{array}{l}NH\cdot CO\cdot C\cdot NH\\ \;| \qquad\quad \| \qquad\quad \rangle CH,\\ CH:N\text{—}C\text{—}N\end{array}$$

discovered by Scherer (Annalen, 1850, 73, 328) in milk, spleen, and blood, is widely distributed both in the animal and vegetable kingdoms. Strecker (Phil. Trans. 1858, 10, 121) isolated it from meat juice, and hence called it *sarcine;* it was afterwards found to be identical with Scherer's hypoxanthine. It is a normal constituent of bone marrow (Heymann, Pflüger's Archiv. 6, 184), glands, muscles, liver, brain (Salomon, Ber. 1878, 11, 574; Kossel, Chem. Zentr. 1881, 486), blood (Scherer, *l.c.*; Salomon, Chem. Zentr. 1878, 681) and urine (Strecker, *l.c.*; Salomon, Zeitsch. physiol. Chem. 1887, 11, 410), the amount varying from 0·024 p.c. in the grey matter of the brain (Kossel, *l.c.*) to 0·218 p.c. in the calf's thymus (Schindler, Zeitsch. physiol. Chem. 1889, 13, 432). Piccard found 5–8 p.c. of hypoxanthine and guanine in salmon roe (Ber. 1874, 7, 1714), whilst ox testis and the spermatozoa of carp contain 0·281 and 0·309 p.c. respectively of the former base (Schindler, *l.c.*). In the vegetable kingdom hypoxanthine occurs in beer yeast (Schutzenberger, Chem. Zentr. 1877, 73); potato juice to the extent of 0·0037 gram per 1 c.c. (Schulze, Landw. Versuchs. Stat. 1882, 28, 111); in the leaf buds of plane and maple, bark of plane, in lupines, young grass, red clover, oats, vetch, and in sugar beet (Schulze and Bosshard, Zeitsch. physiol. Chem. 1885, 9, 420; Von Lippmann, Ber. 1896, 29, 2645).

The chief source of hypoxanthine in the animal economy appears to be nucleic acid, which, under the action of certain tissue enzymes; most abundant in the liver and spleen, is decomposed; thus *nuclease* liberates the purine bases adenine and guanine, and these are further changed by the deamidising enzymes *adenase* or *guanase* into hypoxanthine and xanthine respectively, and finally *oxydases* convert hypoxanthine into xanthine and xanthine into uric acid (Halliburton, Chem. Soc. Reports. 1909, 168). Salomon (Ber. 1887, 11, 574; 12, 95) obtained hypoxanthine from blood fibrin by the action of pancreas ferment, by simple decay, or by digestion with dilute hydrochloric acid (8 parts in 1000 parts of water); and Kossel (Zeitsch. physiol. Chem. 1881, 5, 152) found that the nuclein from pus cells and goose blood yielded on prolonged boiling 1·03 and 2·64 p.c. respectively of hypoxanthine. On the other hand, Leathes (J. Physiol. 1906, 35, 125, 205), Leonard and Jones (J. Biol. Chem. 1909, 6, 453), and Vögtlin and Jones (Zeitsch. physiol. Chem. 1910, 66, 250), have shown that uric acid excretion is related in some way to muscular exercise, and the most important purine base which contributes to the endogenous uric acid is muscular preformed hypoxanthine. This is not directly connected with nuclein metabolism, since it may occur in the absence of adenase, an essential factor in the passage from nucleic acid to hypoxanthine.

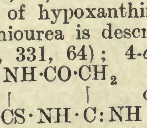
Fischer (Ber. 1897, 30, 2226; D. R. P. 1898, 17673) has synthesised hypoxanthine from trichloropurine by the following reactions: trichloropurine when heated with normal aqueous potassium hydroxide yields 6-*oxy*-2 : 8-*dichloropurine*



$$\begin{array}{l}NH\cdot CO\cdot C\cdot NH\\ \;| \qquad\quad \| \qquad\quad \rangle CCl,\\ CCl:N\text{—}C\text{—}N\end{array}$$

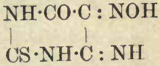
which is reduced to hypoxanthine by the action of hydrogen iodide. Hypoxanthine is also obtained from adenine (6-*aminopurine*) by the action of nitrous acid, or from uric acid by reduction with alkali and chloroform (Sundvik, Zeitsch. physiol. Chem. 1897, 23, 476; 26, 13).

A further synthesis of hypoxanthine from ethylcyanacetate and thiourea is described by Traube (Annalen, 1904, 331, 64); 4-*amino*-6-*hydroxy*-2-*thiopyrimidine*



$$\begin{array}{l}NH\cdot CO\cdot CH_2\\ | \qquad\quad\;\; |\\ CS\cdot NH\cdot C:NH\end{array}$$

obtained by the condensation of ethylcyanacetate and thiourea in the presence of sodium ethoxide, forms an *isonitroso derivative*

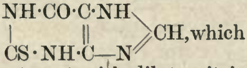


$$\begin{array}{l}NH\cdot CO\cdot C:NOH\\ | \qquad\quad\;\; |\\ CS\cdot NH\cdot C:NH\end{array}$$

which on reduction yields 4 : 5-*diamino*-6-*oxy*-2-*thiopyrimidine*

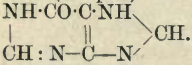
$$\begin{array}{l}NH\cdot CO\cdot C\cdot NH_2\\ | \qquad\quad\;\; \|\\ CS\cdot NH\cdot C\cdot NH_2\end{array}$$

. When the sodium salt of the *formyl* derivative of this compound is heated at 250°–255° it is converted into 6-*oxy*-2-*thiopurine*



$$\begin{array}{l} \mathrm{NH{\cdot}CO{\cdot}C{\cdot}NH}\diagdown \\ \;|\qquad\quad\;\; \| \qquad\quad\; >\mathrm{CH} \\ \mathrm{CS{\cdot}NH{\cdot}C{-}N}\diagup \end{array}$$

, which loses its sulphur on treatment with dilute nitric acid (25 p.c.) at 100°, yielding hypoxanthine



$$\begin{array}{l} \mathrm{NH{\cdot}CO{\cdot}C{\cdot}NH}\diagdown \\ \;|\qquad\quad\;\; \| \qquad >\mathrm{CH.} \\ \mathrm{CH:N{-}C{-}N}\diagup \end{array}$$

Hypoxanthine is a white crystalline powder, crystallising in two modifications, one form consisting of needles containing water of crystallisation, which spontaneously and readily lose their water yielding anhydrous octahedra (Micko, Zeitsch. Nahr. Genussm. 1904, 8, 225); it decomposes without melting at 150°, and dissolves in 69·5 parts of boiling water or 1400 parts at 19° (Fischer, Ber. 1897, 30, 2226).

Hypoxanthine exhibits both acid and basic properties, and combines with one equivalent of an acid, or two equivalents of a base; the following *salts* are described: the *hydrochloride* $C_5H_4N_4O{\cdot}HCl,H_2O$, crystalline plates or needles, yields a sparingly soluble *platinichloride*

$$(C_5H_4N_4O{\cdot}HCl)_2.PtCl_4;$$

and a crystalline *aurichloride*

$$C_5H_4N_4O{\cdot}HCl.AuCl_3$$

the *hydrobromide* $C_5H_4N_4O{\cdot}HBr$ and *nitrate* $C_5H_4N_4O{\cdot}NHO_3$ are crystalline; the *picrate* dissolves in 450–500 parts of water at the ordinary temperature (Krüger and Salomon, Zeitsch. physiol. Chem. 1898, 26, 362). The *barium* derivative $C_5H_4N_4O{\cdot}Ba(OH)_2$ is crystalline, the *silver* salt $C_5H_2N_4OAg_2,H_2O$ loses $\frac{1}{2}H_2O$ at 100°; in the presence of excess of ammonia the salt crystallises with $3H_2O$, and loses $2\frac{1}{2}H_2O$ at 120°.

Hypoxanthine forms characteristic sparingly soluble derivatives with certain metallic salts, and these are used for separating and estimating the base. The *compound* with *mercuric chloride* $C_5H_3N_4O,HgCl_2,H_2O$ is crystalline; the *compound* with *silver nitrate* $C_5H_4N_4O,AgNO_3$ is a flocculent precipitate, crystallising from hot nitric acid (sp.gr. 1·1), 1 part dissolves in 4960 parts cold nitric acid; according to Salkowski (Pflüger's Archiv. 4, 91), the presence of gelatin prevents the precipitation of hypoxanthine by silver nitrate; the *picrate* $AgC_5H_3N_4O,C_6H_3N_3O_7$ is a lemon-yellow crystalline salt, insoluble in cold water, precipitated from a hypoxanthine salt by sodium picrate and silver nitrate (Bruhns, Zeitsch. physiol. Chem. 1890, 14, 555).

Bromohypoxanthine $C_5H_3BrN_4O,2H_2O$ is sparingly soluble in cold water, and is obtained by the action of bromine (1 mol.) on hypoxanthine (1 mol.) at 120°, or by the action of sodium nitrite on a solution of bromadenine at 70°; on heating hypoxanthine for 6 hours at 100°–150° with excess of bromine, *bromohypoxanthine-tetrabromide hydrobromide* $C_5H_3BrN_4O{\cdot}HBr{\cdot}Br_4$ is obtained (Krüger, Zeitsch. physiol. Chem. 1894, 18, 449).

Urethane of hypoxanthine $C_5H_3N_4O{\cdot}COOEt$ prepared by the interaction of ethylchlorocarbonate and hypoxanthine, crystallises in plates, m.p. 185°–190°, and is sparingly soluble (Bruhns and Kossel, Zeitsch. physiol. Chem. 1892, 16, 1). Hypoxanthine combines with adenine to form the crystalline *compound*

$$C_5H_4N_4O{\cdot}C_5H_5N_5,3H_2O$$

(Bruhns, Ber. 1890, 23, 225); and like other purine derivatives containing an imino group in position 7 it yields coloured *derivatives* with diazobenzene salts (Burian, Ber. 1904, 37, 696).

Separation and estimation.—From mixtures of the xanthine bases, adenine and hypoxanthine are separated from xanthine and guanine by means of their sparingly soluble derivatives with silver nitrate in nitric acid solution. The mixed silver compounds are decomposed by hydrochloric acid, the filtrate nearly neutralised with sodium carbonate and the adenine precipitated as picrate. The filtrate is neutralised with ammonia, and the hypoxanthine precipitated with ammoniacal silver nitrate (Bruhns, Ber. 1890, 23, 225; *cp.* also Kossel, Zeitsch. physiol. Chem. 1883, 8, 404; Schindler, *ibid.* 1889, 13, 432: Krüger, *ibid.* 1894, 20, 170). M. A. W.

HYRGOL *v.* SYNTHETIC DRUGS.

HYSTARAZIN *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

I

IBIT *v.* SYNTHETIC DRUGS.

IBOGA. A plant *Tabernanthe iboga* (Baill.), natural order *Acanthaceæ*, found in the Congo, the root of which is chewed by the natives and which is said to possess properties similar to those of coca and kola. It enables persons to withstand fatigue, is used as a remedy for sleeping sickness and acts as an aphrodisiac. According to Dybowski and Landrin, its active principle is an alkaloid, *ibogaïne* $C_{26}H_{33}N_3O$, which readily oxidises on exposure to air. It is lævorotatory and forms well crystallised salts (Compt. rend. 133, 748).

ICACIN *v.* OLEO-RESINS.

ICHTHARGAN *v.* SYNTHETIC DRUGS.

ICHTHYOL. A pharmaceutical product distilled from fossilised fish remains, found in the Tyrol and on the coasts of the Adriatic.

Crude ichthyol from the Seefeld district between Southern Bavaria and the Tyrol has long been used as an antiseptic remedy. The crude 'rock oil' is obtained by simple distillation from the shale or 'stinkstein,' a bituminous substance of a grey or black colour occurring in the upper dolomites. The amount of oil obtained varies from 1 to 10 p.c. An installation of nine stills yields, on an average, 15 to 20 kilos. of oil per charge. In one works the output of crude oil is over 3000 kilos per annum. As found in pharmacy, the substance consists mainly of the ammonium sulphonate. It is not a simple substance but a mixture of ammonium ichthyol sulphonate with about 1 p.c.

of a powerful-smelling empyreumatic oil, 5 to 7 p.c. of ammonium sulphate, and about 50 p.c. water.

According to Baumann and Schotten, ichthyol-sulphonic acid has the formula

$$C_{28}H_{26}S(SO_2OH)_2.$$

An odourless ichthyol has been prepared by Knorr & Co. which has the therapeutic activity of the original strong-smelling product (J. Soc. Chem. Ind. 1903, 1304; 1910, 44, 174, 264).

For ichthyol preparations *v.* Synthetic drugs.

ICICA and **ICACIN** *v.* Oleo-resins.

ICOSANE $C_{20}H_{42}$. A hydrocarbon found in paraffin. M.p. 36°; b.p. (under 15 mm. pressure) 205°; sp.gr. 0·778 at 37°/4°. Formed by the action of sodium on normal decyl iodide.

ICOSONENE *v.* Resin oil.

IDRYL *v.* Fluoranthene.

IGNOTINE *v.* Carnosine.

ILICIC and **ILICYLIC ALCOHOLS** *v.* Bird-lime.

ILLIPÉ-NUT FAT. Illipé-nuts yield a considerable quantity of a fat which is imported from the Dutch East Indies, and used in conjunction with palm-kernel oil in the manufacture of candles. It is well adapted for the saponification method of stearin manufacture. In the autoclave it yields about 10 p.c. of glycerol of 28°B. (J. Soc. Chem. Ind. 1898, 161, 358); *v.* Bassia oil.

ILMENITE, or titaniferous iron-ore. A common mineral with approximately the formula $FeTiO_3$, but of variable composition. In its rhombohedral crystalline form it shows a close agreement with hæmatite, and it has consequently, until recently, been regarded as an isomorphous mixture of ferric oxide and titanium sesquioxide, the formula being written as an oxide $(Fe,Ti)_2O_3$. The discovery of the rhombohedral titanates of magnesium and manganese, geikielite ($MgTiO_3$) and pyrophanite ($MnTiO_3$), and the frequent presence of magnesium (and manganese) in ilmenite, suggest, however, that the mineral is really a titanate of ferrous iron, $FeTiO_3$ (S. L. Penfield, Amer. J. Sci. 1897, 4, 108). In the variety *picroilmenite* a considerable amount of iron is replaced by magnesium, the formula then being $(Fe,Mg)TiO_3$ (T. Crook and B. M. Jones, Min. Mag. 1906, 14, 165).

Ilmenite is black with a sub-metallic lustre, and often a smooth and lustrous conchoidal fracture, sp.gr. 4·5–5; H. 5–6. The massive mineral in appearance somewhat resembles magnetite, from which it is readily distinguished by its feeble magnetic character. It is of constant occurrence as isolated grains in the more basic igneous rocks (gabbro, diabase, basalt, &c.); and in certain instances it forms rich segregations in such rocks. Enormous deposits of ilmenite are found under these conditions at several places in Norway, Sweden, Canada, and the United States. With the weathering and breaking down of these igneous rocks, grains of ilmenite (*Manaccanite*, from Manaccan in Cornwall) collect in the beds of streams, sometimes forming considerable deposits of 'black iron-sand.'

Although large deposits of ilmenite are available for mining, the mineral has not yet found any important applications. It has been used for the preparation of titanium paints and enamels; and in the future it may be more utilised for the manufacture of titanium-steel, which possesses great ductility and a high limit of elasticity. L. J. S.

IMPERIALINE $C_{35}H_{60}NO_4$. An alkaloid discovered by K. Fragner in *Fritillaria Imperialis* (Linn.). It is a heart-poison, and is probably closely related to the older alkaloid *Tulipine*, discovered by Gerard in *Tulipa Gesneriana* (Linn.).

IMPERIAL GREEN. *Emerald Green v.* Pigments.

IMPERIAL SCARLET *v.* Azo- colouring matters.

IMPERIAL YELLOW *v.* Aurantia.

INACTIVE CAMPHOR *v.* Camphors.

INCANDESCENT MANTLES *v.* Gas mantles.

INCARNATRIN *v.* Glucosides.

INCENSE TREE RESINS *v.* Gum-resins; Oleo-resins.

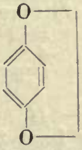
INDALIZARINE *v.* Oxazine colouring matters.

INDAMINES and **INDOPHENOLS.**

Constitution and mode of formation.—The indamines and indophenols are colouring matters most of which are too unstable to be of great practical value, but many of them are interesting as intermediate products in the manufacture of other more important dyestuffs. From a theoretical point of view they can claim great importance, as they form the starting-point of the modern 'quinonoid' structural formulæ now universally adopted for the majority of colouring matters. This is due to the fact that the indamines and indophenols are the simplest real colouring matters derived from the quinones, which are now considered as prototypes of chromogens.

All aromatic hydrocarbons are capable of forming quinonoid derivatives by the displacement of 2 hydrogen atoms by 2 atoms of oxygen. These may stand either in *o*- or in *p*-position to each other, whilst no quinones have ever been discovered which contain the oxygen atoms in *m*- position. The divalent nature of oxygen forces us to consider the quinones either as peroxides of aromatic hydrocarbons or as alicyclic diketones. The first of these possibilities was formerly considered as more probable and was made the basis of this article in the first edition of this dictionary. Since then the diketone formula has come to be generally adopted and it will therefore have to be used in this revision of the article.

The following formulæ represent the two different constitutions which may be given to *p*-quinone, the prototype of all the substances to be mentioned in this article:

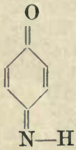


Peroxide formula.

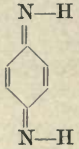
Diketone formula.

All other quinones, no matter from what aromatic hydrocarbon they are derived and whether they belong to the *o*- or *p*- series, may be similarly formulated and neither of these two different constitutions can be claimed as undoubtedly preferable to the other. It is very probable that the quinones are tautomeric and possessed of both constitutions according to the circumstances under which they react.

If the oxygen of *p*-quinone be replaced by divalent imino groups =NH, two compounds may be obtained, *p*-quinoneimide and *p*-quinonediimide, which for many years have been considered as hypothetical but have recently been prepared by Willstätter (Ber. 37, 1494, 4605). They are very unstable substances the constitution of which is expressed by the following formulæ (based, as all the subsequent formulæ of this article, on the diketonic constitution of the quinones):



p-Quinoneimide.



p-Quinonediimide.

The iminic hydrogen of these compounds may be replaced by halogen atoms, and we thus obtain substances of a comparatively stable nature which have been known for a long time and may be used for the preparation of various derivatives. It was by treating quinonedichlorodiimide, dissolved in ether, absolutely free from moisture, with the theoretical quantity of dry hydrogen chloride that Willstätter first succeeded in preparing *p*-quinonediimide. Later on he found a general method for the production of both these imides in the oxidation of either *p*-phenylenediamine or *p*-aminophenol with dry silver oxide. They are slightly basic substances, capable of forming unstable hydrochlorides. In a free state they are white, but they resemble quinone in their reactions. Their great tendency to polymerisation is the cause why previous attempts at their isolation have failed.

Quinonechloroimide  $\begin{array}{c}N{\cdot}Cl\\ \|\\ C_6H_4\\ \|\\ O\end{array}$ has been obtained by Schmitt and Bennewitz (J. pr. Chem. [ii.] 8, 2). It is prepared by allowing a solution of 43 grams *p*-aminophenol hydrochloride in 500 c.c. water and 100 c.c. concentrated hydrochloric acid to flow into a solution of sodium hypochlorite prepared by introducing 35 grams of chlorine into an ice-cold solution of 45 grams sodium hydroxide. The imide settles out and may be recrystallised from light petroleum (Willstätter, Ber. 37, 1499). It forms yellow crystals, melting at 85°; it is slightly explosive, volatile with aqueous vapour, and resembles quinone in many of its properties.

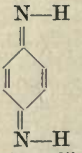
Trichloroquinonechloroimide  $\begin{array}{c}N{\cdot}Cl\\ \|\\ C_6HCl_3\\ \|\\ O\end{array}$ is prepared in the same manner from trichloraminophenol hydrochloride (Schmitt and Andresen, J. pr. Chem. [ii.] 23, 438; 24, 429). Yellow needles, m.p. 118°, similar to quinonechloromide.

Dibromoquinonechloroimide  $\begin{array}{c}N{\cdot}Cl\\ \|\\ C_6H_2Br_2\\ \|\\ O\end{array}$ is obtained by adding a solution of bleaching-powder to an aqueous acidulated solution of the double salt of dibromaminophenol hydrochloride and tin chloride. It separates in flesh-coloured crystals, melting at 80° (R. Möhlau, Ber. 16, 2845).

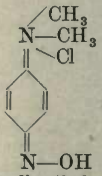
Quinonedichlorodiimide  $\begin{array}{c}N{\cdot}Cl\\ \|\\ C_6H_4\\ \|\\ N.Cl\end{array}$ is formed by acting with a solution of bleaching-powder upon a solution of *p*-phenylenediamine hydrochloride (Krause, Ber. 12, 47). Willstätter (Ber. 37, 1498) prepares it by allowing a solution of 54 grams *p*-phenylenediamine hydrochloride in 120 c.c. hydrochloric acid and 600 c.c. water to flow into a hypochlorite solution prepared by introducing 75 grams of chlorine into the solution of 90 grams sodium hydroxide in 500 c.c. of water. The imide separates in whitish flakes and may be recrystallised from light petroleum. White needles, insoluble in water, soluble in alcohol, benzene, &c., and exploding at 126°.

Quinonedibromodiimide  $\begin{array}{c}N{\cdot}Br\\ \|\\ C_6H_4\\ \|\\ N{\cdot}Br\end{array}$ may be prepared by acting with bromine water upon *p*-phenylenediamine hydrochloride (Krause, Ber. 12, 50). It is similar to the chloro derivative, and explodes at 86°.

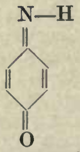
These substances are not colouring matters, as may be seen from the above description. They cannot be colouring matters, because they are indifferent, whilst every dyestuff must be either an amine or a phenol (Witt, Bau und Bildung färbender Kohlenstoffverbindungen, Ber. 9, 522). Their chromophoric character, however, becomes apparent in those of their derivatives which are endowed with either basic or acid properties. Nitrosodimethylaniline and nitrosophenol, which, as their constitutional formulæ show, are closely related to quinonediimide and quinoneimide:



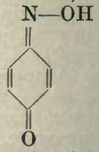
Quinonediimide.



Quinonedimethylamino-oxime chloride (Nitrosodimethylaniline hydrochloride).



Quinoneimide.

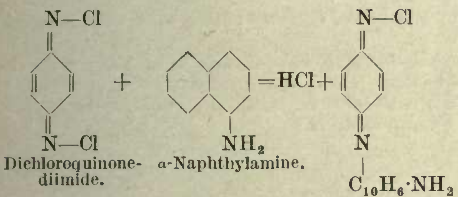


Quinoneoxime (Nitrosophenol).

are by virtue of their basic and phenolic nature, colouring matters possessing some affinity for fibres, although they have no practical value as dyestuffs.

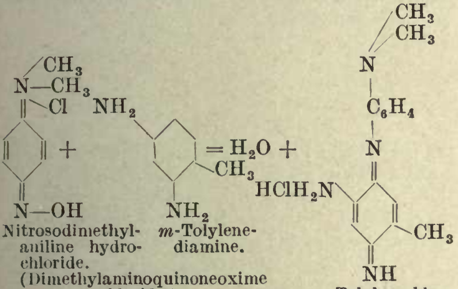
We may, however, obtain real colouring matters, many of which have proved useful and interesting, by preparing substitution products of the quinoneimides in which the substituting radicle is attached to nitrogen. Such products may be prepared by acting with amines or phenols upon quinoneimides, or their equivalents, quinonamidoximes (nitroso bases) and quinoneoximes (nitrosophenols). Various cases may here be cited:

1. By acting with aromatic amines upon quinonedichlorodiimides, indamines are formed, thus:



Dichloroquinonediimide. α-Naphthylamine. Naphthindamine.

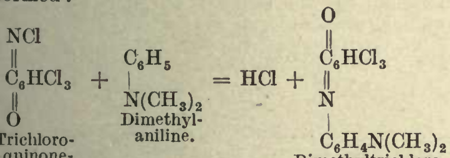
2. By acting with aromatic amines upon quinone-amidoximes (nitroso bases) indamines are formed likewise:



Nitrosodimethylaniline hydrochloride. (Dimethylaminoquinoneoxime chloride.) *m*-Tolylenediamine. Tolylene blue.

In this case, as in many similar ones in this group, the quinonoid character may in the formation of the dyestuff be shifted from one benzene ring to the other. This has been indicated in the formula, although we have no positive proof that such shifting takes place in the formation of tolylene blue.

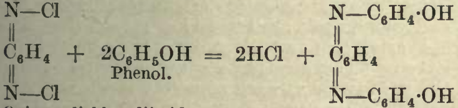
3. By acting with aromatic amines upon quinonechloroimides normal indophenols are formed:



$$\begin{array}{l}NCl\\ \|\\ C_6HCl_3\\ \|\\ O\end{array} + \begin{array}{l}C_6H_5\\ |\\ N(CH_3)_2\end{array} = HCl + \begin{array}{l}O\\ \|\\ C_6HCl_3\\ \|\\ N\\ |\\ C_6H_4N(CH_3)_2\end{array}$$

Trichloroquinonechloroimide. Dimethylaniline. Dimethyltrichlorobenzindophenol.

4. By acting with phenols upon quinonedichlorodiimides indophenols of a more complicated nature may be formed:

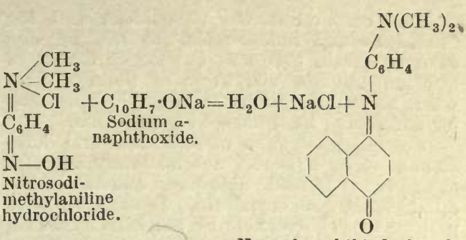


$$\begin{array}{l}N—Cl\\ \|\\ C_6H_4\\ \|\\ N—Cl\end{array} + 2C_6H_5OH = 2HCl + \begin{array}{l}N—C_6H_4{\cdot}OH\\ \|\\ C_6H_4\\ \|\\ N—C_6H_4{\cdot}OH\end{array}$$

Phenol.

Quinonedichlorodiimide. Complex indophenol.

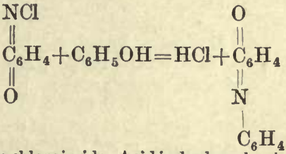
5. By acting with phenols upon quinonamidoximes (nitroso bases) normal indophenols are formed:



Nitrosodimethylaniline hydrochloride. Sodium α-naphthoxide. Normal naphthindophenol.

In this case again, as in No. 2, a migration takes place and the quinonoid nature is shifted from the benzene to the naphthalene nucleus. This can be proved to be the case by the fact that the resulting dyestuff is a weak base but entirely devoid of phenolic properties. It cannot therefore contain an OH group.

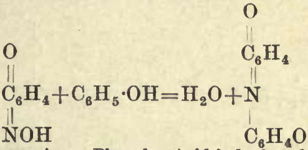
6. By acting with phenols upon quinonechloroimides colouring matters are formed, which although practically belonging to the indophenols are distinguished by the presence of a free hydroxyl group, by which they assume phenolic properties, dissolve in alkalis and have therefore been designated by the name of 'acid indophenols.'



$$\begin{array}{l}NCl\\ \|\\ C_6H_4\\ \|\\ O\end{array} + C_6H_5OH = HCl + \begin{array}{l}O\\ \|\\ C_6H_4\\ \|\\ N\\ |\\ C_6H_4{\cdot}OH\end{array}$$

Quinone chloroimide. Acid indophenol, soluble in alkalis.

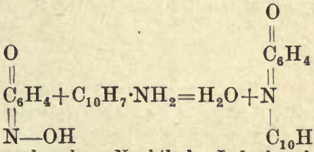
7. The same result takes place if the equivalents of quinoneimide, viz. the quinoneoximes or nitrosophenols be acted upon with phenols:



$$\begin{array}{l}O\\ \|\\ C_6H_4\\ \|\\ NOH\end{array} + C_6H_5{\cdot}OH = H_2O + \begin{array}{l}O\\ \|\\ C_6H_4\\ \|\\ N\\ |\\ C_6H_4OH\end{array}$$

Quinoneoxime (nitrosophenol). Phenol. Acid indophenol, soluble in alkalis.

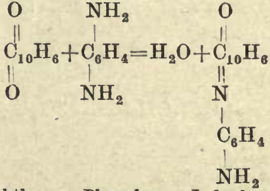
8. If, however, amines be acted upon with nitrosophenols, a normal indophenol is the result:



$$\begin{array}{l}O\\ \|\\ C_6H_4\\ \|\\ N—OH\end{array} + C_{10}H_7{\cdot}NH_2 = H_2O + \begin{array}{l}O\\ \|\\ C_6H_4\\ \|\\ N\\ |\\ C_{10}H_6{\cdot}NH_2\end{array}$$

Nitrosophenol. α-Naphthylamine. Indophenol, insoluble in alkali.

9. The quinones themselves may be utilised for the production of these dyestuffs by being acted upon with suitable diamines or aminophenols:



$$\begin{array}{l}O\\ \|\\ C_{10}H_6\\ \|\\ O\end{array} + \begin{array}{l}NH_2\\ |\\ C_6H_4\\ |\\ NH_2\end{array} = H_2O + \begin{array}{l}O\\ \|\\ C_{10}H_6\\ \|\\ N\\ |\\ C_6H_4\\ |\\ NH_2\end{array}$$

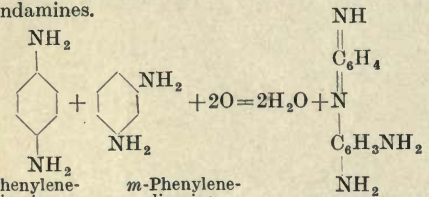
Naphthaquinone. *p*-Phenylenediamine. Indophenol.

This reaction makes it evident that the indamines and indophenols are nothing else than a certain group of the larger family of quinone anilides, viz. those of these anilides which contain the auxochromic groups necessary for developing their nature as dyestuffs.

For the production of indamines and indophenols it is, however, not necessary to start from ready-formed quinones, quinoneimides, diimides, or quinoneoximes. It is possible to prepare these substances by the joint oxidation of amines or phenols with compounds which are capable of producing a quinoneimide or diimide.

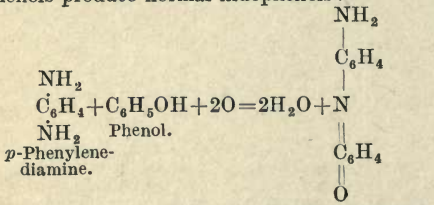
In this process we may assume that the hypothetical quinoneimides and -diimides are formed as intermediate products which immediately react upon the amines or phenols present in the mixture, forming indamines or indophenols, as the case may be. Every p-aminophenol or p-diamine is capable of being used for this reaction, and a large variety of colouring-matters may thus be produced. The following combinations may take place:

10. p-Diamines simultaneously oxidised with aromatic amines give rise to the formation of indamines.



p-Phenylene-diamine. m-Phenylene-diamine. Indamine (phenylene-violet).

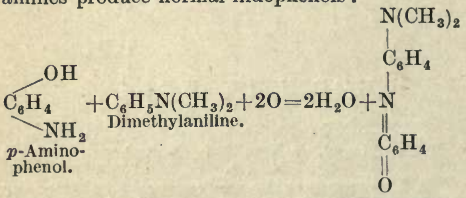
11. p-Diamines oxidised with aromatic phenols produce normal indophenols:



$$\begin{array}{c} NH_2 \\ C_6H_4 \\ NH_2 \end{array} + C_6H_5OH + 2O = 2H_2O + \begin{array}{c} NH_2 \\ | \\ C_6H_4 \\ | \\ N \\ \| \\ C_6H_4 \\ \| \\ O \end{array}$$

p-Phenylene-diamine. Phenol. Typical indophenol.

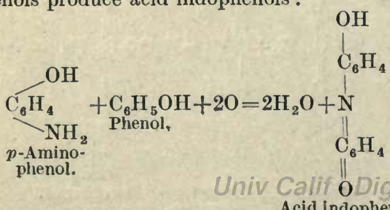
12. p-Aminophenols oxidised with aromatic amines produce normal indophenols:



$$C_6H_4\begin{array}{l} \diagup OH \\ \diagdown NH_2 \end{array} + C_6H_5N(CH_3)_2 + 2O = 2H_2O + \begin{array}{c} N(CH_3)_2 \\ | \\ C_6H_4 \\ | \\ N \\ \| \\ C_6H_4 \\ \| \\ O \end{array}$$

p-Amino-phenol. Dimethylaniline. Indophenol.

13. p-Aminophenols oxidised with aromatic phenols produce acid indophenols:



$$C_6H_4\begin{array}{l} \diagup OH \\ \diagdown NH_2 \end{array} + C_6H_5OH + 2O = 2H_2O + \begin{array}{c} OH \\ | \\ C_6H_4 \\ | \\ N \\ \| \\ C_6H_4 \\ \| \\ O \end{array}$$

p-Amino-phenol. Phenol. Acid indophenol.

From the above it will be seen that all the various colouring matters prepared by these reactions and built up on the quinone type may be subdivided into three varieties:—

a. True *indamines* containing no oxygen, and having the generic formula:

$$\begin{array}{l} R^{II} = NH \\ \| \\ N \\ | \\ R^{II} - NH_2 \end{array}$$

strong bases, forming stable salts with mineral acids.

b. Normal indophenols, containing oxygen in their chromophoric group, being amino derivatives of substituted quinoneimides of the generic formula:

$$\begin{array}{l} R^{II} = O \\ \| \\ N \\ | \\ R^{II} - NH_2 \end{array}$$

very weak bases, incapable of forming stable salts. With these the hydroxy derivatives of quinonediimides:

$$\begin{array}{l} R^{II} - OH \\ | \\ N \\ \| \\ R^{II} = NH \end{array}$$

are practically identical, being transformed into normal indophenols *in statu nascendi* by the shifting or migrating process already mentioned.

c. Acid indophenols, hydroxyl derivatives of quinonimides of the generic formula:

$$\begin{array}{l} R^{II} = O \\ \| \\ N \\ | \\ R^{II} - OH \end{array}$$

distinct phenols, dissolving in caustic alkali solutions with intense colourations.

Like all colouring matters the indamines and indophenols are capable of being reduced by the action of nascent hydrogen, of which two atoms are taken up. Colourless 'leuco-' compounds are formed which stand in the same relation to the original dyestuff as hydroquinone stands to quinone:

$$\begin{array}{ccc} R^{II}\cdot NH_2 & R^{II}\cdot NH_2 & R^{II}\cdot OH \\ | & | & | \\ NH & NH & NH \\ | & | & | \\ R^{II}\cdot NH_2 & R^{II}\cdot OH & R^{II}\cdot OH \end{array}$$

Leuco-indamine. Normal leuco-indophenol. Acid leuco-indophenol.

It will be clearly seen that these formulæ of the leuco derivatives are identical with the formulæ of paradiamino, aminohydroxy, and p-dihydroxy derivatives of secondary aromatic bases. Now as the leuco derivatives of indamines and indophenols are capable of reoxidation into the original dyestuff, it is apparent that we have by this means three additional methods for the production of such colouring matters:

14. Di-p-amino derivatives of secondary aromatic bases may be oxidised into indamines.

15. p-Amino-p-hydroxy derivatives of secondary aromatic bases may be oxidised into normal indophenols.

16. Di-*p*-hydroxy derivatives of secondary aromatic bases may be oxidised into acid indophenols.

The conditions under which these various reactions should be performed are stated below.

The remarkable relations existing between dyestuffs and their leuco compounds were recognised and studied by chemists at an early period. In no group are they so clearly defined as in that of the indamines and indophenols. Their complete elucidation in this group very naturally sheds light upon analogous phenomena observed in other colouring matters and thus the study of this class of substances greatly facilitated the introduction of the modern views of the 'quinonoid' constitution of colouring matters.

Literature on the Constitution of Indamines and Indophenols, Otto N. Witt, J. Soc. Chem. Ind. 1882, 255; R. Möhlau, Ber. 16, 2843; Otto N. Witt, British Association, 1887; Journ. Soc. Dy. Col. 1887; R. Nietzki, Organische Farbstoffe, 5th ed. 1906, 197 *et seq.*

History.—The first indamine observed was the intermediate product obtained in the production of safranine, of which, however, no account was published. In 1879, Otto N. Witt prepared the first indamine in a state of purity by acting with nitrosodimethylaniline hydrochloride upon *m*-tolylenediamine (Ber. 12, 931; Chem. Soc. Trans. 1879, 1, 356). In 1881, Otto N. Witt and Horace Köchlin obtained patents for the production of normal indophenols. The production of 'acid indophenols' by the reaction of quinonechloroimide upon phenol was first mentioned by Hirsch (Ber. 13, 1909), and discussed by Möhlau (*ibid.* 16, 2845). The normal indophenols only have found a practical application in dyeing and calico-printing. Owing, however, to their insufficient resistance to the action of acids and to the difficulties in their application, they did not make very rapid progress in the favour of practical dyers and colourists. A change for the better took place, when it was shown that the typical indophenol is a good vat-dye and capable of being used in combination with indigo. The consumption of indophenol became considerable for a while, but went down again as rapidly as it had gone up when the introduction of synthetic indigo lowered the prices of this 'king of dyestuffs' and the invention of many indigoid colouring matters overwhelmed the dyer with dyes suitable for the vat-process.

In later years some of the indophenols have become important as raw materials for the production of some valuable sulphur dyes, which are prepared from them by the well-known process of boiling or melting with alkaline sulphides. This new application of the indophenols had been first indicated in D. R. P. 132212 of the Gesellschaft für Chemische Industrie, in Basle (14 Dec. 1898), and the corresponding Fr. Pat. 284387 and Amer. Pat. 665547.

Properties.—The properties of the indamines and indophenols are more uniform than those of other classes of colouring matters. It has consequently been necessary to prepare only a small number from the host of possible members of this group in order to obtain a fair notion of the properties of the whole group. With very few exceptions their shade is blue or violet; in some cases a bluish-green. The shade of the dyestuff is exhibited:

a. In the indamine group by the normal salts of the indamine bases.

b. In the group of normal indophenols by the free bases.

c. In the group of acid indophenols by the alkaline salts of the dyestuffs.

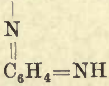
All the indamines and indophenols possess the generic character of the quinone group. They are therefore capable of acting as oxidising agents if brought together with oxidisable substances. In such reactions they take up hydrogen and are transformed into their leuco derivatives. So considerable is their tendency to act as oxidising agents that, under suitable conditions, an indamine or indophenol will attack its own molecules, when a mixture of its oxidation products and its leuco compounds is the result (*v. Safranines*, art. AZINES). The conditions under which such reactions take place are, an elevated temperature and the presence of mineral acids. The indamines and indophenols are consequently unstable in the presence of acids, whilst in alkaline and neutral solution they display but little tendency to decompose. A similar decomposition is caused, especially in the indamines, by the action of sunlight; the normal indophenols may, on the contrary, be called rather fast.

The following is an account of those members of this group of dyestuffs which have been more closely examined or proved important from a technical point of view:—

I. INDAMINES.

Phenylene-blue $C_{12}H_{11}N_3$

Constitution



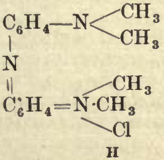
$$\begin{array}{l} C_6H_4-NH_2 \\ \vert \\ N \\ \Vert \\ C_6H_4=NH \end{array}$$

This compound is best prepared by oxidising a mixture of *p*-phenylenediamine and aniline hydrochloride in equal molecules in the cold, with the theoretical quantity of potassium dichromate. A greenish-blue liquid is formed, from which the iodide of phenylene-blue may be precipitated by the addition of potassium iodide solution. This salt forms long needles with a green metallic lustre. It is soluble in water with a greenish-blue colour, which turns into green on the addition of mineral acids. Acid solutions decompose very rapidly, a considerable quantity of *p*-quinone being formed in this decomposition. On reduction phenylene-blue yields di-*p*-aminodiphenylamine, from which phenylene-blue may be regenerated by simple oxidation. Phenylene-blue is transformed into safranine on being boiled in a neutral solution with aniline hydrochloride (*v. Safranine*).

Literature.—R. Nietzki, Ber. 1883, 16, 464; R. Nietzki, Organ. Farbstoffe, 5th ed. 1906, 200.

Tetramethyl derivative of Phenylene-blue (*Dimethylphenylene-green*).

$C_{16}H_{20}N_3Cl$. Constitution



$$\begin{array}{l} C_6H_4-N\!<\!\begin{array}{l}CH_3\\CH_3\end{array} \\ \vert \\ N \\ \Vert \\ C_6H_4=N\begin{array}{l}\diagup CH_3\\ \cdot CH_3\\ \diagdown Cl\end{array} \end{array}$$

This interesting compound, which is the completely methylated derivative of the preceding one, is formed by the joint oxidation of *asym*-dimethyl-*p*-phenylenediamine with dimethylaniline, in equal molecules, with potassium dichromate in the presence of zinc chloride (Bindschedler, Ber. 13, 207). The zinc double salt is at once deposited from the liquid. According to the quantity of zinc chloride present the crystals are either of a copper colour or have a metallic green lustre. These crystals are freely soluble in pure water, with a fine green colouration. Potassium iodide precipitates from this solution the phenylene-green iodide $C_{16}H_{20}N_3I$ in beautiful green needles, which are easily soluble in pure water, very insoluble in the presence of an excess of potassium iodide. The platinum double chloride has the composition $(C_{16}H_{20}N_3Cl)_2PtCl_4$; dimethylphenylene-green is more stable than the majority of indamines. On reduction it yields tetramethyldiaminodiphenylamine from which the green may be regenerated by oxidation.

Dimethylphenylene-green dyes silk and other fibres a yellowish shade of green. It has, however, found no application as a colouring matter, being rather unstable to light.

Its solution, on being boiled with the solution of an equal molecule of the hydrochloride of a primary amine, yields the corresponding safranine. (Also *Safranine.*)

Literature.—Bindschedler, Ber. 13, 207; R. Nietzki, *ibid.* 16, 464; Bindschedler, *ibid.* 16, 865.

Diethylphenylene-green $C_{20}H_{28}N_3Cl$ is obtained by oxidising diethyl-*p*-phenylenediamine with diethylaniline in the presence of mercuric chloride. Very similar to the methyl derivative, but less stable.

Literature.—Bindschedler, Ber. 16, 867.

Homologues of phenylene-blue. These are formed by the joint oxidation of *p*-phenylenediamine and the homologues of aniline or of *p*-tolylenediamine with aniline and its homologues. They play an important part in the manufacture of the commercial safranines, in which they are obtained as intermediate products.

Literature.—O. N. Witt, J. Soc. Chem. Ind. 1882, 256.

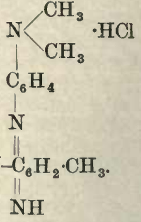
Witt's phenylene-violet $C_{12}H_{12}N_4{\cdot}HCl$. This substance is obtained by the joint oxidation of *p*-phenylenediamine with *m*-phenylenediamine. Its aqueous solution, which exhibits a fine purple shade, is decomposed on boiling, when a corresponding diamino-azine or eurhodine is formed. Similar compounds are obtained by the joint oxidation of other *p*-diamines with *m*-phenylenediamine. This reaction is, therefore, applicable as a test for both *p*- and *m*-diamines.

Witt's phenylene-blue $C_{14}H_{16}N_4{\cdot}HCl$. The dimethyl derivative of the preceding substance is formed either by the joint oxidation of dimethyl-*p*-phenylenediamine and *m*-phenylenediamine hydrochloride, or by mixing together lukewarm solutions of nitrosodimethylaniline hydrochloride and *m*-phenylenediamine, both dissolved in glacial acetic acid. It forms bronze-coloured crystals, readily soluble in water, with a purplish-blue shade. On the addition of mineral acids unstable diacid salts of a yellowish-brown colour are formed. The aqueous solution is decomposed by prolonged boiling, yielding neutral violet, a colouring matter of the eurhodine group (*v. Safranine*).

Literature.—Otto N. Witt, D. R. P. 15272, 1880; Eng. Pat. 4846, 1880.

Tolylene-blue $C_{15}H_{18}N_4{\cdot}HCl$

Constitution



This is the most thoroughly investigated member of the group. It is formed by the action of oxidising agents upon a mixture of dimethyl-*p*-phenylenediamine and *m*-tolylenediamine, or by the direct combination of nitrosodimethylaniline hydrochloride and free *m*-tolylenediamine. It is best prepared by the latter method. On mixing lukewarm aqueous solutions of the two ingredients in the proportion of equal molecules the blue is formed at once, and on cooling settles out in the shape of glistening bronze-coloured crystals which have the composition $C_{15}H_{18}N_4{\cdot}HCl$. On adding hydrochloric acid to an aqueous solution of this compound a much more soluble diacid salt

$$C_{15}H_{18}N_4{\cdot}2HCl,$$

of a reddish-brown colour, is formed. By the action of reducing agents, especially stannous chloride, the leuco derivative of tolylene-blue, dimethyltriaminotolylphenylamine $C_{15}H_{20}N_4$ is formed. An aqueous solution of the blue is decomposed by prolonged ebullition. The products of this decomposition are leucotolylene-blue and dimethyldiaminotoluphenazine (*Tolylene red, v.* Azines).

Literature.—Otto N. Witt (Ber. 12, 931; Chem. Soc. Trans. 1879, 356; D. R. P. 15272, 1880; J. Soc. Chem. Ind. 1882, 256). R. Nietzki (Ber. 16, 1883, 475).

II. Indophenols.

The simplest *indophenol* $C_{12}H_{10}N_2O$

$$\begin{array}{c} O \\ \| \\ C_6H_4 \\ \| \\ N \\ | \\ C_6H_4 \\ | \\ NH_2 \end{array}$$

was prepared in 1880 and described by the inventors, Horace Köchlin and Otto N. Witt in their fundamental patents: D. R. P. 15915, Amer. Pat. 261518, Fr. Pat. 141843, Eng. Pat. 1373, 5249, 1881. It may be obtained by any of the processes indicated for the purpose by theory (see above, modes of formation). The best method for its preparation is the joint oxidation of *p*-phenylenediamine and phenol dissolved in water in equimolecular proportions with oxidising agents, which act in a neutral or alkaline solution, such as sodium ferricyanide, potassium persulphate, or hypochlorites. The last-named are exclusively used in industrial work. The dyestuff, which is of a reddish-blue shade, settles out at once. It is, however, very impure and contains other colouring matters which are formed by the condensation of part of the indophenol formed into more complicated indophenols of a higher molecular weight. According to the D. R. PP. 179294 and 179295, this is not the case if lead or manganese peroxides be used as an oxidising agent. Another method, indicated in the D. R. PP. 160710 and 168229 consists in oxidising a mixture of phenol with the monoacetyl or the monoaryl sulphonic derivatives of *p*-phenylenediamine and subsequent decomposition with alkali.

This dyestuff is insoluble in water, easily soluble in alcohol, ether, or benzene. Acids dissolve it readily with a yellow colour. The solution is quickly decomposed on standing.

A very similar dyestuff of a bluer shade may be obtained by the joint oxidation of a mixture of *p*-phenylenediamine and *p*-xylenol in molecular proportions.

Other nearly allied indophenols are prepared by the joint oxidation of *o*-toluidine and *p*-aminophenol (Cassella and Co., D. R. P. 199963, 1901); and by the action of nitrosophenol upon *p*-chloro-*o*-nitrodiphenylamine (Kalle & Co., D. R. P. 205391, 1907).

All these indophenols are extremely similar in their properties. Notwithstanding the intensity and beauty of their blue colouration they have not acquired any importance as practical dyestuffs, probably because they are so easily attacked and decomposed by mineral acids. But in later years they have assumed great importance as raw materials for the manufacture of very fast blue sulphur dyes and this has caused the appearance of numerous patents for the production of such indophenols, the more important of which only can be mentioned in this article.

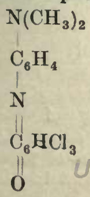
Dimethyl derivative of simplest indophenol, $C_{14}H_{14}N_2O$,

$$O=C_6H_4=N-C_6H_4-N(CH_3)_2$$

is obtained like the preceding compounds by joint oxidation from a mixture of phenol and dimethyl-*p*-phenylenediamine or by oxidising a mixture of dimethylaniline and *p*-aminophenol; it crystallises from alcohol in glistening green needles. Its alcoholic solution is of a brilliant greenish blue colour.

Literature.—Horace Köchlin and Otto N. Witt, D. R. P. 15915, 1881. Leop. Cassella & Co., second addition to D. R. P. 15915.

Dimethyl-trichloroindophenol $C_{14}H_{11}Cl_3N_2O$,



$$(CH_3)_2N-C_6H_4-N=C_6HCl_3=O$$

is obtained by mixing alcoholic solutions of trichloroquinonechloroimide (1 mol.) and dimethylaniline (2 mol.), according to the equation:

$$C_6HCl_3(NCl)O+2C_6H_5{\cdot}N(CH_3)_2$$
$$=C_{14}H_{11}Cl_3N_2O+C_6H_5N(CH_3)_2HCl.$$

Recrystallised from alcohol, it forms long green glistening needles, which have the general character of the indophenols and are comparatively stable. On reduction it yields the corresponding leuco compound, dimethylaminohydroxytrichlorodiphenylamine, $C_{14}H_{13}Cl_3N_2O$.

Literature.—Schmitt and Andresen (J. pr. Chem. [ii.] 24, 435).

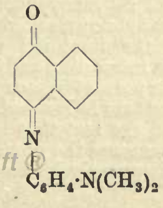
Carbazole indophenol. This curious substance, which has been obtained by Cassella & Co. according to mode of formation No. 8 from carbazole and nitrosophenol has evidently the constitution:

It is of great importance because on being heated with polysulphides it yields *hydron blue*, a sulphur dye insoluble in sodium sulphide solution, but capable of being used in the vat in exactly the same way as indigo and giving deep blue shades which are quite as fine and fast as those obtained with indigo itself. It is therefore expected to become a serious competitor of indigo blue. (*See* INDIGO, ARTIFICIAL, and INDIGOID DYESTUFFS; VAT DYES, MODERN.)

All the indophenols mentioned so far have this in common, that they are derivatives of *p*-quinone, and this accounts for the similarity of their properties and chemical behaviour.

A marked difference in this respect is shown by the indophenols which are derived from naphthaquinone which is itself less reactive and consequently more stable than the benzene derivative. This stability also shows itself in the naphthindophenols which can therefore claim to be applicable and even valuable dyestuffs.

Although a large number of these substances is foreseen by theory, the only well-known member of the group is the one first discovered, the *typical indophenol of commerce* $C_{18}H_{16}N_2O$ (vat blue, Küpenblau), the structure of which is expressed by the constitutional formula



It was discovered in 1880 by Horace Köchlin and Otto N. Witt and described in their fundamental indophenol patents already mentioned.

It is prepared from an alkaline mixture of dimethyl-*p*-phenylenediamine and α-naphthol in molecular proportions by oxidation. On a small scale potassium ferricyanide or ammonium persulphate is the most convenient oxidising agent, whilst on the manufacturing scale air is blown through the liquid, or a solution of sodium hypochlorite is employed. It may also be prepared by adding potassium chromate to the alkaline mixture of the ingredients and acidifying with acetic acid. Another process consists in simply heating on the water-bath an alcoholic solution of free nitrosodimethylaniline and sodium α-naphthoxide; or in bringing together, in an aqueous solution, α-naphthol, nitrosodimethylaniline, and caustic soda; this mixture is rapidly transformed into indophenol if a small quantity of a reducing agent, such as sodium stannite or glucose, be added.

Indophenol forms a dark-blue microcrystalline powder with a coppery metallic lustre, exactly resembling indigo. It is quite insoluble in water, sparingly soluble in spirit, ether, or benzene. It dissolves in dilute mineral acids, forming salts of a yellow colour, which are, however, quickly decomposed. In this decomposition α-naphthaquinone is formed as one of the products. Indophenol is slightly volatile; on being strongly heated it forms a sublimate resembling sublimed indigo. By reducing agents it is transformed into its leuco derivative

$$C_{18}H_{18}N_2O,$$

dimethylaminophenylhydroxynaphthylamine. This has been an article of commerce under the name of indophenol-white. It is quite stable in an acid state, but in the presence of alkalis it rapidly absorbs the oxygen of the air, indophenol being regenerated.

The application of indophenol to dyeing and calico-printing is based either on the formation of the dyestuff on the fibre, or on the oxidation of its ready-formed leuco derivative after fixing the latter on the fibre. The first method is rarely employed. As an example the following description, taken from the patent specification, may serve. Bleached calico is printed with a thickened mixture of aminodimethylaniline and sodium α-naphthoxide; after drying and steaming it is passed through a solution of potassium dichromate, when the blue is instantaneously developed. As a rule ready-formed indophenol is employed for printing, reduced by being mixed with a solution of stannous acetate, then thickened with starch paste and printed on the fibre. The colour is developed by steaming and exposure to the air. Indophenol-blue on calico is very fast to the action of soap, fairly so to the action of light, but rather susceptible to acids.

In spite of its many good qualities, indophenol at first did not meet with an enthusiastic reception in the tinctorial world. This was changed by an interesting and for its time (about 1885–1895) important discovery of the Swiss manufacturing firm L. Durand, Huguenin & Co. It is based on the fact that indophenol, mixed with indigo, assumes the properties of the latter and may consequently be used in the vat process, especially with hydrosulphite as a reducing agent.

It is more than probable that the two leuco compounds of indigo and indophenol are capable of combining chemically and that the resulting substance is endowed with strong affinities for the fibre, especially cotton. It is thus easily taken up from the vat and, on being reoxidised on the fibre, deposits in the molecular interstices of the latter an intimate mixture or even a chemical combination of the two dyestuffs, indigo and indophenol.

An intimate mixture of indigo and indophenol, ground together into an impalpable powder is the 'vat blue' or 'küpenblau' of commerce, which may still occasionally be met with, although it has lost many of its advantages by the great reduction in the price of indigo and by the introduction of the cheap and excellent dark-blue sulphur dyes, many of which are also capable of being applied in the vat.

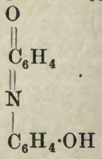
Literature.—Otto N. Witt and Horace Köchlin, D. R. P. 15915, 1881, with several additions; and corresponding patents in England, France, the United States, Sweden, Belgium, and Austria; Otto N. Witt, J. Soc. Chem. Ind. 1882, 144, 225, 405; R. Möhlau, Ber. 16, 2845.

III. Acid Indophenols.

It has already been mentioned that these substances are not true acids, containing no carboxyl groups in their molecule. They owe their name to the fact that, containing no amino and several hydroxyl groups, they readily combine and form stable salts with metallic oxides. Of these only the alkali salts are known. In a solid state they form crystalline powders with a green or copper-coloured metallic lustre. They are easily soluble in water with an intense blue colouration. By the addition of acids the free indophenols are deposited in the shape of brown or reddish flakes, which are soluble with a dark red colour in spirit, ether, benzene, and analogous solvents.

The acid indophenols show in even a higher degree the tendency of the whole group to polymerise into colouring matters of a more complex molecule. It is therefore extremely difficult to prepare them in a state of purity. On the other hand, they do not show the susceptibility to acids so characteristic of the indamines and typical indophenols. It is therefore possible to prepare them not only in alkaline but also in acid solutions and by means of oxidising agents which act in such. Their modes of formation are given above under methods 4, 6, 7, 12, and 15.

Typical acid indophenol $C_{12}H_9NO_2$,

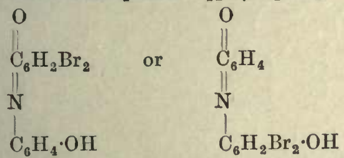


$$\begin{array}{c} O \\ \| \\ C_6H_4 \\ \| \\ N \\ | \\ C_6H_4{\cdot}OH \end{array}$$

The possibility of preparing this compound by the joint oxidation of *p*-aminophenol and phenol is mentioned in Köchlin and Witt's fundamental indophenol patents, but its manufacture seemed at first to offer no interest It is formed if quinoneimide is brought into contact with phenol, and R. Hirsch observed it on adding caustic potash to a solution of quinonechloroimide in phenol, but did not succeed in isolating it (Ber. 13, 1909). The cause of these difficulties was revealed by the D. R. P. 157288 of the Actiengesellschaft für Anilinfabrikation of Berlin. The formation of the dyestuff must take place at unusually low temperatures if its tendency for polymerisation in a nascent state is to be overcome. According to this patent, the product may be prepared with a good yield if an equimolecular mixture of phenol and *p*-aminophenol be oxidised with sodium hypochlorite at a temperature of −15° to −18°, preferably in solutions saturated with sodium chloride so that the sodium salt of the dyestuff is at once salted out of the liquid. It is thus obtained in the shape of glistening metallic green needles.

These dyestuffs become more stable and are therefore more easily prepared if their molecule be weighted by the introduction of various substituents:

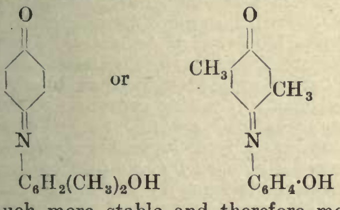
Acid dibromoindophenol $C_{12}H_7Br_2NO_2$,



$$\begin{array}{c} O \\ \| \\ C_6H_2Br_2 \\ \| \\ N \\ | \\ C_6H_4{\cdot}OH \end{array} \quad \text{or} \quad \begin{array}{c} O \\ \| \\ C_6H_4 \\ \| \\ N \\ | \\ C_6H_2Br_2{\cdot}OH \end{array}$$

(See remarks on migration under 2 and 5.) has been prepared in various ways by R. Möhlau (Ber. 16, 2843). It may either be obtained by the joint oxidation of a mixture of dibromoaminophenol and phenol in molecular proportions, or by adding dibromo-quinonechloroimide, suspended in alcohol, to an alkaline solution of phenol. The sodium salt of the indophenol separates out in green glistening needles, which are soluble in water and alcohol with a pure blue colour. On adding acetic acid to the solution the free indophenol settles out in dark-red, almost black prisms with a metallic lustre. It is soluble in alcohol with a magenta colour. Mineral acids decompose this compound into dibromo-aminophenol and *p*-quinone. If a current of sulphur dioxide be introduced into the solution of the sodium indophenolate, the corresponding leuco compound $C_{12}H_9Br_2NO_2$, dihydroxydibromodiphenylamine, is formed. It crystallises in white glistening needles, melting at 170°.

Acid dimethylindophenol $C_{14}H_{13}NO_2$,



is also much more stable and therefore more easily prepared than the typical acid indophenol. This was shown in 1902 by L. Cassella & Co. in their D. R. P. 191863 and the corresponding Eng. Pat. 4653, 1902; 2617, 1902. According to these patents, 1:4:5-(*p*-) xylenol and *p*-aminophenol give a good yield of this dyestuff if subjected to joint oxydation in equimolecular proportions.

All these acid indophenols have assumed a new interest and are being largely investigated, since it has been shown that they are valuable raw materials for the manufacture of the sulphur dyes which have come so much to the front in these later years. O. N. W.

INDANE *v.* INDENE.

INDANTHRENE. Within recent years, considerable advances have been made in the discovery and commercial production of certain compounds belonging to the class of the vat dyes. By the term 'vat dye' is understood an insoluble pigment which, when reduced by an alkaline reducing agent, passes into a hydro derivative soluble in the alkaline reducing solution. The hydro derivative is absorbed by fabrics steeped in this solution and is then reconverted into the pigment when the material is exposed to the oxidising action of the air. Indigo, the most important of all colouring matters, is a typical vat dye, and it is apparent that the process entailed by the use of these colours not only produces the shades fastest to light and washing but is also one of the simplest with which the dyer has to deal.

For many years research on the formation of new vat dyes was confined to the indigo group, but in the year 1901 it was demonstrated by R. Bohn that certain derivatives of anthraquinone could be applied for this purpose. The vat dyes of this series possess, however, one important property which distinguishes them from all other members of the class, that is, the vat formed by the alkaline reduction of the pigment is always strongly coloured. The hydro derivatives are, therefore, themselves coloured substances, whereas the hydro derivatives from other vat dyes, for example indigo white, are colourless or at most faintly yellow.

The vat dyes of the indanthrene series may be conveniently divided into five groups:—

(1) Indanthrene.
(2) Flavanthrene.
(3) Benzanthrone colours.
(4) Anthraquinoneimide colours.
(5) Acyl derivatives of aminoanthraquinone.

Indanthrene: *Preparation* (R. Bohn, D. R. P. 129845; Zusatze, 129846, 129847, 129848, 135407, 135408, 138167, 155415, 210223, and 216891; Scholl and Berblinger, Ber. 1903, 36, 3427).

The colouring matter is prepared by fusing β-aminoanthraquinone with caustic potash at 200°–300° and is found in the melt as the soluble potassium salt of the blue hydro derivative of indanthrene which, when dissolved in water with free access of air, is converted into the insoluble blue colouring matter. At a lower temperature (150°–200°) alizarin is formed at the same time as indanthrene, but at the higher temperature this is transformed into a brown substance soluble in alkali; the separation of the blue colouring matter is, therefore, simple owing to its insolubility in the alkaline liquid. Whether produced at the higher or lower temperature, the indanthrene is not a homogeneous substance but consists of two compounds, indanthrene A and indanthrene B, the latter being worthless as a colouring matter. It is possible so to regulate the conditions as to cause indanthrene A to be the chief product; thus, when the fusion is carried out in the presence of potassium nitrate the product consists almost entirely of indanthrene A, and indanthrene B is only formed in small amount. By fusing β-aminoanthraquinone with caustic potash at a still higher temperature, that is at 330°–350°, the product is a yellow vat dye, flavanthrene (*v. infra*).

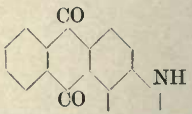
500 grams of caustic potash together with a little water are placed in a nickel basin which is heated by means of an anthracene bath. The melt is then heated to 200° and mixed with 20 grams of potassium nitrate; 100 grams of β-aminoanthraquinone are now gradually added with constant stirring. The temperature is raised to 250° and maintained at this point for half an hour when the melt is poured into water, the solution boiled, and the precipitated colour filtered and washed. The small quantity of indanthrene B present in the product is separated by taking advantage of the greater solubility of its hydro derivative in dilute alkali. 100 grams of the crude indanthrene in the form of paste are diluted with 10 litres of water and warmed to 60°–70°; 200 grams of a 25 p.c. caustic soda solution and 1500 grams of sodium hydrosulphite solution (sp.gr. 1·074) are then added and the temperature of the mixture maintained at 60°–70° for 1 hour. By this time the colour will have completely dissolved, and the solution, when cooled, will slowly deposit the sodium salt of the hydro derivative of indanthrene A as well-defined glistening needles with marked copper reflex. The salt is collected by filtration, washed with a little dilute caustic soda solution to which a small quantity of hydrosulphite solution has been added, and is then converted into pure indanthrene A by dissolving in hot water and allowing free access of air. The brown-red mother liquor contains the more soluble salt of the hydro derivative of indanthrene B from which the colour separates as blueish-green flocks when air is led into the solution.

Indanthrene prepared in this manner is a dark blue powder with strong metallic reflex, and is practically insoluble in all the usual solvents. It dissolves with great difficulty in boiling aniline and in nitrobenzene, in the latter case to the extent of one part in 5000, forming a greenish blue solution. It dissolves to the extent of 1 part in 500 in boiling quinoline, forming a blue solution from which the colour separates as characteristic curved needles resembling pure indigo in appearance; the solutions are without fluorescence. When heated it partly sublimes in the form of its characteristic needles and then decomposes with charring between 470° and 500°.

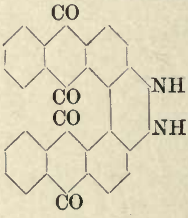
Constitution of indanthrene (Scholl, Ber. 1903, 36, 3410). Indanthrene as shown by its elementary analysis and molecular weight determination by the ebullioscopic method in quinoline has the molecular formula $C_{28}H_{14}O_4N_2$ and is therefore formed by the condensation of two molecules of β-aminoanthraquinone with loss of 4 atoms of hydrogen.

$$2C_{14}H_9O_2N - 4H \rightarrow C_{28}H_{14}O_4N_2.$$

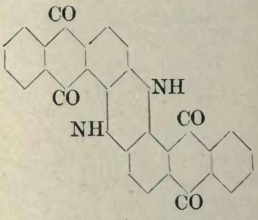
That these 4 hydrogen atoms are not removed from the amino groups alone—in other words, that an azo compound is not formed—is shown by the fact that indanthrene when reduced does not yield β-aminoanthraquinone or a reduction product of this base. Moreover, as indanthrene no longer contains a free amino group, it is probable that two of these hydrogen atoms are supplied by the two amino groups and that the other two belong to the rings bearing the amino groups in the two molecules of β-aminoanthraquinone taking part in the reaction. From the fact that 1:2-dihydroxyanthraquinone (alizarin) is always a product of the fusion in its earlier stages, it is reasonable to assume that the hydrogen atoms removed from the two rings are those in the ortho position to the two amino groups. This leads to two formulæ for indanthrene, namely—



β-Aminoanthraquinone residue.



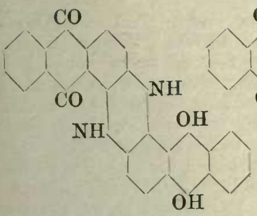
(1)



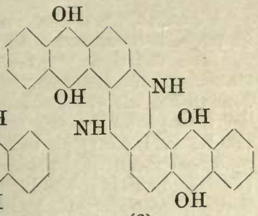
(2)

Since indanthrene is not reduced to a diamine, which would be the case if it possessed an ortho diazine formula represented by (1), it follows that it must be a dihydro paradiazine represented by formula (2), or in other words, that it is *N*-dihydro-1:2:2′:1′-anthraquinoneazine. This view of the structure of indanthrene is completely upheld by its chemical behaviour. It has been suggested by Nietzki (Chemie der Organ. Farbstoffe, 5 Aufl. S. 121, 1906) that the formation of indanthrene is due to the intermediate production of 1-hydroxy-2-aminoanthrahydroquinone, two molecules of which combine to form tetrahydroindanthrene. This has, however, been disproved by Scholl, Berblinger, and Mansfield (Ber. 1907, 40, 320), who find that neither 1-hydroxy-2-aminoanthrahydroquinone nor 1-hydroxy-2-aminoanthraquinone yields indanthrene when fused with potash.

Properties of indanthrene.—When indanthrene in dilute alkaline solution is heated at 40°–50° with sodium hydrosulphite, it passes into a blue hydro derivative, dihydroindanthrene. This substance possesses the property of dyeing unmordanted cotton blue, and when the fibre so dyed is exposed to the oxidising action of the air the hydro derivative is reconverted into indanthrene. When indanthrene is reduced by zinc dust, a brown hydro derivative is formed; this hydro derivative is also converted into indanthrene on exposure to the air. Scholl, Steinkopf, and Kabacznik (Ber. 1907, 40, 390) have shown that the blue substance is *N*-dihydro-1:2:2′:1′-anthraquinoneanthrahydroquinoneazine (1), and that the brown solution contains *N*-dihydro-1:2:2′:1′-anthrahydroquinoneazine (2)



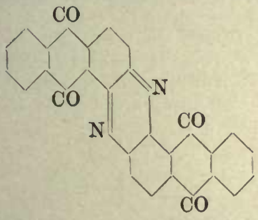
(1)
Blue hydro derivative.



(2)
Brown hydro derivative.

The compound commercially known as indanthrene S is the disodium salt of formula 2, and this is the substance which is always formed in the indanthrene vat.

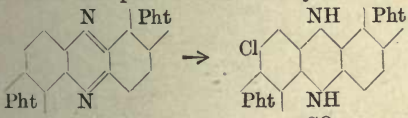
When indanthrene is oxidised by nitric acid (sp.gr. 1·24), it is converted into the yellow 1 : 2 : 2′ : 1′-anthraquinoneazine (Scholl and Berblinger, Ber. 1903, 36, 3427; *cp.* Scholl, Berblinger, and Mansfield, *ibid.* 1907, 40, 321).



This substance is reconverted into indanthrene on reduction, a reaction which may be effected by means of direct sunlight.

Indanthrene is one of the most stable substances known; sodium hypochlorite, which destroys most colouring matters such as the alizarins, indigos, &c., merely converts indanthrene into the above yellow azine, which can be readily reconverted into indanthrene by means of sodium hydrosulphite.

When halogen atoms enter the molecule of indanthrene, the shade becomes greener. Indanthrene blue GC (D. R. P. 138167) is a bromindanthrene; indanthrene blue GCD and CE are chloro derivatives (D. R. P. 155415). Monochlorindanthrene is prepared by the action of boiling concentrated hydrochloric acid on anthraquinoneazine whereby chlorination and reduction take place simultaneously—



$$\text{Pht}=\text{Phthaloyl } C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}$$

The reaction is analogous to the formation of chlorhydroquinone from quinone and hydrochloric acid. Owing to the alkali required in the preparation of the indanthrene vat, this substance cannot be used for the dyeing of wool. The sulphonic acid (D. R. P. 216891) can be employed, however, for this purpose. The blue produced on cotton by the aid of indanthrene is one of the fastest known. (For the method of dyeing compare D. R. P. 139834; for printing, compare D. R. P. 132402, 140573.)

Flavanthrene (indanthrene yellow). As already mentioned, flavanthrene was discovered by R. Bohn (D. R. P. 138119), in the products formed by the fusion of β-aminoanthraquinone with potash. At the present time it is prepared by treating β-aminoanthraquinone with antimony pentachloride in boiling nitrobenzene. (*V.* art. FLAVANTHRENE.)

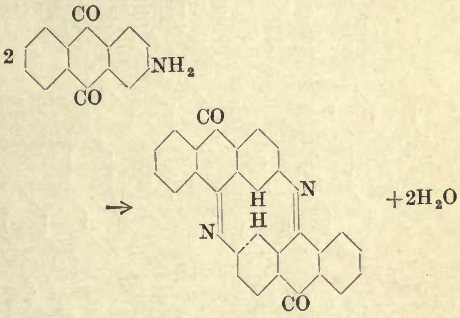
When reduced by alkaline hydrosulphite, flavanthrene yields a violet-blue vat in which cotton is dyed a deep blue; when exposed to the oxidising action of the air the colour changes, in the course of a few minutes, to the light yellow of flavanthrene.

Preparation.—Ten grams of β-aminoanthraquinone are gradually added to a solution of 35 grams anhydrous antimony pentachloride in 100 grams nitrobenzene, heated at 60°–80°. The mixture is then heated to the boiling-point and maintained at this temperature for one hour, the containing flask being without a condenser. The yellow-brown solution deposits, on cooling, chemically pure flavanthrene as brownish-yellow needles.

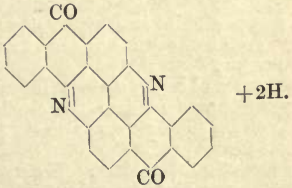
The constitution of flavanthrene has been determined by Scholl (Ber. 1907, 40, 1691). The molecular formula is $C_{28}H_{12}O_2N_2$, and it must therefore be formed from β-aminoanthraquinone in accordance with the equation

$$2C_{14}H_9O_2N \rightarrow C_{28}H_{12}O_2N_2+2H+2H_2O.$$

The two molecules of water formed in the reaction at once suggest the interaction of the hydrogen atoms of the amino groups with the carbonyl oxygens, an assumption which leads to the following formula:—

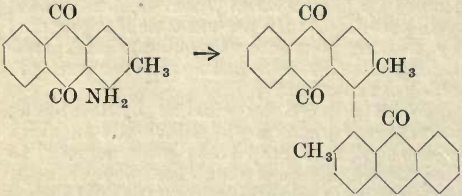


The ring then closes thus:



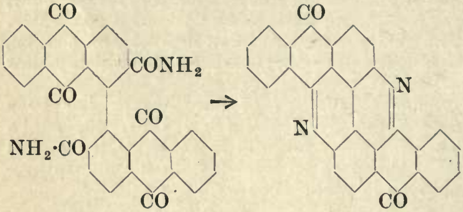
The hydrogen thus formed is not eliminated in the free condition, but reduces the colour to the dihydro base, the state in which it always occurs in the melt.

This view of the constitution of flavanthrene has been confirmed by Scholl by the actual synthesis of this substance in the following way: 2-methyl-1-aminoanthraquinone (1) is converted into 2 : 2′-dimethyl-1 : 1′-dianthraquinonyl (2) either by heating the corresponding iodide with copper powder or by the action of copper powder and acetic anhydride on the diazonium sulphate:



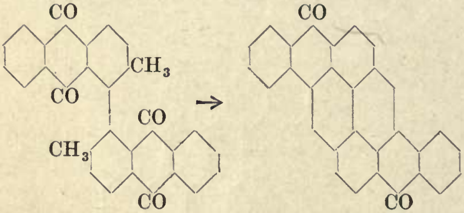
(1) (2)

This substance is then oxidised to the dicarboxylic acid which is converted, through the acid chloride, into the acid amide (3). An attempt to prepare the amino compound from this by the action of bromine and potash led to the formation of flavanthrene :



(3)

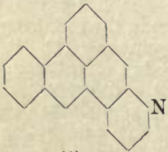
Pyranthrene (indanthrene golden orange) (D. R. P. 175067 ; Ber. 1910, 43, 346 ; R. Scholl). This substance is a valuable orange vat dye which is formed by the elimination of two molecules of water from 2:2′-dimethyl-1:1′-dianthraquinonyl (formula (2) above). It differs from flavanthrene in having two methin groups in place of the azine nitrogen atoms :



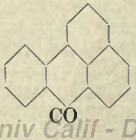
The condensation proceeds readily in the presence of a dehydrating agent such as zinc chloride or by merely heating alone at 350°–380°. Pyranthrene forms a magenta red vat with alkaline hydrosulphite in which cotton is dyed a deep red ; on exposure to the air this oxidises to a fast orange.

The entrance of halogen atoms into the molecule of pyranthrene reddens the shade and of these derivatives dibromopyranthrene (D. R. P. 218162) is the most red.

The benzanthrone colours. The vat colours of this class were discovered by O. Bally (Ber. 1905, 38, 194 ; D. R. P. 176018), who found that when the Skraup quinoline synthesis was applied to 2-aminoanthraquinone, two glycerol residues entered into the molecule, forming benzanthronquinoline (1) :



(1)



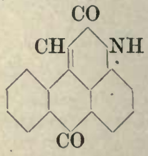
(2)

When this reaction was applied to anthraquinone, benzanthrone (2) was formed.

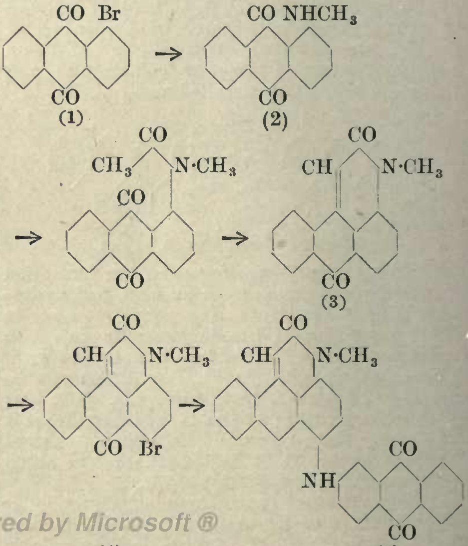
Blue vat dyes are formed from these substances on fusion with potash, two molecules condensing with loss of four atoms of hydrogen. To this group belong indanthrene dark blue (D. R. P. 185221) as well as its isomeride and halogen substitution product, indanthrene violet (D. R. PP. 177574, 194252, 217570); indanthrene green (D. R. P. 185222) is an amino-derivative of indanthrene dark blue ; if the last-named colour is strongly chlorinated a deep, very fast black is formed. Cyananthrene and violanthrene also belong to this group.

Colours derived from anthraquinoneimide. These colours consist of several anthraquinone residues joined together in much the same manner as in flavanthrene. They are, for the most part, trianthraquinonediimides and their substitution products which are formed by the condensation of aminoanthraquinones and halogenanthraquinones. Indanthrene Bordeaux (D. R. PP. 184905 and 206717) and indanthrene red (D. R. P. 197554) belong to this group.

Acyl derivatives of aminoanthraquinone. Colours of this group are derived from anthraquinonepyridone :



by the replacement of the hydrogen atom in the para- position to the imino group by arylamino residues. Thus algol red is formed when 1-bromanthraquinone (1) is converted into methyl-1-aminoanthraquinone (2) by means of methylamine. This is acetylated and condensed to *N*-methylanthraquinonepyridone (3), which is then brominated, yielding 4-brom-*N*-methylanthraquinonepyridone (4), and this, on condensation with 2-aminoanthraquinone, yields algol red (5) :



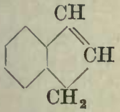
(1) (2) (3) (4) (5)

Other members of this class are algol yellow, algol rose, algol scarlet, algol green, algol blue, and algol brown. They all yield coloured vats with sodium hydrosulphite in which cotton is dyed the colour of the dihydro derivative; on exposure to the air the colour on the fibre is quickly oxidised to the algol dye.

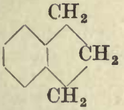
The following indanthrene colours are formed from anthraquinone derivatives by the aid of various reactions, but have not as yet had a definite constitution assigned to them. Indanthrene maroon (D. R. P. 160814) and indanthrene grey (D. R. P. 157685) are derived from diaminoanthraquinones. Indanthrene orange and indanthrene copper (D. R. P. 198048) are prepared from the acetyl derivatives of aminoanthraquinone by means of phosphorus oxychloride. Cibanon yellow, cibanon orange, and cibanon brown, are derived from methylanthraquinone and its derivatives. J. F. T.

INDAZINE *v.* AZINES.

INDENE. The compounds of the indene group are derived from the hydrocarbons indene and hydrindene



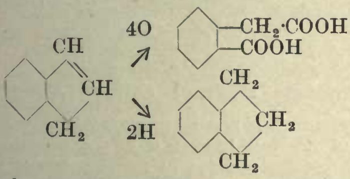
Indene.



Hydrindene.

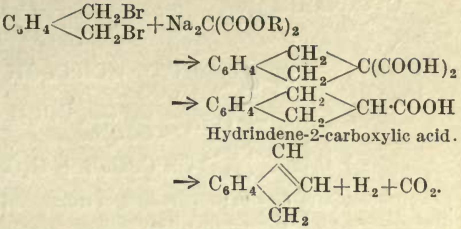
by the replacement of the hydrogen atoms either in the five-membered ring or in the aromatic nucleus. They therefore yield two classes of derivatives: (1) Those of aromatic character which are formed when the hydrogen atoms of the benzene ring are substituted. (2) Those of aliphatic character which are produced by the replacement of the hydrogen atoms attached to the five-membered ring.

Constitution.—The constitution of indene follows from its conversion into homophthalic acid by oxidation with permanganate:



and the structure of hydrindene is shown by the production of this substance from indene by reduction with sodium and alcohol.

Occurrence and preparation of indene and indene derivatives. Indene was isolated from coal-tar by Krämer and Spilker (Ber. 1890, 23, 3276) who obtained it from the higher boiling fraction of the light oil in which it occurs to the extent of about 30 p.c. It is formed, accompanied by hydrindene, in the dry distillation of paraindene $(C_9H_8)x$, a white substance which is formed when benzene containing indene is treated with concentrated sulphuric acid (Ber. 1900, 33, 2261). It has, moreover, been prepared synthetically by Perkin and Revay (Chem. Soc. Trans. 1894, 65, 228; *cp.* Kipping and Hall, *ibid.* 1900, 77, 469), by the distillation of barium hydrindenecarboxylate, a substance which can be prepared from *o*-xylylene dibromide by the following series of reactions.



$$C_6H_4\left<\begin{matrix}CH_2Br\\CH_2Br\end{matrix}\right. + Na_2C(COOR)_2$$

$$\rightarrow C_6H_4\left<\begin{matrix}CH_2\\CH_2\end{matrix}\right>C(COOH)_2$$

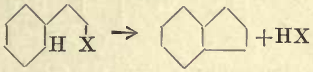
$$\rightarrow C_6H_4\left<\begin{matrix}CH_2\\CH_2\end{matrix}\right>CH{\cdot}COOH$$

Hydrindene-2-carboxylic acid.

Owing to the ease with which the five-membered ring is usually formed, derivatives of indene and of hydrindene are readily produced from the corresponding benzene derivatives, having a side chain containing the requisite number of carbon atoms. The benzene derivatives which lend themselves to this change may therefore be divided into two classes: (1) those having one side chain of three carbon atoms; (2) those having two side chains, attached in the ortho position to the benzene nucleus, one of these side chains being composed of one carbon atom the other of two carbon atoms.

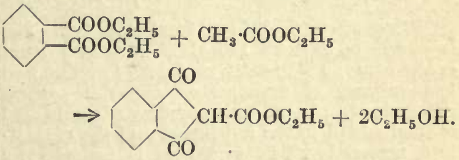
The derivatives of hydrocinnamic acid fall within the first class and a large number of indene compounds have been prepared from this substance and its derivatives (*v.* Miller and Rohde, Ber. 1902, 35, 1762).

The general character of this reaction may be expressed by the scheme

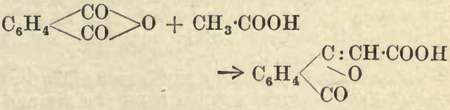


(X=halogen).

As an illustration of the formation of hydrindene derivatives by the method indicated under class (2), the formation of 1:3-diketohydrindene can be given. The ethyl salt of the carboxylic acid of this substance is formed when ethyl phthalate is condensed with ethyl acetate in the presence of sodium or sodium ethoxide (W. Wislicenus, Ber. 1887, 20, 593).



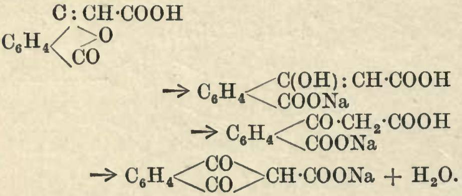
A curious molecular rearrangement, leading to the formation of hydrindene derivatives, has been discovered by Gabriel and Neumann (Ber. 1893, 26, 951). The condensation of phthalic anhydride and sodium acetate in the presence of acetic anhydride leads to the formation of phthalylacetic acid:



$$C_6H_4\left<\begin{matrix}CO\\CO\end{matrix}\right>O + CH_3{\cdot}COOH$$

$$\rightarrow C_6H_4\left<\begin{matrix}C{:}CH{\cdot}COOH\\ \quad >O\\ CO\end{matrix}\right.$$

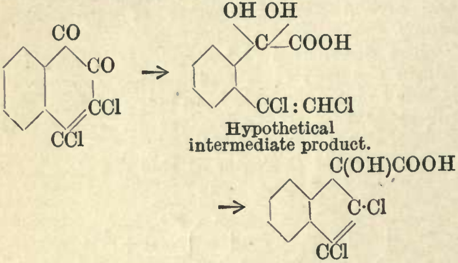
and this substance, when treated with sodium methoxide, passes into a derivative of 1:3-diketohydrindene. The reaction may be explained as follows:—



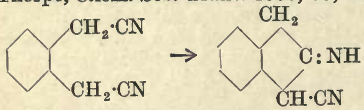
$$C_6H_4\!<\!\begin{matrix}C:CH\cdot COOH\\ \quad >O\\ CO\end{matrix} \rightarrow C_6H_4\!<\!\begin{matrix}C(OH):CH\cdot COOH\\ COONa\end{matrix} \rightarrow C_6H_4\!<\!\begin{matrix}CO\cdot CH_2\cdot COOH\\ COONa\end{matrix} \rightarrow C_6H_4\!<\!\begin{matrix}CO\\ CO\end{matrix}\!>\!CH\cdot COONa + H_2O.$$

It can be applied to the preparation of numerous derivatives of 1:3-diketohydrindene.

The formation of indene derivatives from compounds containing the naphthalene nucleus in which the stability of the ring is weakened by the presence of strongly negative groups has been investigated by Zincke and his pupils (Ber. 1886, 19, 2500; 1887, 20, 1265, 2894, 3216; 1888, 21, 491, 2381, 2379; 1894, 27, 744; Annalen, 1892, 267, 319; 1894, 283, 341; 1898, 300, 197). This type of reaction may be illustrated by the transformation of dichloro-β-naphthaquinone into dichlorohydroxyindene carboxylic acid by the action of caustic alkali.



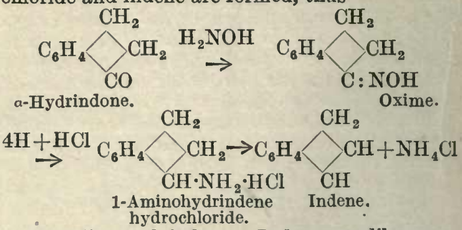
Derivatives of hydrindene can also be formed from ortho benzenoid dinitriles. Thus *o*-phenylenediacetonitrile passes into β-imino-α-cyanohydrindene when its solution in alcohol, containing a trace of sodium ethoxide, is warmed (Moore and Thorpe, Chem. Soc. Trans. 1908, 93, 165).



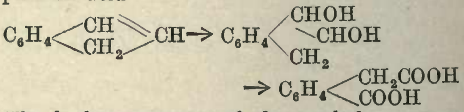
Preparation of indene from coal-tar. The fraction boiling at 176°–182° obtained from crude benzene is first titrated with bromine and the amount of unsaturated material present determined. A sufficient quantity of picric acid is then added to the hot liquid and the crystalline material which separates is isolated by filtration. The impure picrate is then distilled with steam, under which conditions the naphthalene picrate contained in it is only slowly decomposed whereas the indene picrate is readily transformed into indene which passes over with the steam. The crude hydrocarbon is then again converted into the picrate and the operation repeated until pure indene is obtained. Indene picrate forms golden yellow needles which melt at 98°.

Indene is a clear mobile liquid boiling at 179·5°–180·5° (corr.).

It is obtained pure only with great difficulty, as it rapidly absorbs oxygen from the air and when kept in a sealed vessel polymerises to a resin. The most convenient synthetic method for the preparation of indene is from α-hydrindone, the oxime of which passes on reduction into 1-aminohydrindene, and when the hydrochloride of this base is distilled, ammonium chloride and indene are formed, thus—

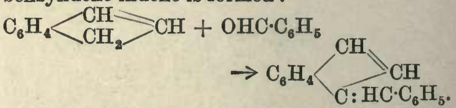


Reactions of indene. Indene readily combines with bromine, forming 1:2-dibromohydrindene  and when oxidised passes first into hydrindene glycol and then into homophthalic acid



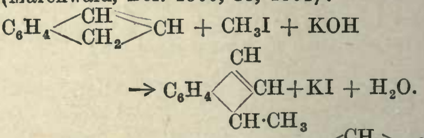
$$C_6H_4\!<\!\begin{matrix}CH\\ CH_2\end{matrix}\!>\!CH \rightarrow C_6H_4\!<\!\begin{matrix}CHOH\\ \quad CHOH\\ CH_2\end{matrix} \rightarrow C_6H_4\!<\!\begin{matrix}CH_2COOH\\ COOH\end{matrix}$$

The hydrogen atoms of the methylene group present in indene are reactive; thus, when the hydrocarbon is condensed with benzaldehyde, benzylidene indene is formed:



$$C_6H_4\!<\!\begin{matrix}CH\\ CH_2\end{matrix}\!>\!CH + OHC\cdot C_6H_5 \rightarrow C_6H_4\!<\!\begin{matrix}CH\\ \quad CH\\ C:HC\cdot C_6H_5.\end{matrix}$$

In fact, this grouping behaves in much the same manner as the corresponding complex in ethyl malonate and analogous compounds; thus, when indene is treated with methyl iodide and powdered alkali, methyl indene is formed (Marckwald, Ber. 1900, 33, 1504):



Hydrindene (Indane) $C_6H_4\!<\!\begin{matrix}CH_2\\ CH_2\end{matrix}\!>\!CH_2$.

This hydrocarbon can be prepared by dissolving 1 part of indene in 10 parts of 90 p.c. alcohol and adding metallic sodium in small portions until the product is no longer converted into a resin by concentrated sulphuric acid. It is a mobile oil boiling at 176°–176·5° (corr.).

The ketones derived from hydrindene. The ketones derived from this substance may be classified as follows: (1) The mono-ketones (hydrindones), which comprise:

$$C_6H_4\!<\!\begin{matrix}CH_2\\ CO\end{matrix}\!>\!CH_2$$

α-Hydrindone.

$$C_6H_4\!<\!\begin{matrix}CH_2\\ CH_2\end{matrix}\!>\!CO$$

β-Hydrindone.

(2) **The di-ketones** (di-ketohydrindenes), which are

$$C_6H_4\!<\!\begin{matrix}CO\\ CO\end{matrix}\!>\!CH_2$$

1:3-Diketohydrindene.

$$C_6H_4\!<\!\begin{matrix}CO\\ CH_2\end{matrix}\!>\!CO$$

1:2-Diketohydrindene.[1]

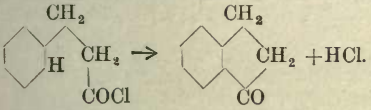
[1] This substance has been prepared by Perkin, Roberts and Robinson (Chem. Soc. Trans. 1912, 101, 232) from isonitroso-α-hydrindone (Kipping, *ibid.* 1894, 65, 492). It crystallises from benzene as golden yellow plates, m.p. 95°–115°, and gives a semicarbazone (m.p. 230°–233° with decomposition), an osazone (m.p. 230°–235°), and an indenoquinoxaline (m.p. 164°–165°).

(3) The tri-ketone is

$$C_6H_4\left<\substack{CO\\CO}\right>CO$$

1 : 2 : 3-Triketohydrindene.

α-Hydrindone $C_6H_4\left<\substack{CH_2\\CO}\right>CH_2$. This substance is best prepared by the action of aluminium chloride on the chloride of hydrocinnamic acid in accordance with the following equation:—



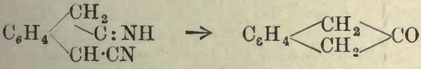
It forms rhombic plates from dilute alcohol, melts at 40° and boils at 243°–245°. The oxime melts at 146° and the phenyl hydrazone at 130°–131°. The methylene group adjacent to the carbonyl group in α-hydrindone is reactive and derivatives of the ketone can be formed by the usual reagents. Thus amyl nitrite gives the oxime of 1 : 2-diketohydrindene

$$C_6H_4\left<\substack{CO\\CH_2}\right>C : NOH,$$

and the action of benzaldehyde leads to the formation of the benzylidene derivative

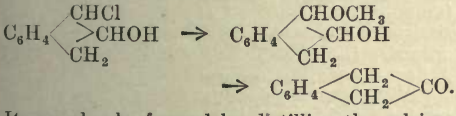
$$C_6H_4\left<\substack{CO\\CH_2}\right>C : CHC_6H_5.$$

β-Hydrindone $C_6H_4\left<\substack{CH_2\\CH_2}\right>CO$. This ketone is best prepared from β-imino-α-cyanohydrindene by distilling with dilute sulphuric acid (Moore and Thorpe, Chem. Soc. Trans. 1908, 93; *cf.* also Chem. Soc. Proc. 1911, 27, 128).



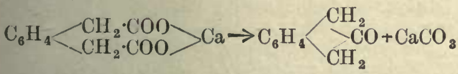
$$C_6H_4\left<\substack{CH_2\\ >C : NH\\ CH\cdot CN}\right. \rightarrow C_6H_4\left<\substack{CH_2\\CH_2}\right>CO$$

It can also be prepared from the indene of coal-tar (Heusler and Schieffer, Ber. 1899, 32, 28). The method most convenient for this purpose is to convert indene into the oxychloride by the method of Krämer and Spilker (Ber. 1890, 23, 3280) and then to transform this into the methoxy derivative which, with dilute sulphuric acid, yields β-hydrindone:



$$C_6H_4\left<\substack{CHCl\\ >CHOH\\ CH_2}\right. \rightarrow C_6H_4\left<\substack{CHOCH_3\\ >CHOH\\ CH_2}\right. \rightarrow C_6H_4\left<\substack{CH_2\\CH_2}\right>CO.$$

It can also be formed by distilling the calcium salt of *o*-phenylenediacetic acid (Benedikt, Annalen, 1893, 275, 353; Schad, Ber. 1893, 26, 222):



$$C_6H_4\left<\substack{CH_2\cdot COO\\CH_2\cdot COO}\right>Ca \rightarrow C_6H_4\left<\substack{CH_2\\ >CO\\ CH_2}\right. + CaCO_3$$

β-Hydrindone crystallises from dilute alcohol as long needles, melts at 61° and boils with partial decomposition at 220°–225°. The oxime melts at 155°, the phenylhydrazone at 120° and the semi-carbazone at 210°.

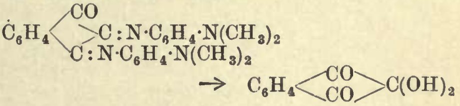
1 : 3-Diketohydrindene $C_6H_4\left<\substack{CO\\CO}\right>CH_2$, is probably the best known derivative of indene and is formed by the method of W. Wislicenus already described. It may be isolated (Kaufmann, Ber. 1897, 30, 385) by dissolving the sodium compound of ethyl diketohydrindene-carboxylate, prepared from ethyl phthalate and ethyl acetate, in as little boiling water as possible, cooling to 70°–75° and adding dilute sulphuric acid. A vigorous evolution of carbon dioxide then ensues and the diketone separates in the crystalline form. 1:3-diketohydrindene melts and decomposes at 129°–131°.

As is to be expected, the methylene group between the two carbonyl complexes of 1 : 3-diketohydrindene is exceedingly reactive and this substance shows all the reactions of the β-diketones. When oxidised by hydrogen peroxide or potassium persulphate, it is converted into the oxygen analogue of indigo, having the formula

$$C_6H_4\left<\substack{CO\\CO}\right>C : C\left<\substack{CO\\CO}\right>C_6H_4$$

This substance crystallises from aniline as glistening red needles.

1 : 2 : 3-Triketohydrindene $C_6H_4\left<\substack{CO\\CO}\right>CO$. A substance of this formula was prepared in small quantity by Kaufmann (Ber. 1897, 30, 387) by the oxidation of 1 : 3-diketohydrindene with hydrogen peroxide. The compound prepared in this way crystallised from glacial acetic acid as brown leaflets which melted and decomposed at 190°–206°. It is probable that the substance obtained by Kaufmann possesses another structure and that the true triketohydrindene is the compound prepared by Ruhemann, in the form of a hydrate, by the action of dilute sulphuric acid on the compound formed by the condensation of α-hydrindone with *p*-nitrosodimethylaniline



$$C_6H_4\left<\substack{CO\\ >C : N\cdot C_6H_4\cdot N(CH_3)_2\\ C : N\cdot C_6H_4\cdot N(CH_3)_2}\right. \rightarrow C_6H_4\left<\substack{CO\\CO}\right>C(OH)_2$$

This reaction can also be applied to 1 : 3-diketohydrindene and to β-hydrindone (Chem. Soc. Trans. 1910, 97, 1438, 2025; 1911, 99, 792).

Triketohydrindene hydrate forms prisms from water which redden at 125°, give off gas at 139° and melt with decomposition at 239°–240°. The hydrate colours the skin red and reduces Fehling's solution. The diphenylhydrazone melts at 207°–208° and the disemicarbazone darkens at 175° and melts with evolution of gas at 208°.

Triketohydrindene hydrate may be used as a reagent for proteins and their hydrolytic products (*cp.* Chem. Soc. Trans. 1911, 99, 798).

J. F. T.

INDIAN FIRE is a light used in pyrotechnical displays and for purposes of signalling. It is usually composed of 7 parts of sulphur, 2 of realgar, and 24 of nitre.

INDIAN HEMP RESIN *v.* Resins.

INDIAN INK or **CHINESE INK.** This substance, used for writing or drawing, consists of lamp-black held together with animal or fish glue and dried in the form of cakes or sticks of paint. According to Chinese writers, the invention of ink is due to one Tien-Tchen who lived between 2697 and 2597 B.C. It is said by them that at that time the ink used was a kind of lacquer; later some kind of black stone rubbed in water came into use; lastly, about 250 years B.C., balls of lamp-black from the burning of lacquer and firewood, afterwards mixed with size, became the customary material. It is probable, however, that the Chinese became acquainted with the substance from the Coreans, to whom they are indebted for other useful arts. The material used for producing the lamp-black is in most instances fir timber, although many other media, such as rice treated with a decoction of *Hibiscus mutabilis* (Linn.), the bark of the pomegranate tree infused with vinegar, and rock-oil are employed. The glue or size appears at the present day to be always obtained either from oxen or fish; the points of difference between various makers being (1) the mode of its preparation; (2) the method of incorporation; and (3) the quantity relative to the amount of soot. Sometimes perfumed essences, as of musk or camphor, are added, especially in the choicest qualities. After baking, the sticks or other moulded forms are laid in a cool, dry place, and are said to improve with long keeping.

The manufacture of Indian ink is also carried on in Japan, the following description, from a native source, indicating the method followed in that country. ‘The body of the ink is soot obtained from pine-wood or resin, and lamp-black from sesamum oil for the finest sort. This is mixed with liquid glue made of ox-skin. This operation is effected in a large, round, copper bowl formed of two spherical calottes placed 1 inch apart, so that the space between can be filled up with hot water to prevent the glue from hardening during the time it is being mixed by hand with the lamp-black. The cakes are formed in wooden moulds, and dried between paper and ashes. Camphor, or a peculiar mixture of scents which come from China, and a small quantity of carthamine (the red colouring substance of safflower) are added to the best kinds for improving the colour as well as for scenting the ink.’

M. Merimée (De la Peinture à l’Huile) asserted that the Chinese do not use an animal but a vegetable size; but apparently without warrant. For a curious monograph compiled from native Chinese sources *v.* L’Encre de Chine, son Histoire et sa Fabrication d’après documents chinois traduits, par Maurice Jametel, Paris, 1882.

INDIAN RED. A mineral pigment from the Persian Gulf. In appearance it is a coarse powder of a purplish-red colour.

Howe’s analysis of (1) the entire mineral, and of (2) that portion soluble in hydrochloric acid, gave

	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	SO_3	CO_2	H_2O	
(1)	30·17	56·59	3·79	2·65	1·43	2·28	1·73	1·62	=100·26
(2)	—	3·19	2·22	2·65	0·87	2·28	1·73	—	=12·94

(Edin. New Phil. Jour. New Series, 2, 306.)

The portion insoluble in hydrochloric acid is a ferric silicate $Fe_2O_3{\cdot}SiO_2$. A pseudo-Indian red is composed principally of sesquioxide of iron.

INDIAN YELLOW, PIURI, PURREE, or **PIOURY,** is a pigment mainly used in India for colouring walls, doors, and lattice work, and by artists for water-colour work. On account of its disagreeable smell it is but rarely employed as a dyestuff. It is made almost exclusively at Monghyr in Bengal, and is obtained from the urine of cows which have been fed upon mango leaves. On heating the urine, usually in an earthen pot, the colouring matter separates out; this is pressed into a ball and dried partly over a charcoal fire and finally in the sun. It sells on the spot at about 1 rupee per lb., and is mainly sent to Calcutta and Patna. One cow produces, on the average, 3·4 litres of urine per diem yielding 2 oz. (56 grams) of piuri. The yearly production is stated to be from 100 to 150 cwts., which is probably over-estimated (*v.* Journ. Soc. Arts, 1883, [v.] 32, 16, and Annalen, 254, 268).

Piuri occurs in commerce in the form of round balls, which internally are of a brilliant yellow colour, whereas the outer layers are either brown or of a dirty green colour. The substance has a characteristic urinous smell. The undecomposed part consists only of *euxanthic acid* ($C_{19}H_{18}O_{11}$) in the form of a magnesium or calcium salt; the outer and decomposed portion contains in addition *euxanthone* both free and combined. The composition of piuri seems to be variable: a fine sample, according to Graebe, contained

Euxanthic acid . . .	51·0
Silicic acid and alumina . .	1·5
Magnesium	4·2
Calcium	3·4
Water and volatile matter .	39·0
	99·1

Euxanthic acid is easily obtained by digesting piuri of good quality with dilute hydrochloric acid and treating the residue with a solution of ammonium carbonate. On the addition of hydrochloric acid to the filtered solution euxanthic acid crystallises out with $1H_2O$ in glistening straw-yellow needles, melting at 162°.

Euxanthic acid is, according to Spiegel, decomposed by hydrochloric acid into glycuronic acid and euxanthone:

$$C_{19}H_{18}O_{11}=C_{13}H_8O_4+C_6H_{10}O_7.$$

Külz, in order to prove the animal origin of euxanthic acid, gave euxanthone to rabbits and dogs, and was able to detect euxanthic acid in the urine. Külz’s experiments did not corroborate Schmid’s statement that mangostin (obtained from *Garcinia Mangostana* [Linn.]) is similarly converted into euxanthic acid by animals (E. Külz, Zeitsch. Biol. 33, 475; J. Soc. Chem. Ind. 6, 507).

Although the potassium and sodium salts of euxanthic acid are of the type $C_{19}H_{17}O_{11}M$, the silver salt obtained from the potassium salt by silver nitrate has the composition $C_{19}H_{15}O_{10}Ag$, and is derived from an anhydride of the acid (*Anhydroeuxanthic acid*); the methyl and ethyl esters prepared from the silver salt are of the same type (Graebe, Ber. 1900, 53, 3360).

Potassium euxanthate $C_{19}H_{17}O_{11}K,H_2O$ crystallises readily from water, and is prepared by neutralising euxanthic acid with potassium carbonate.

Magnesium euxanthate $C_{19}H_{16}O_{11}Mg,5H_2O$ is the main constituent of Indian yellow (Graebe, Annalen, 254, 268).

Barium euxanthate $Ba(C_{19}H_{17}O_{11})_2,9H_2O$ is soluble in boiling water, and on cooling separates in the gelatinous condition.

Silver anhydroeuxanthate $C_{19}H_{15}O_{10}Ag$ behaves similarly.

Ethyl anhydroeuxanthate $C_{19}H_{15}O_{10}C_2H_5$, yellow-coloured needles, melts at 198°.

Tetra-acetylethylanhydroeuxanthate

$$C_{19}H_{11}O_{10}C_2H_5(C_2H_3O)_4$$

colourless needles, melts at 216°.

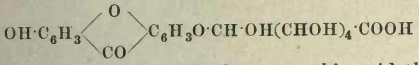
Methyl anhydroeuxanthate $C_{19}H_{15}O_{10}CH_3$, melts at 218°, and closely resembles the ethyl derivative.

Benzoyl anhydroeuxanthate

$$C_{19}H_{11}O_{10}(CO{\cdot}C_6H_5)_5$$

melts at 194°, but has not yet been crystallised.

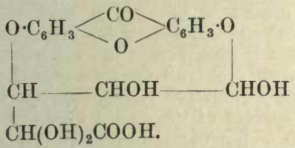
The constitution of euxanthic acid is expressed by Graebe (Annalen, 254, 267) as



whereas for that of anhydro-euxanthic acid the following two formulæ are given:

I.

II.

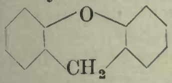


Euxanthone, Purrenone, Purrone $C_{13}H_8O_4$ was first obtained by Stenhouse (Annalen, 51, 425), and soon afterwards by Erdmann (*ibid.* 52, 365) from euxanthic acid. It crystallises in pale yellow needles or laminæ, melting at 240° (corr.), which sublime with little decomposition on gentle heating.

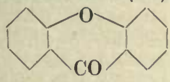
Diacetyl euxanthone, pale yellow prisms (Salzmann and Wichelhaus, Ber. 1877, 10, 1397), melts at 185°.

By distillation with zinc dust (Salzmann and Wichelhaus; Graebe and Ebrard, Ber. 16, 75) euxanthone gives *methylenediphenylene oxide* (I.), which by oxidation is converted into *xanthone* (II.)

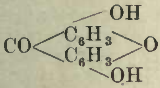
I.



II.

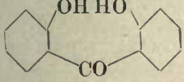


indicating that euxanthone possesses the constitutional formula



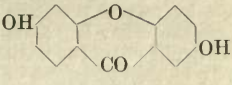
of a *dihydroxyxanthone* (S. and W.).

When fused with alkali euxanthone yields *euxanthonic acid*,

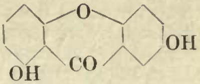


hydroquinone (*v.* Baeyer, Annalen, 155, 257), and *resorcinol* (Graebe, *ibid.* 254, 265).

The first synthesis of euxanthone is due to Graebe (*l.c.*), who accomplished this by distilling a mixture of β-resorcylic acid, and hydroquinonecarboxylic acid, and it was shown later by Kostanecki and Nessler (Ber. 1891, 24, 3983) that if in this reaction the β-resorcylic acid is replaced by resorcinol the same product is obtained. As the result of these syntheses two constitutional formulæ for euxanthone were possible:



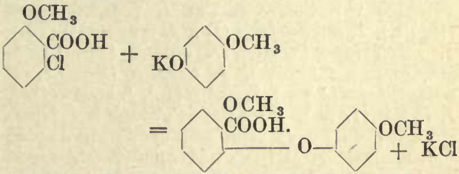
I.



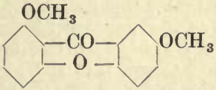
II.

When methylated by means of methyl iodide in the usual manner (Kostanecki, Ber. 1894, 27, 1992), euxanthone yields only a *monomethyl ether* $C_{13}H_7O_3(OCH_3)$ (yellow plates; m.p. 129°), and this on treatment with strong sodium hydroxide solution gives an insoluble yellow sodium salt. The latter, by washing with water, is decomposed with regeneration of the free monomethyl ether. These reactions indicate that euxanthone contains an hydroxyl in the ortho position to a carboxyl group (*cp.* also Herzig, Monatsh. 12, 161), and that, therefore, its constitution is represented by formula II. The final proof of this formula is afforded by a later synthesis of euxanthone (Ullmann and Panchaud, Annalen, 350, 108).

2-Chloro-6-methoxybenzoic acid is condensed with the potassium derivative of hydroquinone monomethyl ether, employing copper powder as a catalyst.



The resulting 4-*methoxy*-2-*phenoxy*-6-*methoxybenzoic acid* when treated with concentrated sulphuric acid is converted into *euxanthone dimethyl ether*



and this by treatment with aluminium chloride in the presence of benzene gives euxanthone.

Disazobenzene euxanthone $C_{13}H_6O_4(C_6H_5N_2)_2$ A. G. Perkin, Chem. Soc. Trans. 73, 666), red needles; m.p. 249°–250° (decomp.) is readily prepared by adding diazobenzene sulphate to a weak alkaline solution of euxanthone.

Acetyldisazobenzene euxanthone ochre-yellow needles, melts at 197°–199°. Euxanthone possesses only feeble tinctorial properties; the respective shades obtained with woollen cloth mordanted with chromium, aluminium and tin being dull brown-yellow, pale bright yellow, and very pale bright yellow (Perkin and Hummel, Chem. Soc. Trans. 1896, 69, 1290). A. G. P.

INDIA RUBBER or **CAOUTCHOUC** *v.* RUBBER.

INDICAN *v.* GLUCOSIDES; INDIGO, NATURAL.

INDICANURIA *v.* INDOXYL COMPOUNDS.

INDICATORS *v.* ACIDIMETRY AND ALKALIMETRY; also art. ANALYSIS.

INDIGO, NATURAL. Indigo has been known in Asia from a remote period of antiquity, and there exist very ancient records in Sanskrit describing its methods of preparation. The Romans appear to have only recognised it as a pigment (*indicum*), but evidence as to its use as a dye by the ancient Egyptians has been abundantly proved from the examination of mummy cloths. Its employment in Europe was very limited, until in 1516 it began to be imported from India by way of the Cape of Good Hope, though, on the other hand, its introduction in large quantity did not occur until about 1602. Owing chiefly to the opposition of the growers of woad, its European rival, its use as a dyeware met with much opposition, and various laws were enacted both on the Continent and in England prohibiting its use. It was, moreover, called a 'devilish drug,' and was said to be injurious to fabrics. In 1737 its employment was legally permitted in France, and from this period its valuable properties appear to have become gradually recognised throughout Europe.

The most important plants which yield indigo are those of the genus *Indigofera* belonging to the natural order of the *Leguminosæ*; these have been cultivated in India, China, Egypt, the Philippines, Caracas, and Brazil.

For the purpose of indigo manufacture the *Indigofera tinctoria* (L.), *I. sumatrana* (Garrtn.) (the Indian plant), *I. disperma* (L.), *I. argentea* (L.), and *I. arrecta* (Hochst.) (the Natal plant), the *I. paucifolia* (Delile) (Madagascar plant), and *I. secundiflora* (Poir.) (Guatemala plant), have been mainly used, though certain less valuable varieties, viz. the *I. pseudotinctoria* (R. Br.), *I. angustifolia* (L.), *I. arcuata* (Willd.), *I. caroliniana* (Walt.), *I. cinerea* (Willd.), *I. longeracemosa* (Boiv.), *I. cœrulea* (Roxb.), *I. endecaphylla* (Jacq.), *I. glabra* (L.), *I. hirsuta* (L.), *I. indica* (Lam.), *I. mexicana* (Benth.), *I. leptostachya* (DC.), have been employed. In Japan, China, and Russia the plant usually cultivated has been the *Polygonum tinctorium* (Ait.), but the *Isatis tinctoria* (L.), or woad plant, at one time very largely grown in Europe, is now used in very limited quantity as an adjunct in the dyeing of indigo (woad vat). The native source of indigo in Western Africa appears to consist almost entirely of the *Lonchocarpus cyanescens* (Benth.) (Perkin, J. Soc. Chem. Ind. 1907, 26).

Other indigo-yielding plants are the *Nerium tinctorium*, *Gymnema tingens* (Spreng.), *Eupatorium laeve* (DC.), *Tephrosia tinctoria* (Pers.), *Marsdenia tinctoria* (R. Br.), and certain species of orchids such as the *Phaius grandiflorus* (Reich.), and *Calanthe veratrifolia* (R. Br.).

In addition to these various plants of which the *Mercurialis perennis* (Linn.), *Fagopyrum esculentum* (Moench), *Fraxinus excelsior* (Linn.), *Baptisia tinctoria* (R. Br.), and *Rhamnus Alaternus* (L.) (Georgievics, Der. Indigo, 1892) may be given as examples, are stated to yield indigo, or a very similar colouring matter, but this requires confirmation.

The production of indigo from the indigo plant is of a simple character and consists mainly of two processes, viz. a steeping of the plant with water (fermentation), followed by the oxidation of the solution with air in a separate vessel. Until very recently but little modification appears to have been introduced into this ancient process, and there is also but little variation to be found in the main features as described by Bancroft (Philosophy of Permanent Colours, 1813), Crookes (Manual of Dyeing and Calico Printing, 1874), Bridges-Lee (Indigo Manufacture, 1892), Georgievics (*l.c.* 1892), and Rawson (The Cultivation and Manufacture of Indigo, J. Soc. Dyers. 1899).

Directly the plants are cut down they are tied in bundles and brought to the factory without delay, because it is necessary that the material should be operated on at once. The tanks for the extraction (steeping vats) and precipitation of the indigo by oxidation (beating vats) are sometimes of stone, but more usually of brick-work lined inside with cement, and are respectively ranged in two rows one above the other, so that the former can be drained into the latter. The steeping vats may have a capacity of about 1000 cub. ft., and are usually of much smaller dimensions than the beating vats, of which less are consequently required. According to Rawson (*l.c.*), who describes a small indigo factory, each range of beating vats runs the whole length of six steeping vats, and has a width of 13 feet 6 inches.

Into each of the upper tanks the bundles of the plant are tightly packed (preferably in a horizontal position, Bridges-Lee, *l.c.*), on the top of this is laid a horizontal trellis of bamboo, and the whole is wedged down into the tanks by means of timber, so that the material is unable to float during the fermentation process. Water is then run in in such quantity that the bundles are entirely submerged. After about 2 hours an active fermentation is observed, and the surface of the liquid becomes covered with froth owing to evolution of a mixture of carbon dioxide, oxygen, and nitrogen (Georgievics, *l.c.*); in the later stages (Rawson, *l.c.*) either marsh gas or hydrogen or a mixture of the two is freely produced. After 10–15 hours, according to the prevailing temperature of the water, the straw-yellow, orange, or olive-green coloured liquid is drawn off into the tanks below, and submitted to oxidation with air.

This is accomplished by 'hand beating,' by machinery (the beating wheel), by blowing air through the liquid, or by the shower-bath method. During this operation the colour of the liquid gradually changes, becoming first dark-green and then blue, and considerable frothing is produced. When it is observed that the indigo precipitate or 'fecula' readily settles, the beating is discontinued and the mixture allowed to rest for some 2 hours. The supernatant liquid or 'seet water,' having been drained off as completely as possible, the indigo sludge or 'mal' is led into a reservoir inside the factory, from which it is subsequently elevated by means of a hand pump or steam injector into a large cauldron known as the 'mal boiler.' It is here heated by direct fire or by the admission of steam, and this has for its object the prevention of a further fermentation, the solution of certain brown impurities, and a more complete granulation of the 'mal.'

The product is then run on to a filter known as a 'table,' consisting of stout cotton or linen cloth stretched over a shallow rectangular basin of stone or cement, with a drainage opening at one corner, and allowed to remain until it has the consistency of a stiff paste. In order to remove excess of moisture the indigo is transferred to perforated wooden boxes lined with sail cloth and cautiously pressed. Finally, the resulting slab is cut into cakes by means of a guillotine or metal wires and allowed to dry at the ordinary temperature on trellis-work shelves in a specially constructed drying house.

The Plant.

Until the last few years the *I. sumatrana* appears to have been exclusively employed in the best-conducted factories in India. According to Leake (Report of the Dalsingh Serai Research Station, 1903–1904) this is a mixture of several sub-varieties of different values. In this, as in apparently all other indigo plants, the indican exists exclusively in the leaf, though Bloxam and Leake (*l.c.*) point out that the midrib or rachis also contains the glucoside. For the manufacture of indigo the main points in connection with the plant are the weight of plant yielded per acre, the percentage of leaf given by the plant, and the indigotin producing value of the leaf. According to Rawson (Cultivation and Manufacture of Indigo, *l.c.*) the good plant contains 40 p.c. of leaf, though occasionally, but not often, the proportion of leaf rises to as much as 60 p.c. Bloxam and Leake have found, however, much higher values, 51·7–61·6 on ordinary Indian plant, and 65 p.c. given by twelve experimental plots, figures which include the rachis. Bergtheil (Report of the Indigo Research Station, Sirsiah, 1906, 8) finds the percentage of leaf to be 40 p.c., and never higher than 45 p.c.; but, on the other hand, in a redetermination, Leake (J. Soc. Chem. Ind. 1907, 26, 1174) records the value as 62·2 p.c. Rawson, who conducted numerous analyses of the leaf by his persulphate process (*l.c.*), shows that the indican content as expressed by indigo yielding capacity varies at different periods of the year. Thus, whereas in one instance on May 28 the figure was 0·20 p.c., on August 25 this had risen to 0·76 p.c. of indigotin. Though the leaf on young plant gives but a small percentage of colouring matter, yet as the plant grows, the new leaf contains more colouring principle than the old on the same plant. As an example, on one occasion the percentages of indigotin recorded with new and old leaf were respectively 0·71 and 0·35 p.c. Finally, there is a gradual increase in colouring matter given by leaves from the bottom of the plant upwards as represented by the figures 0·30, 0·44, and 0·62 p.c. respectively. According to Bergtheil (Report of the Indigo Research Station, 1907, 3) the 'indigotin content' of the plant is rarely so high as 0·3 p.c. Though the leaf, as a rule, contains a maximum of colouring matter from about the middle to the end of August, it does not necessarily follow that this is the best period for manufacture, as by this time the plant will usually have lost a considerable portion of leaf (Rawson). The manufacture, indeed, usually commences about the middle of June. Gaunt, Thomas, and Bloxam (J. Soc. Chem. Ind. 1907, 26, 1174) refer to a sample of the air-dried leaves of the *I. sumatrana*, which, in comparison with other dry samples of the same variety (0·6 approx.) and of the Java plant *I. arrecta* (1·81 p.c.) yielded indigotin to the value of 3·53 p.c., and consider that this indicates that by selection and suitable methods of cultivation it should be possible to obtain an average plant of greater indigo producing power than has hitherto been the case.

The plant formerly employed by the Java planters was the *Indigofera secundiflora* 'Guatemala plant,' but for several years past this has been replaced by the *I. arrecta* or 'Natal plant.' The latter, it is stated, contains not only more leaf than the ordinary Indian plant, but, as a rule, the leaf yields also a considerably larger percentage of indigo. More recently the Indian planters have recognised the value of the *I. arrecta*, and accounts are given by Coventry (Indigo Improvements Syndicate Report, 1901) of experiments in connection with its introduction. Leake (Dalsingh Serai Report, 1905) discusses the difficulties of the germination of the seed of the Natal-Java plant, which is due to the impermeable character of the seed coat. This defect, it is pointed out, can be overcome by a process of scratching, and a practicable method for this purpose is described. Bergtheil (*l.c.*), in conjunction with D. L. Day, treats the seed with strong sulphuric acid, which leads either to a swelling of the seed coat and its eventual rupture or converts it into a body akin to cellulose and permeable to water. Analyses of the indigo-yielding power of this leaf by Rawson (*l.c.*) gave figures up to 0·96 p.c., whereas Bergtheil (*l.c.* 1906) finds in comparison to the *I. sumatrana* (0·585) that the *I. arrecta* produced 1·05 p.c. of colouring matter. The percentage of leaf given by the latter averages 52·2 p.c. Again in 1909 the yield from 100 maunds of the *I. arrecta* was 15 seers 10 chittacks, as against 11 seers 14 chittacks from the same quantity of the *I. sumatrana.* The Natal plant is now established in India, and its superiority over the Indian plant is fully recognised. According to Bergtheil (1907) the indigo made from the Java plant has generally been of a high indigotin content, and (1906) that whereas the yield of indigo per acre was 12·6 'seers,' that given by the *I. sumatrana* was by comparison only 8 seers.

A full account of much detailed work on the cultivation of the indigo plants by Rawson, Bloxam and Leake, and Bergtheil is given in the reports above enumerated (c.p. also Bergtheil, *ibid.* 1908–1911).

The Chemistry of Natural Indigo Manufacture.

According to the early researches of Chevreul (Ann. Chim. Phys. 1808, 66, 8, and 1808, 68, 284) and of Geradin and Preisser (J. Pharm. Chim. 1840, 26, 344) the colouring principle of indigotin present in indigo-yielding plants was considered to consist of indigo white, and this theory remained uncontradicted until Schunck (Phil. Mag. 1855, [iv.] 17, 74, and 1858, 15, 127) isolated from the *Isatis tinctoria* (woad), *Polygonum tinctorium* and *Indigofera tinctoria* (Schunck and Roemer, Ber. 1879, 12, 2311), a glucoside, which was named indican.

To prepare this substance from woad the leaves were extracted with cold alcohol, the solution treated with a little water, and concentrated at the ordinary temperature by blowing air over it. The waxy matter which thus separated was removed by filtration, and the filtrate shaken up with freshly precipitated cupric hydroxide. The mixture was filtered, the liquid freed from dissolved copper by means of sulphuretted hydrogen, and then evaporated at the ordinary temperature. The residue was extracted with cold alcohol, the extract treated with ether to precipitate certain impurities, and the solution evaporated.

Thus obtained it consisted of a yellow or yellowish-brown syrup, which was of an exceedingly unstable nature, and could not be dried without decomposition. With alcoholic lead acetate it gave a yellow precipitate, whereas in aqueous solution it could only be precipitated by means of basic lead acetate. Analyses of the lead compound indicated that it possessed the formula $C_{26}H_{31}NO_{17}$. Schunck found that this compound was a glucoside, and that by the action of dilute acids, alkalis and of a ferment present in the plant, it was readily hydrolysed with the formation of indigotin, and a sugar indiglucin

$$2C_{26}H_{31}O_{17}{\cdot}N+4H_2O=C_{16}H_{10}O_2N_2+6C_6H_{10}O_6$$

For the production of indigotin the presence of air or other suitable oxidising agent was however necessary, and it appeared, therefore, that during the reaction the indigotin at first formed was reduced to indigo white.

Later, however, Schunck and Roemer showed (*l.c.*) that indican, when hydrolysed in the absence of air, gave a product which, on subsequent treatment with oxidising agents, did not yield indigotin. Schunck further obtained by the action of cold dilute acids on his indican a brown powder, from which he isolated six distinct substances, viz. *indihumin, indifuscin,* and *indiretin,* soluble in warm sodium hydroxide solution, and *α*- and *β-indifulvins* and *indirubin,* insoluble in alkalis.

When aqueous solutions of the indican were boiled or heated for some time a decomposition ensued, and the product, on treatment with acid, gave indiglucin, but no indigotin, this being replaced by *indiretin* and *indihumin* brown amorphous substances. The latter closely resembled, and was probably identical with, indigo brown. By the action of alkalis or alkaline earths at the ordinary temperature, indican was converted into a new glucoside *indicanin* $C_{20}H_{23}NO_{12}$, which on treatment with acid gave indiglucin and indirubin.

Oxyindicanin, a brown gummy substance, insoluble in alcohol, was isolated during the preparation of indican, and yielded, under the influence of acids, indiglucin and a brown substance similar to indifuscin.

Marchlewski and Radcliffe (J. Soc. Chem. Ind. 1898, 17, 434), in a theoretical discussion of the subject, suggested that indican $C_{14}H_{17}O_6N$ was a glucoside of indoxyl the hydrolysis of which could be represented by the following equation:

$$C_{14}H_{17}O_6N+H_2O=C_8H_7ON+C_6H_{12}O_6.$$

As a result of the communication of Marchlewski and Radcliffe, Hazewinkel, the director of the experimental station for indigo, Klaten, Java (Proc. K. Akad. Wetensch. Amsterdam, 1900, 2, 512), gave an account of a research, concluded in 1898, which he had hitherto considered to be to the interest of the Java planters to keep secret. In this important paper he gives proof for the first time that indican is an indoxyl glucoside, and that the sugar obtained from it is dextrose.

The elaborate researches of Beyerinck, van Romburgh, and other Dutch chemists, proved that the indican present in the various *Indigoferæ* and in the *Polygonum tinctorium* was far more stable than Schunck supposed, and the experiments of these authors eventually led to the isolation of this glucoside in a crystalline condition from the *Indigofera leptostachya* and *Polygonum tinctorium* by Hoogewerff and ter Meulen (Proc. K. Akad. Wetensch. Amsterdam, 1900, 2, 520).

The leaves were immersed in two and a half times their weight of boiling water, boiled for a few minutes, and further systematically exhausted. Without any sensible decomposition the decoction could be evaporated *in vacuô* if care was taken to keep the reaction alkaline. The dry residue was extracted with methyl alcohol, and to the solution ether was added as long as a precipitate was formed. This was removed, the clear liquid evaporated, the residue completely dried *in vacuô,* and then dissolved in water. The filtered and concentrated solution deposited on cooling well-defined crystals of indican. This process may be modified by treating the decoction of the leaves with baryta water before concentration, by which means a large proportion of the impurities are precipitated. 17 kilos. of the leaves of *Polygonum tinctorium* yielded 5 grams of pure indican.

Thus obtained indican $C_{14}H_{17}O_6N$ crystallises from water in spear-shaped crystals, which contain 3 molecules of water of crystallisation. Heated in a test tube, or on platinum foil, purple-coloured fumes are given off, but this does not take place in an atmosphere of carbon dioxide. By passing a current of air through a hot solution of indican in dilute hydrochloric acid containing a little ferric chloride, 91 p.c. of the indican was converted into indigotin according to the equation

$$2C_{14}H_{17}NO_6+O_2=C_{16}H_{10}N_2O_2+2C_6H_{12}O_6.$$

There was no difference between the indican prepared from the *I. leptostachya* and that obtained from the *P. tinctorium.*

In a paper by Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1900, 3, 101), 'On the Formation of Indigo from Woad,' this chemist discusses Schunck's well-known work on the same subject, and points out that the indigo-yielding substance contained in this plant is not as Schunck regarded it, identical with the indican present in the *Polygonum tinctorium.* The colouring principle of woad Beyerinck names *isatan,* and shows that this compound, unlike indican, is decomposed in feebly alkaline solutions, whereas indican is stable even in concentrated alkaline liquids. In presence of acids both isatan and indican are hydrolysed, but indican with greater difficulty. Isatase, the specific enzyme of woad, does not act on indican, and isatan, on the other hand, is unaffected both by the indigo enzyme or by common bacteria.

Schunck (Chem. News, 1900, 82, 176) considered that the crystalline indican of Hoogewerff and ter Meulen was not the substance obtained by him, and should not be considered as a pure variety of it, but was rather derived from it, by extracting the plant with a hot solvent and the use of chemicals. He preferred to name his compound *a*-indican and theirs *b*-indican.

Bergtheil (Chem. Soc. Trans. 1904, 85, 877), who experimented with the *I. sumatrana* and *I. arrecta,* did not find it possible to prepare indican from the leaves of these plants in the manner described by Hoogewerff and ter Meulen.

It was, however, shown by Perkin and Bloxam (Chem. Soc. Trans. 1907, 91, 1715) that crystalline indican can be isolated from both of these plants by such a method, and is in reality the source of the natural indigo which is derived from them.

In a further communication ter Meulen (Rec. trav. chim. 1905, 29, 444) describes a modification of the method previously given for the isolation of indican from the *Polygonum tinctorium*, which consists in treating a cold solution of the partially purified substance with sulphuric acid, by which means certain impurities are precipitated. The acid is then removed with barium carbonate. The main object of the investigation was, however, the determination of the sugar that this glucoside yields when hydrolysed by its specific enzyme, and this proved to be dextrose, as already indicated by Hazewinkel (*l.c.*).

As a result of the study of the behaviour of indican with solvents, Perkin and Bloxam (*l.c.*) devised a very simple process for the isolation of this glucoside, by the aid of which large quantities of the pure substance could be readily prepared.

The leaves and stems of the *I. sumatrana* (1000 grams) were treated with 4 litres of cold acetone, the mixture being occasionally shaken during 7 days, and the green-coloured extract was evaporated on the steam bath to a very small bulk. To the residue light petroleum was added, causing the deposition of a brown viscous precipitate of crude indican, and this was repeatedly agitated with small quantities of light petroleum. The product on treatment with water gave a pale yellow liquid, containing resinous matter in suspension, and the latter was removed by shaking with ether. The clear aqueous solution, treated with 10 c.c. *N*/2 sodium carbonate, on gradual evaporation *in vacuô* deposited crystals, and eventually a semi-solid mass was obtained. It was collected, drained, and allowed to dry at the ordinary temperature. When exhaustively extracted, 1000 grams of leaf gave 31·66 grams of indican, and by a continuous system of working more than 500 grams of crystalline indican were prepared. The preparation of this glucoside from the leaves of *I. arrecta* is more troublesome, owing partly to the presence of kæmpferitrin, but more especially of a colourless sugar-like compound $C_6H_{12}O_5$; m.p. 186°–187°; possibly a modification of quercitol. The fact that indican can be so readily isolated without the aid of heat, and merely with the use of acetone, light petroleum and ether, is not in harmony with the contention of Schunck (*l.c.*) that the crystalline glucoside is an alteration product of his amorphous substance, and consequently the terms α- and β-indican suggested by him should disappear.

Indican crystallised from water

$$C_{14}H_{17}O_6N,3H_2O$$

melts at 57°–58°, but in the anhydrous condition as obtained by the addition of boiling benzene to its hot alcoholic solution, at 176°–178°. Owing to its somewhat ready solubility in water it can be more economically purified by the latter process, and, according to Perkin and Thomas (Chem. Soc. Trans. 1909, 95, 793), crystallisation from absolute alcohol gives excellent results.

It has been shown by Baeyer (Ber. 1881, 14, 1745) that indoxyl readily condenses with aldehydes and ketones to form the so-called *indogenides*, and Hazewinkel (*l.c.*), in the valuable communication which demonstrated for the first time that indican is an indoxyl glucoside, partly identified this substance by means of its condensation products with isatin, benzaldehyde, and pyruvic acid, relying, however, on their qualitative reactions, as he did not prepare these compounds in a pure enough condition for analysis. Almost simultaneously Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1899, 2, 120) prepared indirubin by hydrolysing crude indican in the presence of isatin.

Perkin and Bloxam (*l.c.*), and Gaunt, Thomas, and Bloxam (J. Soc. Chem. Ind. 1907, 26, 1174), who experimented with the pure substance, found that when indican dissolved in water is added to a boiling solution of isatin, acidified with a little hydrochloric acid, and the operation is carried out in an atmosphere of hydrogen or carbon dioxide, the yield of indirubin is quantitative according to the following equations:—

$$C_{14}H_{17}O_6N+H_2O = C_8H_7NO+C_6H_{12}O_6.$$
$$C_8H_7NO+C_8H_5NO_2 = C_{16}H_{10}N_2O_2+H_2O.$$

This 'isatin' method, for full details of which the original papers must be consulted, affords a ready means, not only for the analysis of the crystalline glucoside, but also for the estimation of the amount which is present in aqueous infusions of the leaf (*v. infra*).

More recently Perkin and Thomas (Chem. Soc. Trans. 1909, 95, 795), who studied in a similar way the condensation of indoxyl derived from indican with *p*-nitrobenzaldehyde, found that the *p*-nitrobenzaldehydeindogenide is deposited in quantitative amount, and that this reaction could also be employed for the analysis, both of crystalline indican and that present in the leaf extract. The reaction takes place with extreme readiness, for with indican solution at a dilution of 1 in 1000, the above compound quickly separates, and even at 1 in 10,000 the condensation can be observed to take place. Piperonal and indican in the presence of dilute acid yield the analogous compound $C_{16}H_{11}O_3N$, orange-coloured needles; m.p. 223°–224°, but this process, under analytical conditions, gave only approximately satisfactory results. As a side issue, *p*-hydroxybenzaldehydeindogenide $C_{15}H_{11}O_2N$ orange-red needles, m.p. 267°–269°, and dihydroxybenzaldehydeindogenide $C_{15}H_{11}O_3H$ orange-red needles, m.p. 264°–265°, were prepared from indican. The latter compound derived from protocatechuic aldehyde dissolves in concentrated sodium hydroxide, with a bluish-violet colouration, and dyes with mordanted woollen cloth well-defined shades.

On the other hand, when indican is hydrolysed with acid in the presence of an oxidising agent it does not appear possible to obtain a quantitative yield of indigotin. Hazewinkel (*l.c.*) states, in regard to this point, that acid oxidising agents convert indican into indigo, and this in turn is oxidised by an excess of the reagent. By the use of ferric chloride and hydrochloric acid, Hoogewerff and ter Meulen obtained from the pure glucoside only 91 p.c. of the theoretical quantity of colouring matter, which appeared to contain indirubin, and was of doubtful purity. Gaunt, Thomas, and Bloxam (*l.c.*), who examined the behaviour of ammonium persulphate, a reagent suggested by Rawson for the analysis of the plant extract (Report on the Cultivation and Manufacture of Indigo, Mozzufferpore, 1904; *cp.* also Bloxam and Leake, Dalsingh, Serai Report, 1904), found that the process was far from quantitative with pure indican, and that the yield of colouring matter averaged but 82 p.c. of the theoretical. Perkin and Thomas (*l.c.*) studied the effect of the hydrolysis of solutions of indican with acid during the aspiration of air through the liquid, under varying conditions of temperature and concentration. The most satisfactory yield of pure colouring matter (93·5 p.c.) was produced when air was passed during 8 hours through a solution of 0·5 gram of the glucoside in 850 c.c. of water acidified with 15 c.c. of 33 p.c. hydrochloric acid, and the temperature maintained at 60°.

When, however, the operation was carried out at 70° less colouring matter was obtained (87·6 p.c.), and, curiously enough, replacement of the hydrochloric acid by an equivalent amount of sulphuric acid, gave under similar conditions, a much lower result. The deficiency in the yields given by these air oxidation processes was due to the fact that a portion of the indoxyl had been converted into substances other than indigotin, and it was observed that whereas in the case of hydrochloric acid the filtrate possessed a pale yellow colour, that containing sulphuric acid had a browner and darker tint. Indirubin was also present in these indigo preparations.

Whereas Schunck (*l.c.*) had described the production of various brown substances by the action of dilute acids on his indican, and Schunck and Roemer (*l.c.*) had obtained a brown-yellow compound by means of hydrochloric acid in absence of air, the behaviour of the pure crystalline glucoside in this respect was studied by Perkin and Bloxam. When 100 c.c. of a 4 p.c. solution of indican was treated with 3 c.c. of sulphuric acid, and digested at a boiling temperature, the liquid, at first yellow, became brown, a brown resinous substance, together with a little indigotin, quickly separated, and the presence of indole was observed. The product of the reaction was almost identical in weight with that required by the amount of indoxyl which the glucoside would yield on hydrolysis, and consisted chiefly of a dark reddish-brown powder (*a*), sparingly soluble in alcohol, together with a small quantity of a similar, though more readily soluble substance (*b*). Analyses of (*a*), which is termed *indoxyl brown*, gave $C=68{\cdot}10$; $H=4{\cdot}10$; $N=9{\cdot}34$, figures almost identical with those found by the same authors for the main constituent of indigo brown, and though these two products differ from one another in certain minor respects, there could be no doubt that they were closely allied. The more readily soluble substance (*b*) also closely resembled the indoxyl brown, and gave on analysis $N=9{\cdot}65$ p.c. Indican, when treated with cold hydrochloric acid in the absence of air, for 90 hours, gave indoxyl brown and a soluble brown substance similar to that described above (Perkin and Thomas). The acid filtrates from the indoxyl brown preparations contained dextrose, and this was identified by means of its osazone, and also by the preparation of its acetyl derivative.

The indigo enzyme discovered by Schunck (*l.c.*) has been elaborately investigated by the Dutch chemists. Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1899, 1, 120) extracts the finely divided leaves of the plant, first with cold 96 p.c. alcohol, and subsequently with more dilute alcohol, which removes chlorophyll, indican, wax, &c., and leaves a snow-white highly active powder. From such preparations the enzyme itself was only imperfectly removed, for in water it is almost insoluble, only sparingly so in glycerol, and rather more readily in 10 p.c. solutions of sodium and calcium chlorides respectively. The residue which remains after extraction in this way is not perceptibly less active than before treatment. A minute study of these leaf preparations was carried out by Beyerinck in regard to their behaviour with partly purified indican solutions, and he indicates the effect of temperature on the intensity of the hydrolysis by means of curves. Among numerous points of interest it was observed that ammonia quickly destroys the enzyme, and also that emulsin slowly hydrolyses indican, although the intensity of its action was only one twentieth of that of *Indigofera* enzyme preparations.

Hazewinkel (*ibid.* 1900, 2, 513), who investigated the subject in 1898, arrived independently at Beyerinck's conclusions. By means of his enzyme preparation he proved for the first time that indican is a glucoside of indoxyl. Finding that emulsin also acted on indican solutions he called the indican enzyme *indimulsin*, and considered that a 10 p.c. solution of sodium chloride is the best medium for dissolving it. A very interesting point which he mentions is that during fermentation no indican passes from the leaf into the surrounding liquid.

In the paper of van Romburgh (*ibid.* 1899, 2, 344) allusion is made to the insoluble character of the enzyme, and to the activity of emulsin with solutions of indican. Finally, Beyerinck (*ibid.* 1900, 3, 101) demonstrated that the ferment present in woad, *Isatis tinctoria*, is not capable of hydrolysing indican, though it reacts with isatan, the peculiar indigotin yielding principle of this plant. Bergtheil (Chem. Soc. Trans. 1904, 85, 877), whose paper covers ground already traversed by Hazewinkel, Beyerinck, and van Romburgh, considers that the difficulty which occurs in extracting the enzyme is due to the presence of tannin in the leaves (*cp.* Brown and Morris, Chem. Soc. Trans. 1893, 63, 604). By pounding the leaves with hide powder the tannin becomes fixed, and a very active solution of the enzyme can be obtained.

Ter Meulen (Rec. trav. chim. 1905, 24, 444) is, however, in agreement with the other Dutch work referred to above, as is evident from his statement 'L'enzyme de l'indigo est insoluble dans l'eau.' According to Gaunt, Thomas, and Bloxam (*l.c.*), Bergtheil's product is not a true solution, as the enzyme is entirely removed from it by means of a Berkfeld filter. Thomas, Perkin, and Bloxam (Chem. Soc. Trans. 1909, 95, 829) again point out that there is no certainty of the presence of tannin in the leaves of the *I. sumatrana* and *I. arrecta*, and that any tannin matter if originally present would be eliminated during the repeated extraction of the material with alcohol. As the result of their experiments the insolubility of the enzyme was confirmed.

A study of the hydrolysis of pure indican by means of the enzyme and subsequent oxidation of the indoxyl solution with air under varied conditions has been made by Thomas, Perkin, and Bloxam (*l.c.*). The fermentation was carried out in an atmosphere of purified hydrogen, and the temperature and dilution of the solution in both this and the subsequent oxidation process were so arranged as to fairly approximate the ordinary factory routine. For full details of apparatus and the analytical precautions adopted the original paper must be consulted.

The results of this investigation show that the hydrolytic action of the enzyme proceeds somewhat rapidly, and that by employing 2 grams of the enzyme and 1 gram of indican under the conditions of dilution stated, the reaction was complete after 2 hours' digestion at 50°. The solution, though free from indican, contains, however, less than the theoretical amount of indoxyl (93 p.c.). This is due to the fact that some quantity of the indoxyl (4 p.c.) is occluded by the enzyme powder, and it was found that by increasing the quantity of this latter a correspondingly greater loss occurs. The residual deficiency (3 p.c. approx.) arises from the instability of indoxyl itself, which even in an atmosphere of hydrogen at 50° is slowly converted into a product which is incapable of giving indigotin on oxidation. This property, which is referred to as the 'decay' of indoxyl, is much more evident when the digestion with the ferment is prolonged for several hours, and the experiments of these authors indicate that by such a treatment for 30 hours, at least 20 p.c. of the indoxyl undergoes this transformation. On the other hand, at 15°, in an atmosphere of hydrogen, the indoxyl solution is comparatively stable, and on standing for 24 hours, had experienced a loss of only 3 p.c.

According to Beyerinck (*l.c.*) great attention should be paid to the degree of the acidity of indican solutions which are undergoing fermentation, and this is corroborated by Thomas, Perkin, and Bloxam. Thus, by the presence of a trace of sulphuric acid during the fermentation, the decay of the indoxyl is practically inhibited, and, moreover, by the addition of a further quantity of the acid at the close of the operation, the occlusion of the indoxyl by the enzyme powder is also prevented. As a result of this procedure the solution contained 99·5 p.c. of the theoretical quantity of indoxyl.

When a dilute aqueous solution of indoxyl is oxidised by air the reaction is more complex than has usually been considered the case, and a quantitative yield of indigotin is not produced. Thomas, Perkin, and Bloxam have, for instance, found that the indoxyl solutions produced by the enzyme hydrolysis of indican, when treated with air at 60°, gave only 88 p.c. of the theoretical quantity of indigotin, admixed with a little indirubin. It thus appears evident that in addition to the oxidation of indoxyl to indigotin some secondary reaction occurs, but of the chemical nature of this change there is as yet no certain evidence. The isolation from the indigo thus produced of traces of substances resembling indoxyl brown or indigo brown indicates the effect, at least in part, of a condensation similar in character to that which is involved in the production of the former product. Moreover, the filtrate from the indigo, which is prepared in this manner, was invariably of a dull yellow colour, and yielded, by extraction with ether, a small quantity of a yellowish-brown resin.

This secondary change of indoxyl is facilitated by the presence of potassium acetate in the liquid during the oxidation, for by this means the yield of indigotin was decreased to 81 p.c., and the filtrate obtained from it possessed a rich dichromate colour. It has long been known that the oxidation of indoxyl solutions, in so far as the crude fermented factory liquid is concerned, is facilitated by the presence of ammonia or lime water, and the subject has been discussed by Rawson and by Beyerinck (*l.c.*). According to Thomas, Perkin, and Bloxam, the employment of a small quantity of either of these reagents during the oxidation of the indoxyl derived from pure indican was beneficial, and an increase of about 5 p.c. in the yield of indigo thus took place. On the other hand, the addition of only a trace of these compounds is advisable, because should an excess be present the amount of indigo produced is rather decreased than increased thereby.

But whilst both ammonia and lime water in suitable amount partially inhibit the secondary change of the indoxyl referred to above, a third factor, well known to manufacturers, comes into play, which is represented by the production of notable amounts of indirubin. For the formation of this colouring matter isatin is necessary, and it is likely that, in the presence of a large amount of the above reagents, an excessive production of this substance occurs, and occasions the decreased yield of indigo which, under these circumstances, has been shown to take place. It has, in fact, been pointed out by Perkin (Chem. Soc. Proc. 1907, 23, 30) that traces of isatin exist in Java indigos, which are rich in indirubin.

Curiously enough the presence of a trace of hydrochloric acid during the oxidation acts in the same manner as ammonia, though to a less extent, in increasing the yield of colouring matter, but in this case the reaction proceeds much less rapidly. The employment of pure oxygen with neutral solutions of indoxyl gives 3–4 p.c. less colouring matter than is obtained when air alone is employed, whereas in presence of ammonia the yield is but little affected. The addition of Chile saltpetre to the fermentation vat has been a custom of Indian planters for some time, and Rawson (Report on the Cultivation and Manufacture of Indigo, 2nd ed., 1907) states that although no increase of colouring matter is thus produced in the oxidation vat, the precipitate settles better. The laboratory experiments of Thomas, Bloxam, and Perkin with pure indican corroborate this statement. Finally, there is but little difference in the yield of colouring matter experienced when the solution of indoxyl is oxidised by air at either

30° or 60°, although, if anything, the advantage is in the case of the higher temperature.

As a result, therefore, of the employment of acid during the enzyme hydrolysis of indican, and oxidation of the resulting indoxyl solution under feebly alkaline conditions, the best yields of colouring matter have been obtained. On the other hand, it has not been found possible either with synthetical indoxyl or indoxyl derived from indican to obtain a quantitative yield of pure indigotin or of an admixture of this colouring matter with indirubin. In regard to the bearing of this work on the commercial process, Thomas, Perkin, and Bloxam suggest that the effect of the addition of a small quantity of sulphuric or oxalic acid to the fermentation vat should be studied. They consider, however, that the most satisfactory laboratory results on the preparation of indigotin from the plant extract, or from pure indican, are given when the solution is hydrolysed by hydrochloric acid, with simultaneous oxidation by air. The cost of hot water extraction of the plant is, however, considered by Rawson to be prohibitive.

Bacterial fermentation. Though in the manufacture of indigo, hydrolysis of the indican is mainly due to the action of its specific enzyme indimulsin, it is well known that the bacteria which are present exert a similar although minor effect.

In 1887 Alvarez (Compt. rend. 115, 286) isolated from an extract of the indigo plant, an organism *Bacillus indigogenus*, which was capable of producing this fermentation. Beyerinck (*l.c.*), who studied the matter in considerable detail, points out that a similar effect is produced by infecting indigo plant infusions with garden soil, and that in this case the common gas-producing bacteria perform the chief part. Alvarez, he suggests, went too far in insisting on the existence of a specific bacterium in indigo fermentation. On the other hand, Bergtheil (*l.c.*) considers that at least one organism capable of producing indigo fermentation is invariably found in large quantities in an infusion of the plant. This corresponds very closely with the description given by Alvarez of his *Bacillus indigogenus*, and is no doubt identical with it.

MANUFACTURE OF INDIGO.

Water. Pure water in large quantity is necessary for the manufacture of natural indigo (Crookes, Handbook of Dyeing and Calico-Printing, 1874; Indigo Manufacture, Bridges-Lee, 1892; Rawson, Report on the Cultivation and Manufacture of Indigo, 1902). When such is not available, Bridges-Lee recommends its purification, if hard, by treatment with lime water, and should much organic matter be present by the use of permanganate. Rawson also lays stress on this point, and recommends a similar method of procedure. In special circumstances the employment of aluminoferric is advisable (Bergtheil, 1909). As the duration of the fermentation varies with the temperature of the water, Rawson recommends, in case this should be lower than 90°F., a preliminary heating in the reservoir.

Fermentation. The duration of this process is given by Crookes (*l.c.*) as 9–14 hours, according to the prevailing temperature of the water, whereas Georgievics (Der Indigo, 1892) suggests 18 hours when the external temperature is 35·6°C. In very hot weather the fermentation is completed in 6 hours. According to Rawson (*l.c.*), when the temperature of the fermentation vat is from 90°–92°F., a 12 hours' steeping gives the best result in the case of the *I. sumatrana*; whereas Bergtheil (Indigo Research Station, Sirsiah, 1906) is of opinion that a 10 hours' fermentation is sufficient. With the *I. arrecta* the steeping should vary from 13 to 15 hours at 90°, according to the indican content of the plant. In other respects, according to Rawson and Bergtheil, there is practically no improvement necessary in the steeping operation as carried out in well-managed factories. The addition of such chemicals as mercuric chloride, sodium and potassium carbonates, lime, carbolic acid, formaldehyde, and sugar are not of advantage, although sodium nitrate, which has been employed by planters for many years past, may facilitate the deposition of the indigo in the oxidising vat. On the other hand, the work of Thomas, Bloxam, and Perkin indicates as beneficial the curtailment, as far as possible, of the steeping operation, and the addition of sulphuric or oxalic acid in small quantity to the vat as advantageous.

Hot-water extraction. The extraction of the indigo plant with hot water has been employed for many years, and in Bancroft's Philosophy of Permanent Colours, an account is given by Dr. Roxburgh, dated 1797, of such a method:—'The hot water process begins to be used over these provinces; . . . with it they can make indigo when the weather is too cold for the usual process of fermentation, and it gives a more beautiful and lighter indigo. . . . A more complete and certain extraction of the basis of indigo is effected by subjecting the plant to the action of water heated to about 150°–160°F.' Bridges-Lee (*l.c.*) claims an advantage by the employment of hot water, and heats the contents of the steeping vat gradually either by direct fire or steam pipes. It is also well known that the Java planters who have employed the *I. arrecta*, for several years past have favoured a hot-water process, and although the exact details of their methods have not been disclosed, it is certain that sulphuric acid is also employed in the manufacture. Perkin (Chem. Soc. Trans. 1907, 91, 435) refers to samples of Java indigo prepared by three distinct methods, viz. 'the new process with hot water,' 'the new process with cold water,' and 'the old process in which no chemicals are used.' There can be no doubt that by these hot water processes the indican is very rapidly hydrolysed by the ferment, and that the indigo eventually produced is of a superior quality. During this hot extraction it appears preferable, as far as possible, to exclude air from the vat by means of a cover, and the necessity in this case is easy to understand, because the evolution of carbon dioxide and other gases which act as a protection to the indoxyl during the ordinary process of fermentation, is greatly decreased when operating in this manner (Roxburgh, *l.c.*). Rawson (*l.c.*), who refers to a patent No. 157, 1892, granted to A. Schulte in Hofe, for manufacturing indigo on these lines, and also to Henly's 'heating process of 1888,' carried out numerous experiments on this subject with the *I. sumatrana.* In order to economise fuel the indigo plant was, in the first instance, extracted by the accumulative method; but, contrary to expectation, this did not give such good results as a simple extraction in ordinary vats fitted with perforated steam pipes. He finally concludes, however, that except in wet or cold weather the hot water system offers no advantage over ordinary steeping carried out under favourable conditions. The indigo made by this method was, however, of better quality (75–77 p.c.) than that made in the ordinary way (50–55 p.c.). In regard to extraction of the plant by means of boiling water, or extraction by steaming, Rawson considers that the cost would be prohibitive.

When the fermented liquid is run off into the oxidising vat, the residual plant still contains a small quantity of indoxyl. The question of a second steeping in order to recover this is referred to by Roxburgh as early as about 1797; he considers that a considerable economy would probably be effected thereby; but Rawson's (*l.c.*) experiments in this direction gave an unsuccessful result. Thomas, Perkin, and Bloxam (*l.c.*) suggest that the employment of a slightly acid water for this purpose should be advantageous, and that the amount of indoxyl retained by the plant residue is probably greater than the 5 p.c. (on the total colouring matter) as believed by Rawson to be the case. The extracted plant, known as 'seet,' is a valuable manure.

The oxidation vat. Although the oxidation of the fermented liquid was until very recently carried out to some extent by 'hand beating,' a method practised over a century ago, according to Bancroft (*l.c.*), this operation is commonly effected by machinery. The apparatus is identical with, or very similar to the 'beating wheel,' a rimless wheel, the spokes of which are paddles, and which is now very generally employed in India. Geneste in 1888 patented the pumping in of air, and Bridges-Lee (*l.c.*) in 1891 a shower-bath arrangement, as improvements in the method of oxidation. Rawson again (1902, Eng. Pat. 173) proposed to treat the liquid with acid and an alkaline persulphate; but although excellent results were obtained in the laboratory, these were not satisfactory on the manufacturing scale. As the outcome of an elaborate investigation, Rawson considers that the oxidation of the fermented liquid by blowers and compressors is superior to wheel beating, the yield being thereby increased about 20 p.c.

It has long been the custom to facilitate the deposition of the indigo by what were termed 'precipitants,' and experiments are recorded by Roxburgh, who employed for this purpose ammonia, stale urine, caustic lye, lime water, and potassium ferrocyanide. That such chemicals must be considered to have assisted in the more rapid oxidation of the indoxyl is certain, and their effect is not to be confused with the mere settlement of the indigo by the use of slaked lime, as adopted by the Chinese.

In 1894 Coventry patented a process which was based on the employment of lime under certain conditions. The invention consisted in the employment of a special vat intermediate between the steeping and oxidising vats, in which the fermented liquor was treated with lime. A copious precipitate of calcium and magnesium carbonates was thus produced, which on settling carried down various impurities. The supernatant liquid was then oxidised in the usual manner. The indigo thus produced is somewhat contaminated with lime, and the removal of this is subsequently effected by the addition of a certain amount of acid to the 'mal' in the boiler. Indigo prepared in this manner is of superior quality, and although not equal to the Java product resembles the latter in containing some quantity of indirubin. According to Rawson a substantially increased yield of colouring matter is given by this process.

Caustic soda added to indigo liquor before oxidising behaves very similarly to lime, and on the large scale gave an increase of 43 p.c. of dry indigo as weighed. Sodium peroxide also gave an average increase of 33 p.c., but on the whole was not so serviceable as caustic soda (Rawson).

The oxidation of the fermented plant extract in the presence of ammonia, first mentioned by Roxburgh (*l.c.*), was patented by Michea in 1876, whereas Geneste in 1889 suggested the use of caustic soda and ammonium sulphate instead of liquid ammonia itself. The use of ammonia is mentioned as beneficial by Georgievics (*l.c.*), and there appears to be no doubt that it is superior to the other reagents which have been employed for this purpose. In its presence the indoxyl is rapidly oxidised to indigotin, and the precipitated colouring matter settles well. The more general employment of ammonia in India has resulted from the work of Rawson, and its use in conjunction with the steam injector blower constitutes the most important improvement which he has recommended to the notice of the indigo planters. The procedure adopted by Rawson consists briefly in connecting the outlet of an ammonia still (containing lime and ammonium sulphate) loosely with the steam blower, so that when in action, ammonia, air, and steam are injected into the vat by means of perforated pipes laid at the bottom of the receptacle. During the operation the temperature rises 10°–15°F., and the oxidation is rapidly completed. The employment of ammonia gas and steam in connection with the beating wheel gives also satisfactory results. By these methods Rawson describes increases in the yields of dry indigo, varying from 37 to 63·8 p.c., and considers that the average increase of colouring matter is about 34 p.c. as compared with that given by the ordinary oxidising process.

On the other hand, Bergtheil (Report of the Indigo Research Station, Sirsiah, 1906, 6) states that the ammonia process effects very little, if any, improvement over ordinary oxidising when this is carried out under optimum conditions of speed, weather, water, &c.

After the indigo has settled in the vat, the supernatant liquid, or 'seet' water, is run off as completely as possible. This seet water, as a rule, contains more or less colouring matter in suspension, and it is during this operation that a considerable loss of indigo occurs, which may reach as much as 20 p.c. (Rawson). This, as a rule, is much reduced by using an alkali in oxidising, on account of the readier settlement of the precipitate. Rawson found that filter pressing cannot be adopted in this respect, but suggests treating the 'seet' water with an alkali by which the suspended indigo more readily subsides. On the other hand, Bergtheil (1909) recommends the employment of alumino-ferric as an aid to the deposition of the indigo precipitate in the oxidation vat.

Final treatment of indigo. According to Bancroft (*l.c.*) it was the practice of some manufacturers in the East Indies to purify their indigo by boiling it with water and fossil alkali (soda), whereas Roxburgh, as well as de Cosigny, recommended also the action of a diluted sulphuric acid. The more general practice, until very recently, in India has consisted in merely boiling the semi-fluid indigo paste in a large cauldron, but the use of a dilute sulphuric acid appears now to be very generally adopted. According to Rawson the quality of the indigo may be in this way improved 5–10 p.c. At the close of the operation the indigo is allowed to settle, the acid liquid run off, and the precipitate treated with fresh water and again boiled.

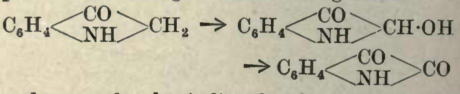
The subsequent filtering, pressing, and drying operations call for no special comment. The slow drying of the product appears to be most advantageous, and in this way an indigo of slightly higher percentage than when the mass is dried artificially is produced. This is accounted for by the fact that certain impurities of the indigo in the presence of moisture undergo gradual decomposition with evolution of ammonia and other gases.

Briggs (Pat. Spec. 292, 1906) has devised an apparatus for drying the indigo paste, and simultaneously converting it into powder. An illustration of this machine, essentially a revolving drum, appears in Bergtheil's Report, 1906, 12. Attempts, moreover, are being made to place natural indigo on the market in the paste form (*ibid.* 1910).

Constituents of Natural Indigo.

In addition to indigotin natural indigo contains varying proportions of indirubin, indigo brown, indigo gluten, and mineral matter. Indigo yellow or kæmpferol is also present as a rule when the *I. arrecta* has been employed for the manufacture.

Indirubin. The identity of the natural indirubin or indigo red, with the artificial product prepared according to Baeyer's method (*l.c.*) about which there was formerly some controversy, appears now to be fully established (Marchlewski and Radcliffe, J. Soc. Chem. Ind. 1898, 17, 434). Bloxam at one time (Chem. Soc. Trans. 1905, 87, 979) considered that a red substance other than indirubin was present in some quantity in natural indigo, whereas Bergtheil (Report of the indigo Research Station, Sirsiah, 1906) has stated that 'decisively there is more than one red body in most commercial indigos.' The investigation of numerous samples of the dyestuff by Perkin and Bloxam (Chem. Soc. Trans. 1907, 91, 279, and 1910, 97, 1461) indicate, however, that this is not the case. Whereas certain varieties of natural indigo, notably Java and Coventry process indigos, contain notable amounts of indirubin, it is probable that a trace occurs in all samples of the natural dyestuff. That the indirubin originates from the indican existing in the leaves of the various species of *Indigofera*, and is due to no second constituent of the plant, is now certain, and its production is to be explained in all cases as due to the condensation of isatin with indoxyl. Thus it has been shown by Thomas, Bloxam, and Perkin (*l.c.*) that indigo containing indirubin can be readily produced from indican by a repetition of the factory method, and again isatin itself has been isolated from natural indigo rich in indirubin (Perkin, Chem. Soc. Proc. 1907, 23, 30). The formation of the isatin is favoured by special circumstances such as the oxidation of the indoxyl by air in the presence of alkali or acid, and may also be affected to some extent by temperature. That indoxyl can be converted into isatin without an intermediate formation of indigotin has been shown by the Badische Anilin und Soda-Fabrik (D. R. P. 107719, 1898), and it has been found by Perkin (Chem. Soc. Trans. 1909, 85, 847) that indoxylic acid, on standing in the presence of moist air, is converted chiefly into indirubin, although some quantity of indigotin together with a substance, probably indigo brown, and traces of isatin are simultaneously produced. Again it has been pointed out (T. B. & P.) that the indican present in air-dried leaves of the indigo plant slowly disappears and, according to Perkin (private communication), this is accompanied in most cases by a development in the leaf of considerable quantities of indirubin. It appears probable that this so-called 'secondary' oxidation of the indoxyl proceeds according to the following scheme:



$$C_6H_4\left<\begin{matrix}CO\\NH\end{matrix}\right>CH_2 \rightarrow C_6H_4\left<\begin{matrix}CO\\NH\end{matrix}\right>CH{\cdot}OH \rightarrow C_6H_4\left<\begin{matrix}CO\\NH\end{matrix}\right>CO$$

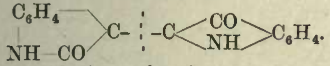
and may also be indirectly the cause of the production of indigo brown. The following are the results of analyses illustrating the percentages of indirubin and indigotin in certain indigos (B. and P.):—

Sample.	Total colouring matter.	Indigotin.	Indirubin.
Java Indigo.—New process with hot water.			
1.	75·20	67·76	7·43
2.	73·60	63·86	9·51
6.	62·91	57·35	5·01
Java indigo.—New process with cold water.			
7.	72·88	69·23	3·06
8.	71·02	66·35	4·04
9.	58·30	55·61	2·15
Java indigo.—Old process without chemicals.			
13.	74·96	72·89	1·74
15.	69·54	68·26	0·99
Coventry.—Process indigo.			
	61·76	56·63	5·23

Finally, Bloxam and Perkin refer to an abnormal sample of laboratory indigo prepared from pure indican, which contained 88·9 p.c. of colouring matter, and of this 25·83 p.c. was indirubin.

Though indirubin was at one time considered to be a valuable constituent of natural indigo (*cp.* Rawson and Knecht, J. Soc. Dyers, 1888, 4; Hummel, *ibid.*; and Bergtheil, Report Indigo Research Station, Sirsiah, 1907, 7) it is now known that such is not the case.

Fasal (Mitt. K. Tech. Gew-Mus. Wien. 1895, 11, 307) found that the shade of colour given by an indirubin vat became bluer from day to day, and that this was due to the formation of indoxyl by the further reduction of the leuco-indirubin. More recently Perkin (Chem. Soc. Proc. 1909, 25, 127) has shown that in addition to indoxyl oxindole is simultaneously produced, and this is in harmony with the formula assigned by Baeyer (*l.c.*) to this substance.



In vat dyeing, therefore, indirubin may produce not more than one-half its weight of indigotin. Matthews (J. Soc. Chem. Ind. 1902, 21, 22), again, points out that indirubin requires for reduction a much stronger reagent than indigotin, and as a result the greater part of this dyestuff is not attacked, but settles to the bottom of the vat.

On the other hand, indirubin disulphonic acid is, according to Fasal (*l.c.*), and also to Rawson and Knecht (*l.c.*), a useful dyestuff, and gives colours much faster to light than sodium indigotin disulphonate, the 'indigo extract' of commerce.

Indigo brown. An important impurity of natural indigo is the so-called indigo brown, a product isolated and cursorily examined by both Chevreul (Gmelin, Handbook of Chem. 1859, 13, 48) and Berzelius (*ibid.*). In order to isolate this product, the latter chemist digested indigo with boiling dilute sulphuric acid to remove indigo gluten, and subsequently with potassium hydroxide to dissolve the brown. The alkaline liquid was neutralised with acetic acid, evaporated to dryness, the residue digested with alcohol, and the solution evaporated. Thus obtained the indigo brown consisted of a dark-coloured resin, soluble in alkaline solutions. According to Schunck (Phil. Mag. 1855, [iv.] 10, 74, and *ibid.* 1858, 15, 127) the indihumin $C_{10}H_9O_3N$ produced in conjunction with other brown amorphous products by the action of dilute acids on his indican was, perhaps, identical with indigo brown.

Perkin and Bloxam (Chem. Soc. Trans. 1907, 91, 279) extracted Bengal indigo, which had been already digested with boiling dilute hydrochloric acid to remove the gluten, with boiling pyridine. In addition to a little indirubin the product contained three substances: (*a*) the main constituent, $C_{16}H_{12}O_3N_2$ (?) insoluble in alcohol and acetic acid, (*b*) $C_{24}H_{22}O_5N_3$ (?) soluble in acetic acid, and (*c*) $C_{16}H_{14}O_4N_2$ (?) soluble in alcohol. These compounds, the molecular weight of which is uncertain, consist of brown amorphous powders, closely resembling one another in general property, and are readily reduced by zinc dust in alkaline solution with formation of pale brown liquids. When digested with boiling 50 p.c. potassium hydroxide solution they give some quantity of *anthranilic acid*, a point which indicates that they are derived from indoxyl. At the same time a brown resinous substance is also produced, and this studied in the case of the main constituent (*a*) $C_{16}H_{12}O_3N_2$ contained C=71·39; H=4·05; N=7·94. Natural indigo further contains a small quantity of a brown substance (*α*), insoluble in pyridine, but soluble in boiling dilute alkali (Chem. Soc. Trans. 1910, 97, 1473), and is distinguished from the substances above enumerated by the fact that it is not susceptible to sulphonation (with 96 per cent. sulphuric acid) or conversion by this means into a product soluble in water. In the analytical method described by Rawson (J. Soc. Chem. Ind. 1899, 18, 251) this brown material, at least in part, consists of the impurity which is carried down by a precipitation of barium sulphate in the liquid. There is now considerable evidence in favour of the view that the constituents of indigo brown are derived from indoxyl during the manufacture of indigo from the plant. The fact that indican itself, when boiled with dilute acids, produces the very similar indoxyl brown, and the isolation of brown substances, although in trifling amount, from indigo prepared by the hydrolysis of pure indican in the laboratory, harmonises with this suggestion.

Beyerinck (Proc. Roy. Akad. Scien. Amsterdam, 1899, 120) observed that the disappearance of indoxyl in a dying woad (*Isatis tinctoria*) leaf is accompanied by the appearance of brown substances. Again, he states that 'strong acids, just as alkalis . . . favour the formation of indigo from indoxyl, but then part of this substance constantly changes into a brownish-black matter.' It has also been noted by Thomas, Perkin, and Bloxam that the disappearance of indican in the leaves of the *I. sumatrana* on keeping is accompanied by the formation of brown extractive matter. Rawson, again (Report on the Cultivation and Manufacture of Indigo, Mozzufferpore, 1904), says, 'The blower . . . by quickly getting rid of CO_2 gas . . . prevents decomposition of a portion of the colouring matter into worthless brown substances, which takes place to a greater extent under other conditions.' All indigos, moreover, appear to contain indigo brown so that this property is irrespective of their origin, which may have been due to such distinct plants as the *Indigoferæ*, the *Polygonum tinctorium*, or the *Lonchocarpus cyanescens* of West Africa. Finally, it has been shown by Perkin (*l.c.*) that among the decomposition products of commercial indoxylic acid which has been kept for a long time, a brown compound exists, which has a very similar percentage composition, and is probably identical with the main constituent of indigo brown. It is quite possible that indoxylic acid is produced during the fermentation process (Perkin). The percentage of indigo brown, soluble in pyridine in natural indigos is very variable, and appears to depend upon the details of manufacture. Analyses made by Bloxam and Perkin (Chem. Soc. Trans. 1910, 97, 1472) gave the following result:—

Java indigo, new process, hot water.	*Java indigo, new process, cold water.*	*Java indigo, ordinary process.*	*Coventry process indigo.*	*New Bengal indigo.*
5·4	5·2	4·15	8·7	9·60

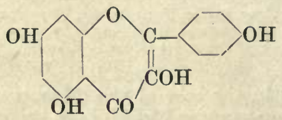
Except in the case of the Coventry process indigo, these samples had all been derived from the *I. arrecta*. The average amount of crude indigo brown—containing, however, some mineral matter—in numerous samples of Bengal indigo was 14 p.c. (Chem. Soc. Trans. 1907, 297).

Indigo brown dissolved in alkaline hydrosulphite solution does not colour fabrics, and appears to be entirely devoid of tinctorial property. The frequently asserted superiority of the natural over the artificial variety of indigo cannot therefore be accounted for in this manner.

Indigo gluten. Indigo gluten was first isolated from crude indigo by Berzelius (Berz. Jahresb. 7, 26), who extracted it with dilute acid, neutralised the extract with chalk, evaporated to dryness and dissolved out the gluten with alcohol. It was subsequently prepared by Orchardson, Wood, and Bloxam (J. Soc. Chem. Ind. 1907, 26, 4), who describe it as a horny mass, which on grinding gives a light biscuit-coloured powder, and when heated evolves ammonia. In cake indigo it appears to exist in combination with mineral matter, possibly as a calcium compound, for though itself readily soluble in water it can only be removed from the dyestuff by means of dilute mineral acid. A considerable quantity of this substance is frequently present in indigo, and Perkin and Bloxam (*l.c.*) found that when the crude Bengal variety containing approximately 62 p.c. of indigotin was digested with dilute hydrochloric acid, it lost 21·5 p.c. of its weight. This figure naturally includes some quantity of mineral matter simultaneously removed by the acid. It has been suggested that this compound plays an important rôle in the dyeing operation, and accounts in part for the alleged superiority of natural over artificial indigo. This point, however, has not been scientifically investigated.

Indigo yellow. The first application of the term 'indigo yellow' to a substance existing in natural indigos is due to Bolley and Crinsoz (J. 1866, 573), who state that it is to be found in the Bengal variety, and can be isolated by sublimation. It is described as golden-yellow needles, subliming at 130°, and soluble in soda lye. Crude Bengal indigo, however, gives no sublimate of this character (Perkin, Chem. Soc. Proc. 1906, 22, 198), but by submitting refined indigo, or the commercial synthetical variety to sublimation with limited access of air, a trace of a yellow compound $C_{15}H_8O_2N_2$ is produced. This substance, however, is insoluble in alkaline solutions, and cannot, therefore, be the indigo yellow of Bolley and Crinsoz.

Rawson (J. Soc. Chem. Ind. 1899, 18, 251) detected in Java indigos a yellow compound, present usually to the extent of 2–3 p.c., although in one special sample as much as about 20 p.c. occurred. This substance was soluble in alkalis with a yellow colour; on heating it partially sublimed, and had the properties of an adjective yellow dyestuff. A more recent investigation (Perkin, Chem. Soc. Proc. 1904, 20, 172) has indicated that this in reality is *kæmpferol*



a trihydroxy flavonol known to exist (Chem. Soc. Trans. 1902, 81, 587) in the flowers of the *Delphinium consolida* (Linn.) and other plants. Ultimately it was shown that the leaves of the *I. arrecta*, from which Java indigo is prepared, contain sometimes as much as 4 p.c. of a glucoside *kæmpferitrin* $C_{27}H_{30}O_{14}$, almost colourless needles, m.p. 201°–203°, which when digested with acid gives kæmpferol and rhamnose

$$C_{27}H_{30}O_{14}+4H_2O=C_{15}H_{10}O_6+2C_6H_{12}O_5,H_2O.$$

This compound is not hydrolysed by the indigo enzyme, and no enzyme has as yet been isolated from the plant possessing such a property. It is likely (Chem. Soc. Trans. 1907, 91, 435) that the use of sulphuric acid, when manufacturing Java indigo, may result in the contamination of the dyestuff with kæmpferol. When the wet indigo sludge or 'mal' is boiled in the 'mal' boiler with addition of a little of the acid, the kæmpferitrin present in the adhering water will be hydrolysed, and the insoluble colouring matter remain with the indigo. Samples of Java indigo more recently obtained contained only a trace (0·2 p.c. approx.) of kæmpferol, whereas in a sample of the new Bengal indigo manufactured from the *I. arrecta* approximately the same quantity was detected (Perkin, private communication). If indigo mixed with kæmpferol is cautiously sublimed the sublimate then contains appreciable quantities of this yellow colouring matter, and it seems likely, therefore, that this is in reality the indigo yellow of Bolley and Crinsoz, but that the indigo experimented with by these authors did not, as they supposed, originate from Bengal. The leaves of the *I. sumatrana*, the Indian indigo plant, contain but the merest trace of a yellow dyestuff resembling kæmpferol, but according to Henry (Gmelin's Handbook of Chem. 1846, 13, 50) the *Polygonum tinctorium*, or Chinese indigo plant, contains appreciable quantities of a yellow colouring matter.

THE ANALYSIS OF INDIGO.

The methods which have been proposed for the analysis of indigo are of a varied character, and the literature upon the subject is extremely voluminous.

These may be classified as follows: methods (*a*) involving the extraction of impurities with volatile solvents (Schützenberger, Die Farbstoffe, ii. 526); (*b*) the extraction of indigotin with coal tar oil (Stein, Die Prüfing der Zeugfarben); with aniline (Hönig, Zeitsch. angew. Chem. 1899, 280); with phenol (Brandt, J. Soc. Dyers. 1898, 34); with naphthalene (Schneider, *ibid.* 1895, 194); with nitrobenzene (Gerland, J. Soc. Chem. Ind. 1897, 108); with aceto-sulphuric acid (Möhlau and Zimmermann, Zeitsch. farb. text. Chem. 1903, 10, 189); (*c*) the extraction of indigotin by sublimation (Lee, Chem. News, 1884); (*d*) the extraction of indigotin by processes of reduction, lime, and ferrous sulphate (Berzelius), stannous chloride and caustic soda (Dana, Jahres. f. prakt. Chem. 26, 398), zinc and caustic soda (Owen, J. Amer. Chem. Soc. 10, 178), grape sugar, alcohol, and alkali (Fritzsche, Dingl. poly. J. 1842, 86, 306), and hydrosulphite and lime (Rawson, *l.c.*); (*e*) estimation of nitrogen (Voeller, Zeitsch. angew. Chem. 1891, 110).

More important, however, are the methods based upon the titration of a solution of the sulphonated indigo by oxidising agents (*f*) chlorine water (Berzelius), chloride of lime (Chevreul, Lecons. d. chem. appliq. de la teinture, ii.), potassium chlorate and hydrochloric acid (Bolley, Dingl. poly. J. 119, 114), potassium dichromate and hydrochloric acid (J. pr. Chem.

1851, 18, and Schlumberger, Bull. de la Soc. Mullhouse, 1863, 210, 284) potassium dichromate and oxalic acid (Kinley, Chem. News, 1863, 210, 284), potassium ferricyanide (Ullgren, Annalen, 136, 96), and potassium permanganate (Mohr, Dingl. poly. J. 132, 363), and by reducing agents, (*g*) sodium hydrosulphite (Müller, Ber. 1880, 13, 2283), and titanous chloride (Knecht, J. Soc. Dyers. 1904, 97, and *ibid.* 1905, 292).

Finally (*h*) colorimetric methods (Dingl. poly. J. 27, 54, and 40, 448); (*i*) spectrum analysis (Wolff, Zeitsch. anal. Chem. 17, 65, and *ibid.* 23, 92); and (*k*) dye trial methods (Chevreul, *l.c.*, and Grossmann, J. Soc. Dyers. 1897, 124) have been proposed.

Of these methods of indigo analysis, modifications of Mohr's permanganate process are most generally employed, although others involving the reduction of sulphonated indigo with titanous chloride and sodium hydrosulphite are to some extent in vogue.

The permanganate methods. In order to eliminate the error due to the oxidising action of permanganate upon substances other than indigotin which are present in natural indigo, Rawson, who has been the pioneer in this respect, has devised two processes.

Salting out method. 0·5 gram of finely powdered indigo mixed with its own weight of ground glass is sulphonated in a porcelain crucible by means of 20 c.c. of concentrated sulphuric acid at 70° for $\frac{3}{4}$-1 hour; the product is diluted with water to 500 c.c., and the liquid filtered to remove insoluble impurities. 50 c.c. of this solution are mixed with 50 c.c. of water and 32 grams of common salt, and after standing for 1 hour the precipitated sodium indigotin sulphonate is collected and freed from certain soluble impurities by washing with about 50 c.c. of salt solution (sp.gr. 1·2). The precipitate is dissolved in hot water, treated with 1 c.c. of sulphuric acid, diluted to 300 c.c., and titrated with a solution of $N/50$ potassium permanganate. The liquid gradually takes a greenish tint, and the final disappearance of this constitutes the end point of the reaction. According to Rawson, 1 c.c. of the $N/50$ permanganate corresponds to 0·0015 of pure indigotin (J. Soc. Dyers., 1885, 74 and 201; A Manual of Dyeing, Knecht, Rawson, and Löwenthal, 1910, 817).

Barium chloride precipitation process. 0·5 gram of indigo is sulphonated as before, and after diluting with water, but before making up to 500 c.c., 10 c.c. of a 20 p.c. solution of barium chloride are added. The barium sulphate formed carries down with it the suspended impurities of the indigo, and the clear liquid can be pipetted off and titrated as before. The results are practically identical with those given by the 'salting out' method (Rawson, J. Soc. Chem. Ind. 1899, 251).

Bloxam (*ibid.* 1906, 735) notes that the barium precipitate thus produced is always coloured blue, and this is confirmed by Bergtheil and Briggs (*ibid.* 1906, 729). The latter authors contend that the results given by this modification of Rawson, are therefore too low, and consider that this defect is obviated by adding instead of barium chloride freshly precipitated barium sulphate to the indigo mixture.

Grossmann (*ibid.* 1905, 308) throws down the impurities from the indigo solution with calcium carbonate. Bergtheil and Briggs (*l.c.*), and also Bloxam (*l.c.*), find that some quantity of the colouring matter is also precipitated in this way. Knecht, however, recommends its successful use even in larger quantity (J. Soc. Dyers. 1904, 97, and 1905, 292) in connection with his titanous chloride method; but Bloxam (*l.c.*) points out that such being the case this can only be due to the observance of conditions which are not stated in Knecht's paper.

Hydrosulphite method. This process, devised by Müller (Ber. 1880, 13, 2283), depends upon the fact that sodium hydrosulphite ($Na_2S_2O_4$) quantitatively reduces pure indigotin sulphonic acids to their corresponding leuco compounds. The solution of the hydrosulphite contained in a stone bottle, is covered with a layer of petroleum to prevent oxidation and connected with a supply of hydrogen gas. By means of a siphon, or other convenient arrangement, the liquid can be drawn into a burette. The solution should be equivalent to about 1 c.c. = 0·0025 gram of indigotin, and the titrations are performed in an atmosphere of hydrogen or coal gas.

Titanous chloride method. This reagent is much more stable than sodium hydrosulphite, and Knecht (J. Soc. Dyers. 1904, 97, and 1905, 292) was the first to recommend its use for the analysis of indigo. The apparatus employed is similar in character to that required for the hydrosulphite process, and the titration is carried out in an atmosphere of carbon dioxide. If the reduction of the indigotin is effected by the titanium chloride in the presence of mineral acid, no definite end-point can be observed (Knecht), but by the addition of salts of tartaric acid this end-point is rendered quite definite.

In working with natural indigo, Knecht (Manual of Dyeing; Knecht, Rawson, and Löwenthal, 822) sulphonates 1 gram of indigo with 5 c.c. of 100 p.c. sulphuric acid at 90° for 1 hour. The solution diluted to 300 c.c. is warmed and slowly treated with 12 grams of chalk, cooled, made up to 500 c.c., and 50 c.c. of the clear liquid to which 25 c.c. of a 20 p.c., solution of Rochelle salt has been added, is titrated whilst boiling with titanium chloride.

On account of the sparing solubility of Rochelle salt, Bloxam (*l.c.*) recommends the use of sodium tartrate, but states that the presence of excess of this or of Rochelle salt (as advocated by Knecht) is to be avoided, or otherwise too high percentages of indigotin are indicated. In the case of pure indigotin (1 gram) sulphonated with 20 c.c. of 100 p.c. sulphuric acid, and made up to 500 c.c. with water, 25 c.c. of this liquid (containing 1 c.c. of acid) requires 4 grams of the sodium tartrate to give quantitative results when titrated with a solution of titanium chloride containing 1 c.c. of concentrated hydrochloric acid per 50 c.c. of solution.

Bloxam (Chem. Soc. Trans. 1905, 87, 975; J. Soc. Chem. Ind. 1906, 25, 735), Orchardson, Wood, and Bloxam (*ibid.* 1907, 26, 4), and Gaunt, Thomas, and Bloxam (*ibid.* 1907, 26, 1174), have critically investigated the subject of indigo analysis. Among the methods for preparation of pure indigotin, that involving the crystallisation of crude material from nitrobenzene was discarded as untrustworthy, but the elaborate process of the B. A. S. F. Co. (Brochure, 1900) was found to give a pure substance. On the other hand, sublimation under reduced pressure in Jena flasks immersed in fusible metal at 370°–390°, gave, with synthetical indigo of 92 p.c. (approx.), a beautifully crystalline substance, which, after washing with boiling acetic acid, followed by boiling alcohol, was usually chemically pure. The permanganate factor resulting from experiments with these specially purified materials was 1 c.c. of permanganate solution 1/1000=0·00222 gram indigotin solution 1/5000, and is in agreement with that previously adopted by the B. A. S. F. Co., but differs considerably from that employed by Rawson (1 c.c. of *N*/50 permanganate=0·0015 indigotin) (*l.c.*). Wangerin and Vorlander (Zeitsch. Farben und Textilchemie, 1902, 1, 281) have stated that indigotin suffers loss of strength by oxidation, even when it is sulphonated by 94 p.c. sulphuric acid at 95°–100° for half an hour, whereas acid of 8 p.c. fuming acid gives a deterioration of from 2 to 14·2 p.c., according to the time of heating. With the indigotin, however, purified as above, Bloxam showed that heating with 20 p.c. fuming acid for $\frac{3}{4}$ of an hour at 97° gave no loss, whereas with 30 p.c. acid for 20 minutes at 97° a deterioration of only 1 p.c. could be observed. In both these cases indigotin tetrasulphonic acid was produced.

The tetrasulphonate method. As a result of these experiments a method for the analysis of indigo based on sulphonation with fuming acid was devised. 1 gram of the indigo, and 2–3 grams of purified sand (powdered glass contains iron, and should not be employed), is treated with 5 c.c. of 25 p.c. fuming sulphuric acid for half an hour in the water oven, and the solution is made up to 500 c.c. with water. 100 c.c. of this solution is treated with 100 c.c. of potassium acetate solution (450 grams per litre) which causes the precipitation of indigotin tetrasulphonate. The mixture is now warmed, and on cooling finally in ice-water, the salt completely separates in a crystalline condition. This is collected by means of the pump on a Gooch crucible, and washed free from the brown supernatant liquid with a solution containing 90 grams of potassium acetate and 5 c.c. of acetic acid in 600 c.c. of water. The product is dissolved in 200 c.c. of water, and 20 c.c. of this solution, diluted with 80 c.c. of water, is treated with 0·5 c.c. of sulphuric acid, and titrated with permanganate (1/1000). In order to verify the accuracy of this method, Orchardson, Wood, and Bloxam studied the behaviour of indigo brown and indigo gluten, the main impurities of indigo, when submitted to the analytical process, as this subject had not been investigated by previous workers. Indigo brown, when sulphonated with 96 p.c. acid gives, when dissolved in water, a dark-brown liquid, which is attacked by permanganate, though not perhaps so readily as the indigotin sulphonic acids, whereas indigo gluten gives similarly a light yellow solution, which is very rapidly oxidised by the reagent. On the other hand, kæmpferol or indigo yellow, treated in the same manner, gave a product which most readily absorbs permanganate, and, indeed, Rawson (J. Soc. Chem. Ind. 1899, 251) had already pointed out its deleterious effect in indigo analyses. Finally, these authors prepared and submitted to analysis by Bloxam's process mixtures containing known quantities of indigotin and one or other of all of these impurities, with the result that the colouring matter was thus estimated with considerable exactness. Bloxam (Chem. Soc. Trans. 1910, 97, 1473), by an adaptation of the pyridine method for the estimation of indirubin (*l.c.*), in which the impurities are eliminated by a process of extraction, has analysed natural indigos, and obtained the same figures as those given by the tetrasulphonate method. Again, by Knecht's titanium chloride method, and employing the modifications above described, this process can also be effectively worked. It is only reasonable to suppose that an analysis based on the selective precipitation of the sulphonated colouring matter is more likely to be efficient, than that which presumes the deposition of varied impurities of a diverse chemical character by one specific reagent, and the somewhat lower results given by the tetrasulphonate method, as distinguished from those yielded by the processes previously in use, are in reality due to the almost complete elimination of these impurities from the indigotin sulphonic acid during the analysis. Rawson (*l.c.*) is, however, of opinion that the effect of these impurities on the analytical results has been much overrated; but, on the other hand, no experimental evidence is given in support of this view (Manual of Dyeing, *l.c.* 818).

The action of potassium permanganate on solutions of the indigotin sulphonic acids is of interest, because the amount of the reagent necessary for the decolorisation of the liquid varies to some extent with the concentration (Rawson, A Dictionary of Dyes, Mordants, &c., by Rawson, Gardner, and Laycock, 1901, 187). At the concentrations employed by the B. A. S. F. Co., and adopted by Bloxam (*l.c.*), 1 gram of indigotin as sulphonic acid requires 0·45 gram of permanganate for decolorisation, whereas the equation

$$5C_{16}H_{10}O_2N_2+4KMnO_4+6H_2SO_4$$
$$=10C_8H_5O_2N+2K_2SO_4+4MnSO_4+6H_2O$$

implies that 0·4824 gram of the reagent is necessary. Again, for the oxidation under similar conditions of indirubin sulphonic acid considerably less permanganate is required, although the oxidation in this case is of a slower character. Bloxam and Perkin (J. Chem. Soc. 1910, 97, 1462) consider, therefore, that the oxidation is of a complex nature, and consists either (*a*) of two distinct stages in the formation of isatin sulphonic acid, or (*b*) of two distinct reactions involving the production of two separate substances. According to the first suggestion the isatin formation from indigotin would be preceded by that of an intermediate compound (I.), whereas by the latter, in addition to isatin, a dehydroindigotin sulphonic acid (II.) is produced.

I. 
$$C_6H_4{<}\genfrac{}{}{0pt}{}{CO}{NH}{>}C\overset{O}{—}C{<}\genfrac{}{}{0pt}{}{CO}{NH}{>}C_6H_4$$

II. 
$$C_6H_4{<}\genfrac{}{}{0pt}{}{N}{CO}{>}C—C{<}\genfrac{}{}{0pt}{}{N}{CO}{>}C_6H_4.$$

In case the first product of the reaction consists entirely of dehydroindigotin sulphonic acid; this must, prior to further oxidation to isatin, take up two molecules of water with formation of dihydroxy-indigotin (III.).

$$C_6H_4<^{NH}_{CO}>C(OH)C(OH)<^{CO}_{NH}>C_6H_4.$$

In regard to the very small amount of permanganate required for the decolorisation of the indirubin sulphonic acid a similar explanation can be adopted.

THE ESTIMATION OF INDIGOS RICH IN INDIRUBIN.

It is well known that indirubin is more resistant to oxidation and reduction than indigotin, properties which also apply to the sulphonic acids of these colouring matters. When dealing, therefore, with mixtures of these substances and employing either potassium permanganate, titanium chloride, or sodium hydrosulphite, the indigotin is to some extent preferentially attacked, so that towards the end of the operation the colouring matter consists entirely of indirubin sulphonic acid. In the case of the former reagent, however, Koppeschaar (Zeitsch. anal. Chem. 1899, 38, 1) finds that it is not possible to obtain trustworthy analytical figures with indigos in which some quantity of indirubin is present, although Rawson (*l.c.*) considers that the indirubin may be approximately estimated in this manner. Bloxam and Perkin (Chem. Soc. Trans. 1910, 97, 1462), however, support the view of Koppeschaar. The latter authors, who also experimented with titanous chloride, show that this reagent behaves in an identical manner towards both indigotin and indirubin sulphonic acids, but although the former is somewhat preferentially attacked, it is not possible in this way to differentiate as to the amount of each of the sulphonated colouring matters which may be present in a mixture of the two. On the other hand, according to Knecht, Rawson, and Löwenthal (A Manual of Dyeing, 821) indirubin present in mixtures of the two colouring matters may be approximately estimated by the hydrosulphite method.

For analysis of indigos rich in indirubin, processes of extraction based on the greater solubility of the latter, have been usually employed.

Extraction with ether (Rawson, *l.c.*). From 0·1 to 0·25 gram of the sample is boiled with about 150 c.c. of ether for half an hour. When cold the solution is made up to 200 c.c. with ether, mixed with 10 c.c. of water and well shaken. The suspended particles of indigotin settle immediately, and a clear solution of indirubin is obtained. A measured quantity of the solution is withdrawn, and compared in a colorimeter with a standard solution of indirubin.

Extraction with acetic acid (Koppeschaar, *l.c.*). The indigo is extracted with glacial acetic acid, and the solution, which contains a mixture of indirubin and indigo brown, is treated with caustic soda. The indirubin, which is thus precipitated, is collected, redissolved in acetic acid, and estimated by comparison with a standard solution of the pure colouring matter.

Extraction with acetone (Gardner and Denton, J. Soc. Dyers. 1901, 170). 0·2 gram of the indigo is digested for half an hour with 100 c.c. of boiling acetone. After cooling the solution is made up to 100 c.c. with acetone, and then to 200 c.c. with 10 p.c. salt solution, and well shaken. The precipitate of indigotin, indigo brown, and other impurities, is removed by filtration, and the indirubin solution estimated colorimetrically with a standard solution of indirubin prepared with acetone and salt solution in a similar way.

Extraction with pyridine. Bloxam and Perkin (Chem. Soc. Trans. 1900, 97, 1460) find, as the result of experiments on mixtures of indigotin and indirubin, that neither commercial ether nor acetone are reliable solvents for the complete extraction of indirubin, and that their action, especially in the former case, is chiefly due to the presence of alcohol. Whereas acetic acid is efficient in this respect, and Koppeschaar's process gives approximately good results, pyridine is a much better solvent, and a method for the complete analysis of indigos containing indirubin based on the application of this liquid is described by these authors.

The indigo (0·25–1 gram) evenly incorporated with purified sand (20–30 grams) is introduced into a thin-walled glass tube, termed the 'container,' closed at one end by means of cotton cloth, on which has been placed a layer of asbestos and sand or of sand alone. Sufficient sand is then added to form a layer on the surface of the indigo mixture, which is then covered with asbestos, and the container is now placed in a Soxhlet tube and extracted with boiling pyridine. The extract is distilled down to a small bulk, the residue treated with boiling water and again distilled, and this operation is repeated until the last traces of pyridine have disappeared. The precipitate, which consists of indirubin together with a little indigotin and indigo brown, is collected, freed from the latter by means of dilute alkali, and the residue is sulphonated with 5 c.c. of sulphuric acid at 100°. The product is dissolved in water, filtered, and the amounts of indigotin and indirubin present ascertained by means of the Duboscq tintometer.

The residue in the container is percolated with water, followed with boiling dilute hydrochloric acid to remove indigo gluten, and is now introduced into a beaker and dried. The colouring matter present is sulphonated with 20 c.c. of sulphuric acid in the usual way, the product after dilution is filtered, and the solution of the indigo sulphonic acid is estimated with permanganate, employing the directions given by Bloxam (*l.c.*). Analyses of mixtures of pure indigotin and indirubin, and also of commercial indigos are given in the paper, and it is also pointed out that by this method an approximate estimation of the indigo brown present in the latter can be carried out.

THE ESTIMATION OF INDICAN IN THE LEAVES OF INDIGO PLANTS.

Although some indication of the indigo-yielding capacity of the plant can be obtained by ordinary steeping experiments, this method was found by Rawson (Cultivation and Manufacture of Indigo, *l.c.*) to possess several drawbacks, and numerous experiments were therefore carried out by him on the quantitative formation of indigo from the leaf extract by the simultaneous action of acids and oxidising agents. As regards the latter, ferric chloride, potassium chlorate, and hydrogen peroxide were tried, but persulphuric acid gave much the best results.

Persulphate method. 20 grams of leaves are extracted for 2 minutes with 250 c.c. of boiling water, the solution is strained through muslin, and the residues squeezed and washed with boiling water. The solution is treated with 5 c.c. of 20 p.c. hydrochloric acid, and 40 c.c. of a 5 p.c. solution of ammonium persulphate. The persulphate is not added all at once; at first 2 c.c. are added, after half an hour 2 c.c. more, and again 2 c.c. after another half an hour. After 2 hours the remainder of the ammonium persulphate is added, and when the mixture has stood for a further period of an hour, the indigo is collected and estimated by permanganate in the usual manner. Bergtheil and Briggs (J. Soc. Chem. Ind. 1906, 734) point out, however, that this process of Rawson's requires modification, as the addition of the reagents at such a high temperature involves a loss of indigotin. The main features of a modification of the process devised by these latter authors are the addition of acid to the cooled extract, and a determination of the course of the reaction, after addition of small amounts of persulphate, by filtration of a portion of the mixture and the addition to the filtrate of a trace of the oxidising agent.

Orchardson, Wood, and Bloxam (*ibid.* 1907, 40; *cp.* also Bloxam and Leake, Research Work on Indigo, Dalsingh, Serai, 1905), who employ sulphuric acid and persulphate, arrived independently at the same conclusion. To 200 c.c. of the leaf extracts these authors add 100 c.c. of a mixture of equal parts of 2 p.c. ammonium persulphate, and 4 p.c. sulphuric acid, and the mixture is kept at 60° for 1 hour. A comparison of their methods with that of Bergtheil and Briggs indicated an identical result in each case, and an increase of 20–25 p.c. of pure colouring matter in comparison with that yielded by Rawson's original process.

The isatin method. Beyerinck (Proc. K. Akad. Wetensch. 1899, 120), in discussing indican, suggested the possibility that by warming its solution with isatin a quantitative yield of indirubin might be produced. Orchardson, Wood, and Bloxam (*l.c.*) have employed this reaction for the estimation of the leaf, and have devised the following method for this purpose.

250 c.c. of extract, equivalent to 5 grams of the leaf, is treated with 0·1 gram of isatin, and the mixture boiled for 5 minutes to expel air, carbon dioxide being passed through the flask. 20 c.c. of hydrochloric acid is then added by means of a tap funnel, and the whole kept boiling for 30 minutes. The precipitate is collected on a tared filter, washed with hot 1 p.c. soda to remove brown compounds, then with 4 p.c. acetic acid and dried. An aliquot portion of the crystalline product is sulphonated, and analysed by the titanous chloride method, adopting the modifications employed by Bloxam (*l.c.*). The indirubin thus obtained is usually almost pure (98·5 p.c.), so that for an approximate estimation, the latter part of the process is unnecessary. Gaunt, Thomas, and Bloxam (*ibid.* 1907, 26, 56) have examined the process in greater detail, and point out that by its employment pure indican gives quantitative figures (*cp.* also Perkin and Bloxam, Chem. Soc. Trans. 1907, 91, 90). On the other hand, this method gives considerably higher figures, both with pure indican (15 p.c.) and the leaf extract (25 p.c.), than those which are obtained by the persulphate process (Orchardson, Wood and Bloxam; and Gaunt, Thomas, and Bloxam, *l.c.*). The unsatisfactory figures in the latter cases arise from a further oxidation of the indigo by the persulphate. That this isatin method does not appear to be affected by other plant constituents was shown by the successful estimation of indican, purposely added to an extract of the leaves of the *Tephrosia purpurea* (Pers.), a plant in which this glucoside is absent.

Efficiency of the Process.

The actual yield of indigotin from the plant during the manufacture is not discussed by Rawson (*l.c.*), but this author considers that if the suggestions enumerated in his report are adopted, there is little or no room for a remunerative alteration of the process. Bergtheil, on the other hand, considers that under the conditions he describes (1906, 12) the efficiency is represented by an 82 p.c. yield, or that if to this be added the 5 p.c. believed by Rawson to be retained by the extracted plant, 87 p.c. is thus accounted for. The quantity of indigo estimated refers to the precipitate present in the vat after oxidation, and from this must be, therefore, deducted the indigo (10–20 p.c.) lost by the 'running off' of the 'seet' water, so that the actual yield of dry colouring matter will thus represent from 62 to 72 p.c. of the theoretical quantity. Recent experiments, however, indicate that by adding aluminoferric to the oxidation a more perfect settlement of the indigo is to be anticipated (*ibid.* 1909).

Bloxam (Dalsingh Serai Report, and J. Soc. Chem. Ind. 1906, 25, 735), who examined the daily output of indigo (as pressed cake) from the Pembarandah factory, found that the first cuttings of the plant (Moorhun mahai) represented an approximate value of 0·1495 p.c. of indigotin from the plant, whereas the second cuttings gave a value of but 0·1526. Assigning to the plant the low value of 0·3 p.c., a considerable and serious loss is thus apparent. Moreover, the estimation of the results given by the 'isatin' method of leaf estimation, and of the finished cake by the 'tetrasulphonate' process (*l.c.*), both of which have been standardised with extreme care, point to a loss during the manufacture much greater than has hitherto been acknowledged (Report to Government of India, 1908).

Apart from the retention of indoxyl by the residual plant in the steeping vat, and the mechanical carrying over of indigo by the 'seet' water, the deficiency of colouring matter is chiefly to be attributed to the conversion of indoxyl into products other than indigotin. Rawson (*l.c.*) has pointed out that if the fermented liquid is allowed to stand before oxidation a considerably decreased yield of indigo is ultimately observed. Thus, on the large scale, by standing for 6 hours a loss of 16·1 p.c. was apparent. Perkin and Bloxam (*l.c.*) have found, as a result of their experiments with pure indican, that this alteration or 'decay' of indoxyl takes place not only in this manner during the fermentation process, but they consider that the indoxyl from the moment of its production by the hydrolysis of indican until its final conversion into indigotin is continually suffering this alteration. This peculiar reaction, representing an important defect in natural indigo manufacture is according to these authors, considerably inhibited by the presence of acid.

Commercial Natural Indigos.

When natural indigo was at its zenith very numerous varieties of this dyestuff were placed on the market, but more recently, owing to its severe competition with the artificial colouring matter, many of these are now rarely met with. From Asia came the indigos of Bengal, Oudh, Madras, Java, Manilla; from Africa those of Egypt and Senegal; and from America those of Guatemala, Caracas, Mexico, Brazil, South Carolina, and the Antilles.

The best varieties are the Bengal, Java, and Guatemala, although in England the Bengal is now mainly employed. Java indigo, formerly largely esteemed for the manufacture of indigo extract, chiefly because of its general purity, at the present time appears to find its market chiefly in the East.

A good quality of natural indigo has a deep violet-blue colour; it acquires a coppery lustre when rubbed with the finger nail; it is light, porous, adhering to the tongue, and can be readily broken and ground. Low qualities, which contain much extractive and mineral matter, are dull and greyish in appearance, heavy, tough, and hard, and do not become bronzy by rubbing with the finger nail.

Synthesis of Indigotin.

In attempting to reconvert the oxidation product isatin into indigotin by reduction, Baeyer and Knop (1865–66) obtained successively dioxindole $C_8H_7NO_2$, oxindole C_8H_7NO, and, finally, indole C_8H_7N (Annalen, 140, 29). This last product, which is to be regarded as the parent substance from which indigotin is derived, was prepared synthetically in 1869 by Baeyer and Emmerling by heating a mixture of nitro-cinnamic acid, caustic potash, and iron filings (Ber. 2, 680). In 1870 these same chemists succeeded in producing indigotin from isatin by heating the latter with a mixture of phosphorus trichloride and acetyl chloride.

Already in 1869 (Ber. 2, 748) Kekulé suggested, but did not prove, that isatin might be an inner anhydride of *o*-amino-phenyl-glyoxylic acid  $C_6H_4\left<\begin{array}{l}CO\cdot COOH\\ NH_2\end{array}\right.$. In 1878 Baeyer and Suida prepared oxindole synthetically from *o*-aminophenylacetic acid  $C_6H_4\left<\begin{array}{l}CH_2\cdot COOH\\ NH_2\end{array}\right.$, of which they proved it to be an inner anhydride; and in the same year Baeyer produced isatin from oxindole, thus completing the chain of transformations necessary to prepare indigotin, artificially from coal tar (Ber. 11, 582, 584, 1228).

Oxindole  was first changed by the action of nitrous acid into nitroso-oxindole , and this by reducing agents into amino-oxindole , and this finally, by oxidising agents or by nitrous acid, into isatin .

A further synthesis of isatin, and therefore also of indigotin, was effected by Claisen and Shadwell in 1879 (Ber. 12, 350). By the action of silver cyanide on *o*-nitrobenzoyl chloride  $C_6H_4\left<\begin{array}{l}COCl\\ NO_2\end{array}\right.$ they obtained *o*-nitrobenzoyl cyanide  $C_6H_4\left<\begin{array}{l}COCN\\ NO_2\end{array}\right.$, which, by successive treatment with hydrochloric acid and caustic potash, yielded the potassium salt of *o*-nitrophenylglyoxylic acid  $C_6H_4\left<\begin{array}{l}CO\cdot COOK\\ NO_2\end{array}\right.$; this, by reduction in alkaline solution, gave the potassium salt of *o*-aminophenylglyoxylic acid  $C_6H_4\left<\begin{array}{l}CO\cdot COOK\\ NH_2\end{array}\right.$, which on the addition of acid yielded isatin . In this manner the original view of Kekulé concerning the constitution of isatin was verified.

In 1880 (Ber. 13, 2259) Baeyer obtained indigotin in various ways from cinnamic acid, which already, in 1869, had been made to yield indole. By treating *o*-nitro-cinnamic acid

$$C_6H_4\left<\begin{array}{l}CH:CH\cdot COOH\\ NO_2\end{array}\right.$$

with bromine, there is produced *o*-nitrodibromhydrocinnamic acid

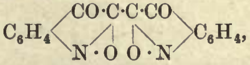
$$C_6H_4\left<\begin{array}{l}CHBr\cdot CHBr\cdot COOH\\ NO_2\end{array}\right.,$$

which, on treatment with caustic alkali, yields *o*-nitro-phenyl-propiolic acid

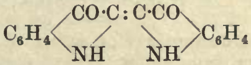
$$C_6H_4\left<\begin{array}{l}C\vdots C\cdot COOH\\ NO_2\end{array}\right..$$

On boiling this substance with caustic alkali, isatin is produced, but if reduced in alkaline solution—*e.g.* with glucose, or xanthates—it yields indigotin. This process was used industrially for some time for the production of *o*-nitro-phenyl-propiolic acid (propiolic acid), its transformation into indigotin being effected on the fabric (calico).

Another method of changing *o*-nitro-phenyl-propiolic acid into indigotin is as follows (Annalen, 143, 325; 147, 78; 154, 137). It is first converted by boiling with water into *o*-nitro-phenyl-acetylene  $C_6H_4\left<\begin{array}{l}C\vdots CH\\ NO_2\end{array}\right.$, the copper compound of which, by oxidation with potassium ferricyanide, yields dinitro-diphenyl-diacetylene  $C_6H_4\left<\begin{array}{l}C\vdots C\cdot C\vdots C\\ NO_2\quad NO_2\end{array}\right>C_6H_4$. This body is changed by fuming sulphuric acid into its isomeride diisatogen



which, by reduction, yields indigotin



(Ber. 15, 50, 746).

Another of Baeyer's indigotin syntheses (D. R. P. 11857, 1880; Friedl. 127) is to treat *o*-nitro-cinnamic acid in alkaline solution with chlorine, whereby there is produced *o*-nitrophenylchlorlactic acid

$$C_6H_4\begin{matrix}CH(OH)CHCl\cdot COOH\\ NO_2\end{matrix},$$

which, by treatment with alkalis, changes into *o*-nitrophenylhydroxyacrylic acid

$$C_6H_4\begin{matrix}C(OH):CH\cdot COOH\\ NO_2\end{matrix}.$$

On heating this substance to 110°C. indigotin is produced.

In 1882 (Ber. 15, 2856) Baeyer and Drewsen prepared indigotin from *o*-nitrobenzaldehyde  $C_6H_4\begin{matrix}CHO\\ NO_2\end{matrix}$. If this substance is treated with acetone, acetaldehyde, or pyroracemic acid, products are formed which, under the influence of caustic alkali, readily yield indigotin. The reaction proceeds differently according to the reagent used. With the use of acetone the intermediate product is probably *o*-nitro-β-phenyl-lactic-methyl-ketone

$$C_6H_4\begin{matrix}CH(OH)CH_2\cdot COCH_3\\ NO_2\end{matrix},$$

which, by the action of the alkali, yields indigotin and acetic acid. With acetaldehyde the intermediate body is *o*-nitro-phenyl-lactic-aldehyde  $C_6H_4\begin{matrix}CH(OH)CH_2\cdot CHO\\ NO_2\end{matrix}$, and this the alkali decomposes to form indigotin and formic acid. With pyroracemic acid the intermediate substance is *o*-nitrocinnamylformic acid

$$C_6H_4\begin{matrix}CH:CH\cdot CO\cdot COOH\\ NO_2\end{matrix},$$

which, under the influence of alkali, produces indigotin and oxalic acid.

Meister, Lucius, and Brüning (D. R. P. 20255, 1882; Frdl. 142) patented a method similar to the first of the foregoing processes. Benzaldehyde and acetone are condensed according to Claisen's method to form benzylidene-acetone (cinnamylmethyl-ketone)

$$C_6H_5\cdot CH:CH\cdot COCH_3;$$

this is nitrated, and of the para- and ortho-nitro- derivatives thus obtained the latter is treated with alkali, and thereby yields indigotin. The yield is small, and the process was soon abandoned. The same firm also patented the manufacture of *m-methyl-indigotin* by the following method, nitrating *m*-methylbenzaldehyde and treating the *o*-nitro- derivative produced, with alkali according to Baeyer and Drewsen's method given above. The methyl-indigotin obtained is very similar in appearance to indigotin, but is remarkable for its solubility in alcohol.

In 1882 (D. R. P. 21592, 1882; Frdl. 138; Ber. 17, 963) Baeyer and Bloem prepared indigotin from *o*-amino acetophenone

$$C_6H_4\begin{matrix}CO\cdot CH_3\\ NH_2\end{matrix},$$

and from *o*-amino phenylacetylene

$$C_6H_4\begin{matrix}C:CH\\ NH_2\end{matrix}.$$

The acetyl derivatives of either of these substances are dissolved in carbon disulphide and treated with bromine in the cold. On dissolving the bromine compound thus produced, in concentrated sulphuric acid, hydrobromic acid is evolved, and a colourless body is precipitated which, by the action of alkalis, decomposes to form indigotin. To ensure success the bromine must enter the methyl group of the acetyl-*o*-aminoacetophenone, and this takes place if the bromine acts in presence of conc. H_2SO_4 or in the dry condition. If the bromine enters only the benzene group (and this occurs when operating in aqueous or glacial acetic acid solutions), no indigotin is obtained; if the bromine enters both the methyl and the benzene groups—*e.g.* by working with chloroform solution—then brom-indigotin is ultimately obtained. During the formation of the indigotin in the subsequent process, indoxyl  $C_6H_4\begin{matrix}C(OH):CH\\ NH\end{matrix}$ occurs as an intermediate product.

Gevekoht obtained indigotin by the prolonged action of an excess of ammonium sulphide on a cold alcoholic solution of *o*-nitro-brom-acetophenone containing the bromine in the methyl group, and finally evaporating the solution (Annalen, 221, 330; D. R. P. 23785, 1883; Frdl. 139). This method is probably essentially the same as that of Baeyer and Bloem, since the first action of the ammonium sulphide is no doubt to produce *o*-amino-brom-acetophenone.

P. Meyer (Ber. 16, 2261; D. R. PP. 25136 and 27979, 1883; Frdl. 148, 149) obtained indigotin or substituted-indigotins by first preparing isatin or substituted-isatins, and then reducing their chlorides by means of zinc or hydrochloric acid in glacial acetic acid in the manner previously known. If 1 molecule dichloracetic acid is heated with 4 molecules aniline there is produced the intermediate substance phenyl-imesatin, which, by boiling with strong acids or bases, yields isatin, thus:

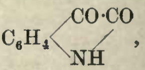
$$\underset{\text{Phenylimesatin.}}{C_8H_5NO\cdot N(C_6H_5)}+H_2O=\underset{\text{Isatin.}}{C_8H_5NO_2}+C_6H_5\cdot NH_2.$$

If in place of aniline in this reaction a *p*-monoamine is employed, *e.g.* *p*-toluidine, the intermediate product obtained is *p*-toluyl-*p*-methylimestan or *p*-methylisatin-*p*-toluylimid $C_8H_4(CH_3)NO\cdot N(C_7H_7)$, and this yields by the action of acids or alkalis methylisatin

$$C_8H_4(CH_3)NO_2$$

and toluidine.

In consequence of Baeyer's synthesis of *indole* from *o*-nitro-cinnamic acid (Ber. 2, 680), its constitution is regarded as being  $C_6H_4\begin{matrix}CH:CH\\ NH\end{matrix}$. Claisen and Shadwell's synthesis of *isatin*, already referred to, indicates its constitution as



$$C_6H_4\begin{matrix}CO\cdot CO\\ NH\end{matrix},$$

but numerous observations of Baeyer show that it contains a hydroxyl group, and that its formula is  $C_6H_4\begin{matrix}CO\cdot C(OH)\\ N\end{matrix}$. In its substitution products, however, it appears to exist in the above pseudo form.

Isatin  $C_6H_4{<}\begin{array}{l}CO\cdot C(OH)\\ \quad\diagup\!\!\diagup\\ N\end{array}$ may be obtained by oxidation of indigotin with chromic acid or nitric acid (J. pr. Chem. [i.] 24, 11; 25, 434); by the oxidation of amino-oxindole or of carbostyril (Ber. 11, 1228; 14, 1921); by boiling *o*-nitrophenylpropiolic acid with caustic alkali (Ber. 13, 2259); and according to other methods already given. Its constitution is that of an inner anhydride of *o*-amino-phenylglyoxylic acid (Ber. 12, 350). It forms orange-red prisms; m.p. 200°C. With thiophen it forms a blue colouring matter called indophenin ($C_{12}H_7NOS$) (Ber. 18, 2637). By the action of dilute nitric acid it yields nitro-salicylic acid. Heated with caustic alkali it gives aniline. Reduced with ammonium sulphide, isatid ($C_{16}H_{12}N_2O_4$) is formed (J. pr. Chem. [i.] 24, 11; 25, 434). It combines with hydroxylamine to form nitroso-oxindol (Ber. 16, 518, 1714; Annalen, 140, 29).

Isatinic acid  $C_6H_4{<}\begin{array}{l}CO\cdot COOH\\ NH_2\end{array}$, in the form of its salts, is obtained by heating isatin with strong caustic alkali or by reduction of *o*-nitro-phenyl-glyoxylic acid. Only its salts are stable, the free acid decomposing into isatin and water, by merely boiling its aqueous solution. Its constitution is that of *o*-amino-phenylglyoxylic acid (Ber. 12, 350).

Isatogenic acid ether  $C_6H_4{<}\begin{array}{l}CO\cdot C\cdot COO\cdot C_2H_5\\ \quad\diagup\,|\\ N\cdot O\end{array}$ (Ber. 14, 1741; 15, 50, 746) is produced by the action of concentrated sulphuric acid on *o*-nitro-phenylpropiolic-acid-ether, with which it is indeed isomeric. It forms yellow needles; m.p. 115°C.

Diisatogen  $C_6H_4{<}\begin{array}{l}CO\cdot C\cdot C\cdot CO\\ \quad\diagup| \quad |\diagdown\\ N\cdot O\ \ O\cdot N\end{array}{>}C_6H_4$ (Ber. 15, 50, 746) is obtained by the action of concentrated sulphuric acid on dinitro-diphenyldiacetylene. It forms red needles, soluble only in chloroform, nitrobenzene, and concentrated sulphuric acid.

A. G. P.

INDIGO, ARTIFICIAL, AND INDIGOID DYESTUFFS. The elucidation of the constitution of indigo, the result of the brilliant and indefatigable researches of A. von Baeyer (*v. supra*), has led to consequences of extraordinary importance. The methods discovered for the synthetical production of indigo offered at first little or no prospect of the artificial production of this most important dyestuff at prices which could compete with the natural product. But the patient and unceasing work carried on for that purpose in the laboratories of the Badische Anilin- & Soda-Fabrik in Ludwigshafen gradually surmounted the existing difficulties. Artificial indigo appeared in the market in the year 1897, and was soon acknowledged to be cheaper, purer, and more easy of application than the natural product. New synthetical manufacturing processes which have since then been introduced, combined with a strong competition between the various manufacturers, led to a steady reduction of prices, so that at present (1911) the synthetical dyestuff may be said to have driven out the natural one everywhere, even in countries in which the indigo plants are grown, such as India, the Dutch colonies, China, Japan, and South America. The history of artificial alizarin has been repeated in all its details in the progress of artificial indigo. But the consequences of this new triumph of synthetical chemistry have gone further, in that they have revolutionized the old-established European industries engaged in the production as well as the application of artificial dyestuffs.

The old, but difficult and uncertain process of vat-dyeing, necessary for the application of indigo, has been carefully studied by the factories which had taken up the production of the synthetical product. Sodium hydrosulphite, long known to be the best means for reducing indigo in the vat, but unstable and difficult to prepare, has been brought into new forms in which it is quite stable and easily applied. Thus vat-dyeing has become an operation almost as easy and simple as any other process of dyeing, and the consumers of artificial colouring matters became anxious to be furnished with products similar to indigo in its mode of application and its fastness, but differing in shade. This wish has been satisfied almost simultaneously with its being felt. A large and constantly increasing number of new vat-dyes of every conceivable shade has been offered to the dyer and calico-printer, who is able to use them jointly or in mixtures with indigo, and thus to produce goods, the shades of which are quite as durable as the fibre itself. Some of the new vat-dyestuffs not only equal, but actually exceed indigo in fastness to light, air, and all the other influences which attack and destroy the colour of dyed fabrics. The introduction of the new synthetical vat-dyestuffs has inaugurated a new epoch of fast dyeing, the full importance of which will only be recognised in time to come.

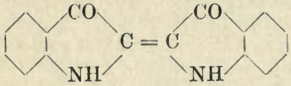
The synthetical manufacture of new colouring matters similar to indigo in their properties was at first the natural consequence of the numerous new syntheses of indigo itself gradually discovered by various chemists, and many of which proved applicable to the production of compounds similar to indigo in their constitution, but differing from it in certain details of composition, and consequently also in their shades. Many of these substances could be made on a large scale, and offered to the consumer at moderate prices. They are now known under the name of 'Indigoids,' and the more important of them will be mentioned further on.

The investigation of indigo and the indigoid dyestuffs led, however, to another result of no small importance. The connection existing between the constitution and the properties of indigo as a dyestuff, so long a mystery, was at last recognised, and the atomic configuration was disclosed which causes a dyestuff to be applicable to vat-dyeing. The natural consequence of this discovery was the possibility of producing, by synthetical methods, a vast number of new vat-dyes, which in their constitution have no longer any similarity to indigo, and the majority of which has been derived from anthraquinone, the mother-substance of alizarin, which has thus assumed a new importance.

The description of these dyestuffs supplementing indigo in its applications, and now already exceeding the indigoids in number is dealt with elsewhere (*see* VAT-DYES, MODERN; INDANTHRENE).

The number of vat-dyes now already in practical use or in the stage of being introduced may be estimated at from 80 to 90, and is constantly increasing. Their discovery is due to the inventive genius of many chemists, amongst whom René Bohn may be considered as the pioneer.

A. **Artificial indigo.** The constitution of indigo is expressed by the formula:



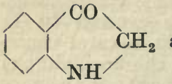
Of the numerous methods which lead to the synthetical production of such a compound very few are applicable to its manufacture, and only the latter will be here mentioned.

The first attempt at a technical synthesis of indigo was made in 1880 by A. von Baeyer in his German patent 11857, which was sold to the Badische Anilin- & Soda-Fabrik and the Höchster Farbwerke jointly. In this *ortho*nitrocinnamic acid is used as a raw material, and transformed into indigo by three different methods. Of these only the one which passes through *ortho*nitrophenylpropiolic acid as an intermediate product found for a short time a limited and almost experimental application as a means of producing indigo on the fibre in calico-printing.

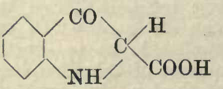
Another method (1882), which consists in adding caustic soda to a solution of *o*-nitrobenzaldehyde in acetone, when the methyl-*o*-nitrocinnamylketone formed as an intermediate product is immediately condensed into indigo, was also, in spite of its simplicity, unable to compete with the natural product.

In 1890 K. Heumann observed that phenylglycine and its *ortho*carboxylic acid are transformed into indoxyl and indoxylcarboxylic acid by being melted with caustic potash; the orange-coloured melts obtained yield indigo on being oxydised with air in aqueous solution. The patents obtained for these reactions (D. R. P. 54626 and numerous additions; also D. R. P. 56273 and additions) passed into the hands of the Badische Anilin- & Soda-Fabrik, but were not considered very promising by the majority of chemists. Yet they were destined to assume fundamental importance in the subsequent development of the indigo industry. It is true that a good many other inventions were necessary to raise them to that position.

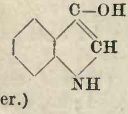
Indoxyl and indoxylcarboxylic acid have the constitution expressed by the formulæ:—



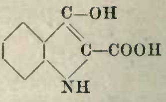
and



These formulæ represent the so-called 'pseudo'-forms, which are the first products of the reaction. Isolated indoxyl and indoxylcarbonic acid are better represented by the tautomesic formulæ:



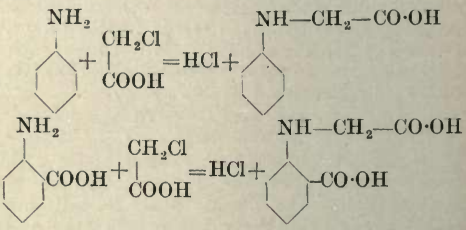
and



(Baeyer.)

On being treated with atmospheric oxygen in alkaline solution the one loses H_2 in the shape of water, the other H_2CO_2 in the shape of carbonic acid (H_2CO_3), and the so-called 'indigo bridge' $>C=C<$ is formed by two such indoxyl complexes being united by double valencies.

Phenylglycine and its *ortho*carboxylic acid are prepared by the action of monochloracetic acid[1] upon aniline and anthranilic acid:—



It was observed, that phenylglycine-*o*-carboxylic acid gave better yields of indigo than phenyl-glycine itself, which was, on the other hand, cheaper and more easily accessible. Later on it was found that both these glycines are capable of being transformed into indigo with very good yields if *every trace* of water is excluded from the alkaline melt. The glycine itself is in this respect more susceptible than its carboxyl derivative. Not only the water invariably retained by all the caustic alkalis hinders the reaction, but also the water formed in the reaction itself. One of the means of overcoming this difficulty consists in the addition of finely ground lime or baryta to the melt.

In taking up the manufacture of artificial indigo by Heumann's method in the beginning of the nineties the Badische Anilin- & Soda-Fabrik decided to use phenylglycine-*o*-carboxylic acid as a raw material. This decision was prompted not only by the better yields which were obtained from this product, but even more so by considerations of quite a different nature.

If it had been necessary to produce the anthranilic acid required for the manufacture of indigo by the oxidation of *o*-nitrotoluene and subsequent reduction of the *o*-nitrobenzoic acid thus obtained, all the toluene produced by the distillation of coal-tar would probably not have been sufficient for the purpose. There is, however, another way of producing anthranilic acid which consists in treating phthalimide with alkaline hypochlorites (Hoogewerff's and Van Dorp's process; D. R. P. 55988, Badische Anilin- & Soda-Fabrik, 1890).

---

[1] Instead of this acid, prepared in the old manner from acetic acid and chlorine, ethyl monochloracetate may be used, which can be obtained from acetylene by a simple process (D. R. PP. 154657, 171900, 216940, 209268, 210502, and 216716, Imbert and Consortium für electrochemische Industrie, Nürnberg). See also Chemikerzeitung, 1911, p. 1053.

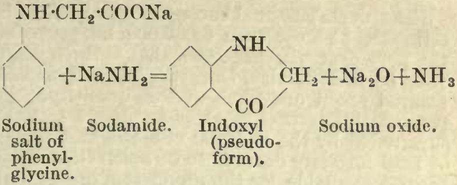
Phthalimide is easily obtained by treating phthalic anhydride with ammonia. Phthalic acid, on the other hand, is best prepared by the oxidation of naphthalene.

Thus it became possible, by using phenylglycine-*o*-carboxylic acid as a starting-point for the synthesis of indigo on a large scale, to base this manufacture on the use of naphthalene as its first raw material, a hydrocarbon which is contained in coal-tar in much larger quantities than any other of its constituents.

Even when these conclusions had been arrived at a great deal remained still to be done. It is now known that the Badische Anilin- & Soda-Fabrik had to invest about 1,000,000*l.* in experiments and new plant before artificial indigo could enter the world's market as a rival to the natural product, and that the ultimate success obtained is mainly due to the courage, inventive genius and perseverance of Rudolf Knietsch, who superintended the whole development of this new industry. But it must also be said that the latter found its advent well prepared by the development which chemical industry as a whole had taken towards the end of the nineteenth century. One of the principal advantages produced by that development was the possibility of obtaining chlorine (which is required both for the chloracetic and the anthranilic acid used in the indigo process) and caustic alkalis at extremely low prices owing to the introduction of the electrolytic decomposition of alkaline chlorides.

The oxidation of naphthalene into phthalic acid as practised in former times was cumbrous and difficult, and gave very poor yields. A new method was discovered for the purpose which consists in the oxidation of naphthalene polysulphonic acids by means of very strong pyrosulphuric acid. To obtain the latter a new process had to be worked out, now known to the world as the catalytic or contact process (*see* SULPHURIC ACID). A certain quantity of mercuric sulphate must be added in the oxidation of the naphthalene sulphonic acid; its action is purely catalytic and indefinite. The sulphur dioxide formed by the reduction of the pyrosulphuric acid returns continuously into the manufacture of the latter. The oxidation of the naphthalene thus practically takes place by means of atmospheric oxygen, and phthalic anhydride is exceedingly cheap if manufactured on a large scale by this process.

The employment of naphthalene as a raw material rendered it possible for artificial indigo to compete commercially with the natural product. But it was destined to meet itself with a very serious competition which arose from a discovery made by J. Pfleger of the Deutsche Gold- & Silber-Scheide-Anstalt in Frankfurt o/M., who observed that the destructive influence of water in the alkali melt of phenylglycine could be completely eliminated by using, not sodium hydroxide, but sodamide for effecting the transformation of the glycine into indoxyl. Sodium oxide and gaseous ammonia are instantly formed by the water produced in the condensation of the glycine according to the following reaction :—



The low melting-point of sodamide, which may be diluted with potassium or sodium cyanides (which also have a low melting-point) makes it possible to carry out the process at the low temperature of 180°–230° C. which favours the production of almost theoretical yields. Of course the process is also applicable to the transformation of phenylglycine-*o*-carboxylic acid into indigo.

It is true, that sodamide can only be prepared by the action of ammonia upon metallic sodium; its price is therefore a high one; on the other hand, the advantages to be obtained by its use are very great and make it possible for this process to compete with the one adopted by the Badische Anilin- & Soda-Fabrik. It was therefore acquired by the Höchster Farbwerke, who are now producing a considerable share of the world's consumption of indigo.

The enormous increase of the world's production of benzene, caused by the general introduction of by-product coke-ovens, and the very low prices of aniline caused by this over-production, has also favoured the success of Pfleger's invention.

Other synthetical methods have been devised which lead from aniline to indigo, such as Sandmeyer's and Blank's. But they cannot compete with the methods described, and have therefore never been carried out on more than an experimental scale. For details about these processes, some of which are exceedingly interesting from a theoretical point of view, the existing works on the chemistry of colouring-matters and more especially the patent literature should be consulted. Some of these processes may possibly assume considerable importance as a means of producing indigoid dyestuffs.

The complete insolubility of indigo in water and aqueous fluids makes it imperative that the dyestuff should be in a state of extremely fine subdivision, and thoroughly moistened before being introduced into the vat. For this reason the dyers used to grind the natural product with a certain proportion of water in the well-known indigo-mills. The unnecessary trouble caused by this preliminary treatment is spared by the form which has been given to the artificial dyestuff, which is generally sold in the shape of a paste containing 20 p.c. of pure indigotin. For export, where the reduction of carriage, and in many countries also the import duties, have to be considered, stronger pastes may be prepared or even the shape of a dry powder is chosen. Much trouble has been taken to reduce the indigo to the greatest possible fineness. All the modern means of powdering and grinding have been utilized, and also the method of precipitating indigo from its solution in sulphuric acid (in which it is contained as a sulphate) by the addition of water has been resorted to.

The world's annual consumption of indigo is estimated at more than 5,000,000 kilograms of the pure dyestuff. In 1900, that is three years after its introduction, the artificial product had secured about one-tenth of this quantity. At present the natural product is almost entirely superseded by the artificial one, and vast tracts of land formerly devoted to its cultivation have become available for the production of rice and other cereals.

The valuable properties of indigo as a dyestuff are a function of the peculiar atomic configuration which connects the two phenylene radicles. By the reduction in the vat 2 atoms of hydrogen are taken up by this complex and indigo white is formed, the exact constitution of which is doubtful. But it is now generally acknowledged, that in leuco-indigo hydroxyl groups have replaced the ketonic oxygens of indigo. These hydroxyl groups possess auxochromic characters, and are responsible for the absorption of the indigo white by the fibre. It follows that every other strongly coloured aromatic substance which contains at least two reducible carbonyl groups must be endowed with the properties of a vat-dye. This conclusion has been strictly confirmed by modern investigations and the whole modern development in the production of vat dyes has been built up on it.

B. **Indigoids.**—The congeners of indigo may be divided into two different classes. One of them contains the true derivatives of indigo, in which one or more of the 8 hydrogen atoms of the two phenylene groups are replaced by other substituents; the other embraces substances which are strictly analogous to indigo in their constitution but different from it in the construction of the complex connecting the two phenylene groups, which in this case as well as in that of indigo may have their hydrogen atoms replaced by other substituents. An enormous variety of new dyestuffs may thus be synthesised, all of which contain the characteristic chromophoric group of indigo:

$$-CO-\underset{|}{C}=\underset{|}{C}-CO-$$

(*a*) *Substitution products of indigo.*—These may be prepared by treating indigo with suitable reagents or by using suitably substituted ingredients in any of the synthetical methods for the production of indigo.

One group of these substitution products has been known for almost a century, and used formerly to be manufactured from natural indigo, viz. the sulphonic acids derived from it, commonly known under the name of *Indigo Carmine.* As these cannot be used as vat-dyes, they need only be mentioned here. They are now invariably prepared from artificial indigo and still used to a moderate extent in wool-dyeing, although they have been largely superseded by other soluble blues. Though derived from one of the fastest dyestuffs known, the indigosulphonic acids are, strangely enough, of an extremely fugitive nature.

The halogen derivatives of indigo are very numerous. As many as six atoms of chlorine or bromine may be introduced into the molecule of indigo. The properties of the products thus obtained, their shade and fastness, vary strongly not only with the number of halogen atoms introduced, but also with their relative position in the molecule. Of the mono- and di-substituted indigos those which contain their halogen atoms in the *p*-position to the imino groups are very similar to indigo itself; those, on the other hand, in which the *p*-positions to the keto groups are taken up are no longer blue but reddish-violet in shade. The dibromo-indigo corresponding to this condition has been proved by Friedländer to be identical with the *purple of the ancients* (*q.v.*). In spite of the fame which this dyestuff once possessed modern industry has not thought it sufficiently valuable to be introduced into commerce.

If more than two atoms of halogen be introduced into the molecule of indigo the dyestuffs obtained become more and more brilliant and greenish in shade. The first of these valuable dyestuffs introduced was tetrabromo-indigo; it was prepared by the Gesellschaft für Chemische Industrie in Basle and brought out as '*Ciba*'*-blue*—'Ciba' being the distinctive name adopted for all the vat-dyes of this factory. The corresponding tetrachlorinated derivative is '*Brillant indigo* 2B' of the Badische Anilin- & Soda-Fabrik. Penta- and hexabromo-indigo are still more greenish, and are now being manufactured by various firms.

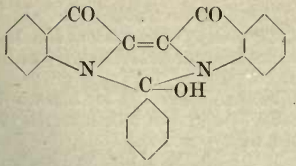
It is, of course, also possible to substitute some of the hydrogen of the indigo molecule by organic radicles. Thus we come to the homologues of indigo, several of which have been prepared. They are all very similar to indigo and offer no special interest. This is also the case with naphtylindigo, the shade of which is a dull green. Its dibromo derivative is much clearer in shade; it has been brought out as '*Ciba-Green G*' by the Basle firm already mentioned.

(*b*) *Indigoids, in which the central complex differs from that of indigo.*—In order to understand the nature of these compounds we must reconsider the constitution of indigo. It consists of two phenylene groups, linked together by the complex

$$\begin{matrix}-CO\\-NH\end{matrix}\!\!>C=C<\!\!\begin{matrix}CO-\\NH-\end{matrix}$$

Now in this complex the group $-CO-\underset{|}{C}=\underset{|}{C}-CO-$ is the indigo chromophore which connects all these dyes into one family and it cannot be touched or altered without destroying the whole character of the compound and its nature as a vat-dye. It follows, that the only changes possible in the central complex of the indigo molecule must be confined to the two imino groups, which may either be altered by their hydrogen being substituted, or by their being shifted into other positions, or by being entirely replaced by other atoms or atomic complexes. All these changes have been accomplished.

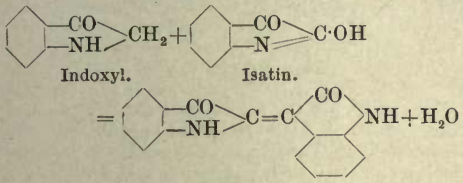
As an interesting example of the first of these alterations two dyestuffs may be mentioned: *Ciba-Yellow G* and *Ciba-Yellow GG.* They are prepared from indigo and tetrabromo-indigo by the substitution of two benzoyl groups for hydrogen in the imino groups. The constitution of Ciba-Yellow G is thus expressed by the formula:—



Benzoyl chloride does not act upon indigo under ordinary circumstances, but if a trace of metallic copper be added, its catalytic action causes the substitution of the hydrogen by the benzoyl group. This interesting manufacturing process has been invented by G. Engi.

If the imino groups are to be shifted or to be exchanged for other complexes, this cannot be done by starting from ready-formed indigo. The new dyestuff has to be built up synthetically. According to the synthetical methods adopted we can obtain indigoids of either symmetrical or asymmetrical constitution.

One of the first instances of such a synthesis was the process by which A. von Baeyer prepared Indirubin, the red dyestuff always contained in natural indigo and first observed by Berzelius. This substance is formed if alkaline solutions of indoxyl and isatin are mixed in the cold—

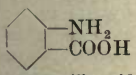


Indoxyl. Isatin.

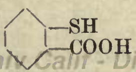
Indirubin.

Indirubin is an assymetrical indigoid in which both the chromophoric complex and the two imino groups are still preserved, but they have changed their relative position in the molecule. Indirubin is of no value as a dyestuff, but its tetrabromo derivative, prepared by G. Engi, is a useful violet and sold under the name *Ciba-Heliotrope.*

If the imino groups are to be exchanged for other divalent complexes, oxygen suggests itself as a suitable substituent. 'Oxygen indigo' has been prepared by Friedländer, but it proved to be a very poor dyestuff. But the same chemist observed in 1905, that sulphur, introduced into the position of the imino groups in indigo, has an excellent effect. A dyestuff of a deep bluish red shade and extraordinary intensity and fastness is formed, which is now known as *Thioindigo red* and manufactured by several firms. It was the first really applicable red indigoid and the process by which Friedländer first prepared it was protected by the German patent 194237 by Kalle & Co. who bought Friedländer's invention. This process is in all its stages strictly analogous to the synthesis of indigo from phenylglycine-*o*-carboxylic acid, but the nitrogen occurring in the latter is everywhere replaced by sulphur. Thus in the first stage anthranilic acid is replaced by thiosalicylic acid—

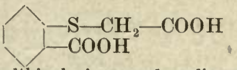


Anthranilic acid.



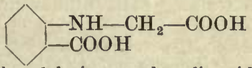
Thiosalicylic acid.

The latter is treated with monochloracetic acid, and thus transformed into



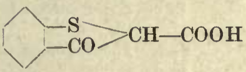
Phenylthioglycine-*o*-carboxylic acid.

which is, of course, quite analogous to

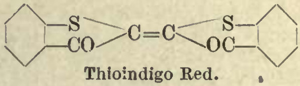


Phenylglycine-*o*-carboxylic acid.

By melting with caustic soda thioindoxylcarboxylic acid—



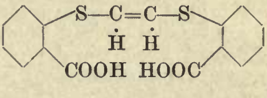
is formed, which, on being oxidised, yields



Thioindigo Red.

This process may be simplified by an invention described in the German patent 187586 of the Gesellschaft für Chemische Industrie in Basle, according to which the phenylthioglycine-*o*-carboxylic acid is simply boiled with nitrobenzene. Condensation and oxydation take place simultaneously and the red dyestuff is deposited in glistening crystals.

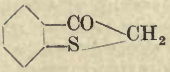
Another extremely simple method for the production of this dyestuff has been invented by E. Münch, and patented by the Badische Anilin- & Soda-Fabrik (French Pat. 385044; German Pat. application B. 47813). It consists in treating the salts of thiosalicylic acid with dichloroethylene. This compound, as a rule so reluctant to part with the chlorine it contains, in this case acts most readily, connecting two molecules of the acid, thus forming the whole chain of atoms required—



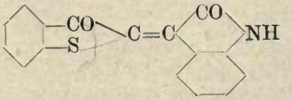
By treating this product with chlorosulphonic acid two molecules of water are eliminated, and the central complex of thioindigo red is formed. It suffices to add water which precipitates the dyestuff in a very pure condition.

Thioindigo red is extremely fast, but unfortunately its shade is not favourable to a very large consumption. An indigoid of a brilliant scarlet shade was required, and this was found in the asymmetrical representative of this group.

Thioindigo Scarlet.—This compound is analogous to indirubin in the same way in which thioindigo red is analogous to indigo, and it is also prepared by the method suggested by this analogy; thioindoxyl—



(or, as it is often called, oxythionaphthene) is treated in an alkaline solution with isatin (see equation for the formation of indirubin). It has consequently the constitution



and is not only asymmetrical, but also a mixed indigoid, containing both sulphur and the imino group.

Both thioindigo red and scarlet yield many new dyestuffs by the substitution of halogens and other substituents for hydrogen in their phenylene groups. They dye various shades of scarlets, bluish reds, and reddish violets, and several of them have come into use as serviceable vat-dyes. O. N. W.

INDIGO COPPER. *Cupric sulphide v.* COPPER.

INDIRUBIN *v.* INDIGO, NATURAL; INDIGO, ARTIFICIAL; INDOXYL COMPOUNDS.

INDIUM. Symbol In. At.wt. 113·97 (Winkler, Bunsen, Thiel, Mathers). Indium belongs to the aluminium group of the elements and was discovered in Freiberg zinc blende by Reich and Richter in 1863 by means of spectrum analysis. It also occurs in small quantities in other zinc blendes, in siderite, and in various manganese ores (Hartley and Ramage, Chem. Soc. Trans. 1897, 533). The metal can be obtained from the oxide by ignition in a current of hydrogen or by fusion with sodium (Winkler, J. pr. Chem. 1867, 102, 273). It can also be obtained pure electrolytically from the chloride, nitrate, or sulphate (Dennis and Geer, Ber. 1904, 37, 961; Thiel, *ibid.* 175; Mathers, J. Amer. Chem. Soc. 1908, 30, 209).

Indium is a white, readily malleable metal, softer than lead, and is not attacked by air at ordinary temperature. It can be obtained as regular octahedral crystals (Sachs, Zeitsch. Kryst. Min. 1903, 38, 495; Thiel, *l.c.*), having sp.gr. 7·12 at 13°/4°, and m.p. 155°. It dissolves slowly in hydrochloric or sulphuric acids but readily in nitric acid, and when heated in the blowpipe gives a blue colour and an incrustation of the oxide. Indium forms a series of isomorphous mixtures with lead (Kurnakoff and Pushin, J. Russ. Phys. Chem. Soc. 1906, 38, 1146; Kurnakoff and Schemtschuschny, Zeitsch. anorg. Chem. 1909, 64, 149). It also combines with selenium and tellurium, forming black masses with a metallic lustre (Renz, Ber. 1904, 37, 2110). In its compounds, indium appears as mono-, di-, and tri-valent, but only the latter are stable in aqueous solution.

Indium oxide In_2O_3 is a pale yellow powder which, according to Renz (Ber. 1903, 36, 1847), is converted into two other amorphous modifications when strongly heated (Meyer, Zeitsch. anorg. Chem. 1905, 47, 281). At 1000° the oxide commences to volatilise and is partially converted into chlorine-green shining crystals (Renz, *l.c.* 2751; Thiel, *l.c.* and Ber. 1906, 48, 201). The lower oxide, InO, possibly also exists.

Indium hydroxide $In(OH)_3$ resembles aluminium hydroxide, is converted into the oxide by heating, dissolves in potash but not in ammonia and readily forms colloidal solutions in the absence of electrolytes.

Indium hydroxide behaves towards bases as a weak acid: when carefully dried at 100°, the *meta* acid $In{\cdot}O{\cdot}OH$ is obtained, and the corresponding magnesium indate $(InO)_2O_2Mg,3H_2O$ is formed by boiling a solution of indium chloride with magnesium chloride (Renz, Ber. 1901, 34, 2763 and *l.c.*).

Halogen salts. Indium forms three *chlorides*, InCl, $InCl_2$, $InCl_3$; the last forms a crystalline compound with pyridine,

$$InCl_3{\cdot}3C_5H_5N,$$

m.p. 253° (Dennis and Geer, *l.c.*; Rengade, Compt. rend. 1901, 132, 472). Three corresponding *bromides* (Thiel, Ber. 1904, 37, 175), a *triiodide*, the *trifluorides*, $InF_3,3H_2O$ and $InF_3,9H_2O$ (Thiel, *l.c.*; Chabrié and Bouchonnet, Compt. rend. 1905, 140, 90), an *oxychloride* InOCl, an *iodate*, and a *perchlorate* (Schleuderberg, J. Amer. Chem. Soc. 1908, 30, 211) are known.

Indium sulphide In_2S_3 is a scarlet powder with metallic lustre which, when heated in hydrogen, forms the lower sulphide In_2S, which is a volatile brown powder. Both sulphides can be obtained in a crystalline form (Thiel, *l.c.*).

Basic indium sulphite $In_2(SO_3)_3In_2O_3,8H_2O$ is a crystalline powder which is obtained when an indium salt is boiled with acid sodium sulphite.

Indium also forms *sulphates*, *nitrates*, the *molybdate* $In_2(MoO_4)_3,2H_2O$, the *platino-cyanide* $In_2[Pt(CN)_4]_3$ (Renz, *l.c.*), a *selenate* (Schleuderberg, *l.c.*), *uranate*, *tungstate*, and *silico-tungstates* (Wyrouboff, Bull. Soc. Franç. Min. 1907, 30, 277).

Indium ammonium alum

$$In_2(SO_4)_3(NH_4)_2SO_4,24H_2O$$

(also with $8H_2O$) forms well-defined regular octahedra. Similar alums are formed with the sulphates of rubidium and cæsium, but the analogous salts with potassium and sodium are not pure alums (Chabrié and Rengade, Compt. rend. 1900, 131, 1300; 1901, 132, 472).

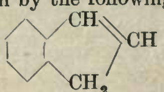
INDOFORM. Trade name for a mixture of salicylic acid, acetyl salicylic acid, moistened with formaldehyde solution, dried, and perfumed with methyl salicylate (*v.* SYNTHETIC DRUGS).

INDOINS (*Safranine azo- colouring matters*). The name Indoin blue R is given to the basic tannin colouring matter which is formed by combining the diazonium salt prepared from safranine and nitrous acid with β-naphthol. The compound is of some technical importance and dyes both unmordanted and tannined cotton fast indigo shades of blue.

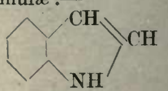
The name indoin was also given by Baeyer (Ber. 1881, 14, 1741) to a blue compound resembling indigo, having the composition $C_{32}H_{20}O_5N_4$, prepared by the action of reducing agents, for example ferrous sulphate, on phenylpropiolic acid dissolved in sulphuric acid. J. F. T.

INDOLES. To this class belong a series of compounds, many members of which are of considerable importance from the bio-chemical standpoint.

They are derived from indole C_8H_7N, a compound which is related to indene in the manner shown by the following formulæ:—



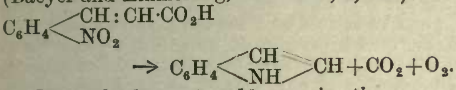
Indene.



Indole.

The indole derivatives which occur in the organism are more or less closely related to tryptophan (*q.v.*), a substance which, according to the latest investigation is an indole-amino-propionic acid.

Indole was first obtained by Baeyer by distilling, with zinc dust, either oxindole  $C_6H_4\left<\begin{matrix}CH_2\\NH\end{matrix}\right>CO$, or the product obtained by reducing indigo with tin and hydrochloric acid. It is also formed when *o*-nitrocinnamic acid is distilled with caustic potash and iron filings (Baeyer and Emmerling, Ber. 1869, 2, 680):



$$C_6H_4\left<\begin{matrix}CH:CH\cdot CO_2H\\NO_2\end{matrix}\right. \rightarrow C_6H_4\left<\begin{matrix}CH\\NH\end{matrix}\right>CH+CO_2+O_2.$$

It can also be produced by passing the vapour of ethyl aniline and other alkyl anilines through a red-hot tube (Baeyer and Caro, Ber. 1877, 10, 692, 1262), but the best method of preparation is by the action of dichlorether

$$CH_2Cl\cdot CHCl\cdot OC_2H_5$$

on aniline. A mixture of 50 grams of aniline with an equal bulk of water is heated, and to the boiling liquid 25 grams of dichlorether are gradually added. The boiling is continued for an hour, after which the water and excess of aniline are distilled off and the residue is heated for about 4 hours at 210°–230°. On distilling the product with steam, indole passes over and may be purified by conversion into the picrate. In this reaction, ethylidene di-aniline is first formed which, on heating to a higher temperature, breaks down into indole and aniline, thus:

$$C_6H_5N:CH\cdot CH_2\cdot NHC_6H_5 \rightarrow C_8H_7N+C_6H_5NH_2.$$

Indole forms colourless, lustrous laminæ, melts at 52° and boils with partial decomposition at 253°–254°. It is readily volatile in steam and is easily soluble in boiling water and in alcohol, ether, and benzene. When nitrous acid is added to an aqueous solution of indole, containing nitric acid, nitrosoindole nitrate is precipitated in the form of small red needles. An aqueous solution, or the vapour of indole, colours a pine chip moistened with hydrochloric acid and alcohol cherry red, the colour afterwards changing to reddish brown. Indole suspended in water and oxidised with ozone yields traces of indigo (Nencki, Ber. 1875, 8, 727). Indole is a weak base and forms, with concentrated hydrochloric acid, a sparingly soluble salt which is dissociated by boiling with water; the picrate is precipitated as dark red needles when a solution of indole in light petroleum is treated with picric acid.

Acetyl indole $C_8H_6N(C_2H_3O)$, which is formed by the action of acetic anhydride, melts at 182°–183°. Indole accompanies scatole as a product of the putrefaction of albumen.

Derivatives of indole.—The homologues of indole are most readily obtained by heating the phenyl hydrazones of ketones of the formula

$$R'\cdot CO\cdot CH_3 \text{ or } R'\cdot CO\cdot CH_2R',$$

or the phenyl hydrazones of the aldehydes of the formula $R'\cdot CH_2\cdot CHO$, with zinc chloride at 180°. The zinc chloride abstracts the elements of ammonia thus:

$C_6H_5NH\cdot N:C(CH_3)_2$

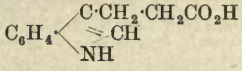
Acetone phenylhydrazone.

$$\rightarrow C_6H_4\left<\begin{matrix}CH\\NH\end{matrix}\right>C\cdot CH_3 + NH_3$$

β-Methylindole.

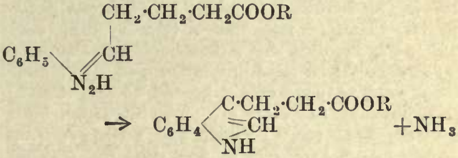
but the reaction is difficult to express by means of structural formulæ. Indole itself cannot be prepared by this reaction.

Indole-3-propionic acid (scatole acetic acid)



$$C_6H_4\left<\begin{matrix}C\cdot CH_2\cdot CH_2CO_2H\\ \gg CH\\ NH\end{matrix}\right.$$

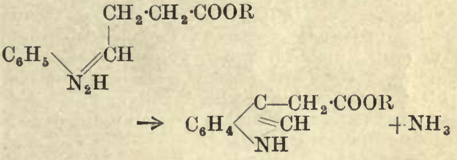
This substance was isolated by Nencki (Monatsh. 1889, 10, 506) from the products of the putrefaction of albumen. It has been synthesised by Ellinger (Ber. 1905, 38, 2884) by the action of alcoholic sulphuric acid on the phenyl hydrazone of γ-aldehydo*iso*butyric ester:



$$C_6H_5\diagdown N_2H \diagup\!\!\diagup CH - CH_2\cdot CH_2\cdot CH_2COOR \rightarrow C_6H_4\left<\begin{matrix}C\cdot CH_2\cdot CH_2\cdot COOR\\ \gg CH\\ NH\end{matrix}\right. +NH_3$$

The acid crystallises from water as prisms which melt at 134°.

Indole-3-acetic acid (scatole carboxylic acid)  $C_6H_4\left<\begin{matrix}C\cdot CH_2\cdot COOH\\ \gg CH\\ NH\end{matrix}\right.$. This substance was isolated by E. and H. Salkowski (Ber. 1880, 13, 2217) from the products of the putrefaction of albumen. It has been prepared by Ellinger (Ber. 1904, 37, 1803) by the action of alcoholic sulphuric acid on the phenyl hydrazone of methyl aldehydopropionate

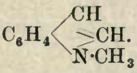


$$C_6H_5\diagdown N_2H \diagup\!\!\diagup CH - CH_2\cdot CH_2\cdot COOR \rightarrow C_6H_4\left<\begin{matrix}C-CH_2\cdot COOR\\ \gg CH\\ NH\end{matrix}\right. +NH_3$$

The acid forms small leaflets from a benzene solution which melt at 165° and at the same time eliminate carbon dioxide, yielding scatole.

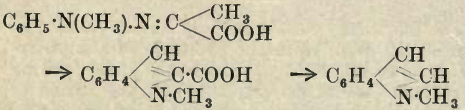
Scatole (3-methylindole)  $C_6H_4\left<\begin{matrix}C\cdot CH_3\\ \gg CH\\ NH\end{matrix}\right.$. This substance occurs as a product of the putrefaction of albumen and is also formed by the fusion of protein substances with potash. It was first discovered in human fæces of which it forms the chief volatile constituent (Brieger, Ber. 1879, 12, 1986); it also occurs in the wood of the *Celtis cinnamomea* (Linol.), Java (Dunstan, Chem. Soc. Proc. 46, 211). It is formed with indole when the product obtained by reducing indigo by means of stannous chloride is distilled with zinc dust (Baeyer, Ber. 1880, 13, 2339), and can be prepared by heating the phenyl hydrazone of propionic aldehyde $CH_3\cdot CH_2CH:N_2H\cdot C_6H_5$, with an equal weight of zinc chloride and distilling the product with steam.

Scatole forms lustrous laminæ, melts at 95° and boils at 265°–266° (corr.) under 755 mm. pressure. It usually has a strong fæcal smell, but when pure is stated to be without odour. It dissolves in concentrated hydrochloric acid, forming a violet solution.



$C_6H_4\left\langle\begin{matrix}CH\\ \geqslant CH\\ N\cdot CH_3\end{matrix}\right.$

1-methyl indole $C_6H_4\langle CH{:}CH\cdot N\cdot CH_3\rangle$. When methyl phenyl hydrazone pyruvic acid is treated with hydrochloric acid it parts with the elements of ammonia yielding 1-methyl indole carboxylic acid



$$C_6H_5\cdot N(CH_3).N:C\left\langle\begin{matrix}CH_3\\ COOH\end{matrix}\right. \rightarrow C_6H_4\left\langle\begin{matrix}CH\\ \geqslant C\cdot COOH\\ N\cdot CH_3\end{matrix}\right. \rightarrow C_6H_4\left\langle\begin{matrix}CH\\ \geqslant CH\\ N\cdot CH_3\end{matrix}\right.$$

On heating this compound to 205° it parts with carbon dioxide, forming 1-methyl indole (E. Fischer and Hess, Ber. 1884, 17, 562). According to Carrasco and Padoa (Gazz. chim. ital. 1907, 37, 11, 49), this substance is also formed when dimethyl-*o*-toluidine is dropped into a tube filled with reduced nickel heated to 300°–330°.

1-methyl indole is a yellow oil which boils at 240°–241° (corr.) under 720 mm. pressure. It has sp.gr. 1·0707 at 0° and does not solidify at −20°. It colours a pine chip moistened with hydrochloric acid reddish violet.

$C_6H_4\left\langle\begin{matrix}CH\\ NH\end{matrix}\right\rangle C.CH_3$

2-Methyl indole $C_6H_4\langle CH=C.CH_3\cdot NH\rangle$. This compound is formed from *o*-nitrophenylacetone by reduction with zinc-dust and ammonia, when the *o*-aminophenylacetone, which is first formed in the reaction, eliminates water and passes into 2-methyl indole (Baeyer and Jackson, Ber. 13, 187). It can also be formed by heating acetone phenyl hydrazone with five times its weight of zinc chloride for half an hour on the water bath and then for a few minutes at 180° (E. Fischer, Annalen, 236, 126). 2-Methyl indole forms needles or laminæ, melts at 59°–60° and boils at 272° (corr.) under 750 mm. pressure. It has a smell resembling that of indole, is sparingly soluble in boiling water, but readily dissolves in alcohol and in ether. It colours a pine chip moistened with hydrochloric acid red. J. F. T.

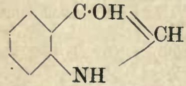
Tryptophan *v.* TRYPTOPHAN.

INDONES *v.* INDENE.

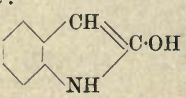
INDOPHENOLS *v.* INDAMINES AND INDOPHENOLS.

INDOPYRIN *v.* SYNTHETIC DRUGS.

INDOXYL COMPOUNDS. When the hydrogen atom attached to one or other of the two carbon atoms present in the five-membered ring of indole is replaced by hydroxyl, two isomeric compounds may be formed which are represented by the two formulæ:

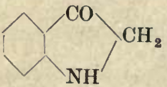


Indoxyl (enol form), stable.

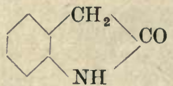


pseudo-Oxindole (enol form), labile.

The presence of the complex CH : C(OH) in these compounds causes them to react in two forms, which may be represented by the further formulæ:



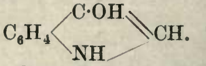
pseudo-Indoxyl (keto form), labile.



Oxindole (keto form), stable.

The two modifications are, in these cases, tautomeric, that is to say, only one form can be isolated (stable form), but this variety can, under certain conditions, yield derivatives of the other modification (labile form).

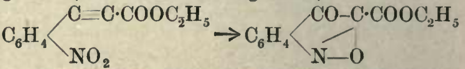
As shown by the above expressions, the enol (or hydroxy) form of indoxyl is the stable variety of this substance, whereas the stable form of oxindole (*q.v.*) is represented by the keto structure.



$C_6H_4\left\langle\begin{matrix}C\cdot OH\\ NH\end{matrix}\right\rangle CH$

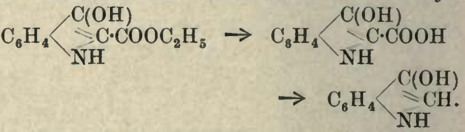
Indoxyl $C_6H_4\langle C\cdot OH{:}CH\cdot NH\rangle$. The isolation of indoxyl was first effected in the following way. It had been noticed from the earliest times that under certain conditions human urine deposited a blue colouring matter, and the first recorded observation of this fact is ascribed by Thudichum (A Treatise on the Pathology of Urine, London, 1877) to Janus Planchus, in the year 1767. Schunck, in 1857, suggested that the chromogen of this blue colouring matter, which had previously been identified as indigo by Heller and Kletzinski, was the same as indican which he had isolated from woad. This was, however, disproved by Baumann (Pflüger's Archiv. 13, 291) who, with Brieger (Zeitsch. physikal Chem. 1879, 111, 258), isolated the chromogen from urine and showed it to be indoxyl sulphuric acid.

Subsequently, Baumann and Tiemann (Ber. 1880, 13, 415) showed that, like phenol sulphuric acid, indoxyl sulphuric acid is decomposed by acids into sulphuric acid and a phenolic substance—indoxyl—and that this compound is quantitatively converted into indigo on oxidation. Subsequently, the synthesis of indoxyl was effected by Baeyer (Ber. 1881, 14, 1741) by the following series of reactions. Ethyl *o*-nitrophenyl propiolate is first converted by shaking with concentrated sulphuric acid into ethyl isatogenate (molecular rearrangement):



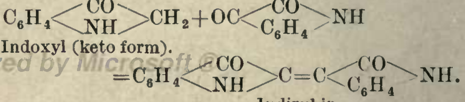
$$C_6H_4\left\langle\begin{matrix}C\equiv C\cdot COOC_2H_5\\ NO_2\end{matrix}\right. \rightarrow C_6H_4\left\langle\begin{matrix}CO-C\cdot COOC_2H_5\\ N-O\end{matrix}\right.$$

This substance on reduction yields ethyl indoxylate, which is then hydrolysed by caustic soda to the sodium salt of indoxylic acid, and the free acid from this, when boiled with water, is transformed into carbon dioxide and indoxyl.



$$C_6H_4\left\langle\begin{matrix}C(OH)\\ \geqslant C\cdot COOC_2H_5\\ NH\end{matrix}\right. \rightarrow C_6H_4\left\langle\begin{matrix}C(OH)\\ \geqslant C\cdot COOH\\ NH\end{matrix}\right. \rightarrow C_6H_4\left\langle\begin{matrix}C(OH)\\ \geqslant CH.\\ NH\end{matrix}\right.$$

Indoxyl when pure forms pale yellow crystals which melt at 85°, but crystallisation cannot be effected in the presence of even slight traces of impurities. It dissolves in water, forming a fluorescent solution and is readily soluble in most organic solvents. It is very unstable and readily oxidises when exposed to the air; the oxidation to indigo takes place rapidly in alkaline solution. It is volatile with steam and when treated with isatin in the presence of potassium carbonate is converted into indirubin, a reaction which may be represented by the following equation:



$$C_6H_4\left\langle\begin{matrix}CO\\ NH\end{matrix}\right\rangle CH_2+OC\left\langle\begin{matrix}CO\\ C_6H_4\end{matrix}\right\rangle NH$$

Indoxyl (keto form).

$$=C_6H_4\left\langle\begin{matrix}CO\\ NH\end{matrix}\right\rangle C=C\left\langle\begin{matrix}CO\\ C_6H_4\end{matrix}\right\rangle NH.$$

Indirubin.

Indoxyl sulphuric acid 
$C_6H_4\Big\langle\begin{matrix}C\cdot O\cdot SO_3H.\\ CH\\ NH\end{matrix}$

This substance occurs as the potassium salt (*indicanuria*) in human urine as well as in the urine of certain carnivora. It occurs to a considerable extent in the urine of a dog which has been fed on indole. It can be prepared synthetically from the potassium compound of indoxyl by treatment with potassium pyrosulphate (Baeyer, Ber. 1881, 14, 1744) and also by fusing phenylglycine-*o*-carboxylic acid and treating the melt with potassium pyrosulphate (Baumann and Thesen, Zeitsch. physikal. Chem. 1896, 23, 23). The free acid is unstable, but the potassium salt forms characteristic glistening leaflets from alcohol in which it is sparingly soluble.

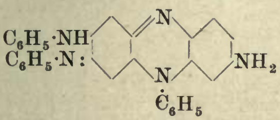
Indoxylic acid 
$C_6H_4\Big\langle\begin{matrix}C(OH)\\ C\cdot COOH\\ NH\end{matrix}$

, separates when a solution of its sodium salt is acidified as a white crystalline precipitate which melts at 122°–123° with vigorous evolution of carbon dioxide. J. F. T.

INDULINES. A very numerous class of blue colouring matters belonging or closely related to the safranine group of colours. They are prepared by heating an aminoazo compound with an amine in the presence of the chloride of the latter. As might be expected, such a process allows of an almost infinite series of variations, and a great number of the colours have at various times been made and used.

By far the most important is also the earliest known; the details of its preparation, described below, are practically those of all the others.

250 kilos. of aniline are mixed with 24 kilos. of hydrochloric acid (35 p.c.) and a solution of 14·4 kilos. of sodium nitrite is run in. The mixture is allowed to remain for some time and then heated with steam to 40°–50° in order to complete the transformation of the diazoaminobenzene into aminoazobenzene. The product is then transferred to a cast-iron still capable of holding twice the volume of the melt made in it and provided with an agitator, swan neck, charging hold, thermometer tube and discharge valve. 60 kilos. of aniline salt (aniline hydrochloride) are added and the mixture is heated gradually so that at the end of about 4 hours the temperature of the melt has reached 175°–180° (Schultz, Chemie des Steinkohlentheers, 3rd edit. 1901, ii. 343). The mass is now rendered alkaline with aqueous sodium hydroxide, the excess of aniline distilled off with a current of steam and the residue ground, washed, and dried. A medium shade, as produced by this method, is known as **Induline 3 B spirit soluble**; the formula of its chief constituent is



Red shade indulines (*e.g.* **Fast blue R spirit soluble**) are formed by heating the mixture for a short time only and at a lower temperature (160°–170°). The bluer shades (*e.g.* **Fast blue spirit soluble**; **Induline 6 B spirit soluble**) are obtained by more prolonged heating.

Much of the induline base prepared in this way is sulphonated, but some is dissolved in acetin, lævulic acid, or ethyltartaric acid, forming blue to violet-blue liquors which are used for printing (**Printing blue, Acetin blue, Lævulin blue,** &c.). When spirit-soluble induline is sulphonated it is converted into a sulphonic acid, the sodium salt of which is soluble in water. In this form, various brands of water-soluble indulines are placed on the market under the names of **Induline** (various marks), and **Fast blues, Nigrosine, Coupier's blue.** Another series of blue to blue-grey or black dyes is produced by heating aniline and aniline hydrochloride with nitrobenzene or nitrophenol or both in the presence of iron borings. Typical processes are (*a*) *With nitrobenzene*: 175 parts of aniline, 175 parts of nitrobenzene, 200 parts of hydrochloric acid, and 16 parts of iron borings are heated for 8 hours at 160°–200° until a test portion can be drawn out into a thread. The melt is then run out into an iron tray and ground. (*b*) *With nitrophenol*: 100 parts of aniline hydrochloride, 50 parts of aniline, 50 parts of nitrophenol, and a little iron are heated for 10 hours to 180°. (*c*) *With nitrobenzene and nitrophenol*: 183 parts of aniline hydrochloride, 183 parts of nitrobenzene, 137 parts of aniline, 12 parts of crude nitrophenol, and 3 parts of iron borings are slowly heated for a day, the final temperature being about 215°. Towards the end the melt must be constantly tested and run out immediately it begins to thicken, otherwise it will set in the pan and then must be chipped out when cold. The spirit-soluble nigrosines produced, as described above, are sulphonated as in the case of the indulines, the products being known as **Nigrosine soluble.** J. C. C.

INDURITE *v.* EXPLOSIVES.

INGRAIN BROWN, -ORANGE, -RED, *v.* AZO- COLOURING MATTERS.

INGRAIN COLOURS *v.* PRIMULINE AND ITS DERIVATIVES.

INK. A coloured fluid used in writing, printing, &c. (Gr. *engkauston—engkaio,* to burn in; Lat. *encaustum,* the purple-red ink used only in the signature of the emperors; It. *inchiostro*; Fr. *encre*; Dutch, *inkt.*)

It may be a convenient although not rigidly accurate division of the subject to recognise a distinction between ink prepared for writing and that prepared for printing.

Writing ink. Black writing ink, as commonly prepared, is a ferroso-ferric gallate suspended in a solution of gum in water, obtained by adding a decoction of substances containing tannin (usually nut-galls) to a solution of copperas.

Galls contain gallotannic and gallic acids, which, with ferric salts, form a black precipitate; with ferrous salts the precipitate is white, but becomes black when oxidised by exposure to air. A proportion of gum is added for the purpose of suspending the precipitate equally throughout the solution and of preventing its deposit.

Although other materials may be used, it has been found that the best properties of writing ink—viz. fluidity, penetration, and permanence—are obtained by the use of the ingredients above-named. Such inks fall into two main classes.

Tannin-iron inks are manufactured from the above materials without additions and without previous treatment of the materials. The following typical recipes are taken from the sources named :—

No. 1 (Cooley's Cyclopædia).—Aleppo galls, well bruised, 4 oz. ; clean soft water 1 quart ; macerate in a clean corked bottle for 10 days or a fortnight, or even longer, with frequent agitation ; then add 1¼ oz. of gum arabic dissolved in a wineglassful of water and ½ oz. lump sugar; mix well, and afterwards further add of ferrous sulphate (green copperas), crushed small, 1½ oz. ; agitate occasionally for 2 or 3 days, when the ink may be decanted for use, but is better if the whole is left to digest together for 2 or 3 weeks. *Product* : 1 quart of excellent ink, writing pale at first, but soon turning intensely black.

No. 2 (Ure).—12 lbs. of nut-galls, 5 lbs. ferrous sulphate, 5 lbs. Senegal gum, 12 gallons of water. The bruised nut-galls are to be put into a cylindrical copper of a depth equal to the diameter, and boiled during 3 hours with three-fourths of the above quantity of water, taking care to add fresh water to replace what is lost by evaporation. The decoction is to be emptied into a tub, allowed to settle, and, the clear liquid being drawn off, the lees are to be drained. The gum is to be dissolved in a small quantity of hot water, and the mucilage thus formed, being filtered, is added to the clear decoction. The ferrous sulphate must likewise be separately dissolved and well mixed with the above. The colour darkens by degrees in consequence of the peroxidation of the iron on exposing the ink to the action of the air. *Product* : 12 gallons.

No. 3 (Lehner, Ink Manufacture, p. 28).

Ingredients—

Galls	1200	parts by weight.
Ferrous sulphate	800	,, ,,
Gum arabic	800	,, ,,
Water	24,000	,, ,,
Creosote	3	,, ,,

Cover the galls with part of the water and dissolve the green vitriol, gum, and creosote separately in the rest of the water. Pour the solution on to the galls, cover up the vessel, and allow to stand for 3 weeks, stirring every day. The ink will then have reached its full blackness and can be bottled for use.

In other processes the galls are repeatedly extracted with boiling water and the extracts united and then mixed with the other constituents ; or the tannin is extracted from the bruised galls with ether and the dry product dissolved in water for ink-manufacture. The quality of the product seems to be equally good whatever method is used, provided the ratio between the weights of galls and of ferrous sulphate taken is always about 3 : 2. The addition of an antiseptic substance such as carbolic acid is to be recommended, as the ink is thus preserved indefinitely from the attacks of mould.

Gallic acid inks are also made from galls, ferrous sulphate, gum, and water, with the difference that the galls are first allowed to ferment, whereby the quercotannic acid is converted into gallic acid. The following is a typical recipe :—

Gall nuts	50 parts.
Ferrous sulphate	10 ,,
Gum	10 ,,
Water	2000 ,,
Carbolic acid	2 ,,

The crushed galls are soaked in the water and allowed to ferment. The mass may be inoculated with mould from a mouldy piece of bread or leather. After 8 to 10 days, boiling water is poured on to kill the ferment and the liquid drawn off and used to dissolve the other ingredients.

These inks have a fine blue-black colour and are not so susceptible to change as the tannin inks, but they have fallen into disfavour because they must be partially oxidised before use and thus take a considerable time to manufacture, and even then give a very pale impression on paper. Most of the inks now used contain a '*provisional colouring matter*,' the function of which is to render the ink easily visible at the time of writing and until such time (7–10 days) as it shall be completely oxidised to black ferric gallate.

Logwood tannin inks are made by substituting logwood chips or logwood extract for part of the galls in a tannin-ink recipe, *e.g.* :—

Galls	36 parts.
Ferrous sulphate	36 ,,
Logwood extract	9 ,,
Gum	36 ,,
Water	300 ,,
Vinegar	60 ,,

The method of preparation is similar to that already described.

Logwood gallic acid inks are similarly made but with preliminary fermentation of the galls. These inks have a deep blue-black colour and attack steel nibs less than pure tannin inks.

Alizarin inks are those inks which contain a provisional colouring matter other than logwood. They contain a sufficient proportion of acid (sulphuric or acetic) to keep the iron gallate or tannate in solution, and therefore may be prepared with much less gum than those previously described.

Of the colouring matters used the most important is indigo-carmine, which is prepared by dissolving dry indigo in fuming sulphuric acid, and after 24 hours neutralising with potassium carbonate. The free acid in the indigo solution may also be used to dissolve metallic iron, thus dispensing with the use of green vitriol.

The following recipe is stated to produce an excellent ink :—

Galls	40 parts.
Iron solution	15 ,,
Indigo-carmine	5 ,,
Gum	10 ,,
Pyroligneous acid	10 ,,
Water	100 ,,

The galls are powdered and soaked in the water and half the acid for a week. The iron solution is prepared from scrap iron and crude pyroligneous acid left together for a week. These solutions are then mixed and the other ingredients added.

At the present time, many other tannin-containing substances, besides galls, are used in the manufacture of inks. It has been shown that *sumach, valonia,* and *logwood* produce an ink which is indistinguishable from gall-inks (Hinrichsen and Kedesdy, J. Soc. Chem. Ind. 1909, 831), and good inks may be produced from tanner's barks (elm, oak, pine, poplar, willow, &c.), cutch, gum kino, fustic, elder-berries, the unripe fruit of the chestnut, walnut, &c.

In many cases other and cheaper synthetic dyes are substituted for the indigo-carmine, but this is not necessarily detrimental to the quality of the ink.

Mitchell (Analyst, 1908, 33, 81) has analysed a large number of English writing inks and finds that, although the composition of any one manufacturer's ink remains fairly constant over long periods, there are marked differences between the inks of different manufacturers. The total solid matter ranges from 1·89 to 7·94 p.c., the ash from 0·42 to 2·52 p.c., and the iron from 0·18 to 1·09 p.c.

The age of handwriting can be estimated up to the seventh or eighth day, when oxidation is complete, but after that no distinction can be made until the provisional colour begins to fade, usually after about a year.

It is probable that in oxidised ink the iron exists as the tannate

$$(C_{14}H_9O_9)_3Fe{\cdot}Fe(C_{14}H_9O_9)_3,$$

described by Wittstein (J. 1848, 28, 221) and by Schiff (Annalen, 1875, 175, 176). (*See* also Ozorowitz, Chem. Zentr. 1908, 2, 1024.)

Runge prepared a writing fluid, under the name of 'chrome ink,' which was cheap, intensely coloured, non-corrosive to steel pens, and extremely permanent on paper. The manner of preparing chrome ink is as follows: 1 part of potassium chromate (not dichromate) is added to 1000 parts of a saturated solution of logwood made by boiling 22 lbs. of logwood in a sufficient quantity of water to give 14 gallons of decoction. The potassium chromate is introduced gradually when the solution is cold, the mixture being constantly stirred during the addition. Gum is injurious to the mixture. It may be prepared more simply by dissolving 2000 parts of logwood extract in a solution of 10 parts of pure potassium chromate in 100,000 parts of water.

Ink powders are very little used but can easily be made either by cautiously evaporating an ordinary ink to dryness and powdering the residue, or by mixing the carefully dried and powdered ingredients in the proportions used for the fluid ink.

Indelible or safety inks. Compositions passing under these names consist of finely divided carbonaceous substances, such as Indian ink or lampblack, held in suspension in a glutinous or resinous liquor. They are devised so as to resist the action of strong acid or alkaline solutions. An ink having these properties may be made of Indian ink rubbed into ordinary writing ink.

A suspension of lampblack in sodium silicate solution makes an excellent safety ink but has the disadvantage that it must be kept in airtight bottles.

Vanadium ink is prepared very simply by adding a small proportion of ammonium vanadate to a filtered decoction of galls. It is a deep black ink, which flows freely from the pen and cannot be removed without destruction of the paper.

Copying ink. Any ink which retains enough solubility to give an impression from the written sheet on to a sheet of damp paper may be used for copying. Runge's chrome ink described above may be so used. Other logwood inks and ferrous gallate inks being soluble only until oxidised by exposure to the air, require the addition of some substance which forms a glaze, arresting the action of the air. This glaze must be soluble when brought into contact with the damped copying paper; the pigment is then freed so as to produce the impression. Such substances are gum arabic, gum Senegal, dextrin, and glycerol. Where several copies are required, the ink employed should contain more staining matter in proportion.

Hektograph inks are used to give a large number of copies, and must therefore contain a powerful colouring matter. The original is written on ordinary paper with the ink and is laid face-down on a sheet of a composition of glue and glycerol (about 1 : 5) until the ink has been absorbed into the surface of the composition.

By applying sheets of paper with slight pressure, 60 to 100 copies can then be obtained.

A typical ink contains: water-soluble blue 10 parts, glycerol 10 parts, and water 50–100 parts.

Dyes not easily soluble in water or glycerol are first dissolved in alcohol and then mixed with the other ingredients. Thus a red hektograph ink may contain: magenta 20, alcohol 20, acetic acid 5, gum 20, and water 40; or magenta 10, alcohol 10, glycerol 10, and water 50.

Red ink was formerly prepared from Brazil wood or extract of Brazil wood, with the addition of alum or stannous chloride: *e.g.*

(1) Brazil wood, 280 parts; tin-salt, 10 parts; gum, 20 parts; boiled with 3500 parts of water and evaporated down until the proper depth of colour is attained.

(2) Extract of Brazil wood, 15 parts; alum, 3 parts; tin-salt, 2 parts; tartaric acid, 2 parts; water, 120 parts.

Cochineal or carmine inks are prepared by boiling cochineal in water, precipitating the colour with alum and tin salt and dissolving this carmine in the requisite amount of strong ammonia. Another method is to dissolve 2 parts of ammonium carbonate in 200 parts of water and macerate for 3–4 hours with 40 parts of cochineal and 2 parts of alum.

Most of the red inks now used are solutions of magenta or eosin in water, together with a little gum. Glycerol also is added if the ink is to be used for copying.

Blue ink. Prussian blue is the colouring matter commonly employed. The pigment is placed in an earthen vessel, and either strong hydrochloric acid, nitric acid, or sulphuric acid is added to it. After the mixture has remained 2 or 3 days, much water is added, and after settling the supernatant liquor is drawn off from the sediment. This sediment is well washed until all traces of iron and free acid disappear from the water, after which it is dried and mixed with oxalic acid in the proportion of 8 parts of Prussian blue to 1 part of acid. The pigment being now soluble in water, so much of this latter is added as will bring it to the required intensity.

An excellent blue ink can be made by

dissolving 10 parts of indigo-carmine and 5 parts of gum in 50–100 parts of water. Solutions of blue aniline dyes may be used but are easily effaced by bleaching agents and fade on exposure to light.

Inks of other colours can be made from decoctions of dyestuffs mixed with alum (used as a mordant) and gum Senegal or gum arabic; as, *e.g.*, brown ink from catechu or logwood, to which a little potassium dichromate is added; violet and purple inks from logwood with a small admixture of chloride of tin or of alum; yellow ink from gamboge, &c., &c. Aniline colours also offer a selection of tints for this purpose.

Gold and silver inks are prepared from gold and silver, or from cheaper substitutes such as bronze powder and Dutch leaf. The leaf metal mixed with honey is carefully ground down to the finest possible condition; it is then well washed and dried. A medium is furnished by a preparation consisting of 1 part of pure gum arabic and 1 part of soluble potash glass in 4 parts of distilled water. As a rule, 1 part of the powder is sufficient for 3 or 4 parts of the medium.

Imitation silver ink is best made by rubbing up aluminium foil or powder with gum.

Sympathetic, Diplomatic, or Secret inks. These preparations are devised to trace words or figures which are invisible when written but which become visible when subjected to heat or appropriate chemical reagents. Examples:—A weak infusion of galls is colourless on paper, but becomes black when moistened with a solution of copperas; and if a weak solution of copperas be used, the writing will be invisible, till the paper is moistened with a weak solution of galls. Equal parts of copper sulphate and sal ammoniac dissolved in water form a colourless ink, the writing of which turns yellow on the application of heat. Weak solutions of silver nitrate or of auric chloride when exposed to the sunlight become dark brown and purple respectively. Solutions of cobalt chloride or nitrate give tracings which become green or blue when heated and disappear again as the paper cools.

Ink for indiarubber stamps. The following preparation produces ink adapted for this purpose. It does not easily dry upon the pad, and is readily taken up by the paper:—Aniline colour in solid form (blue, red, &c.), 16 parts; boiling distilled water, 80 parts; glycerol, 7 parts. The colour is dissolved in the water, and the other ingredients are added whilst agitating. The '*carbon papers*' used for giving two or more copies of written or typed matter are coated on one side with a mixture of yellow wax and tallow containing a suitable pigment such as lampblack or Prussian blue, or some aniline colour.

Ticket-writer's ink is made of good black ink, with liquid gum added to produce a gloss.

Ink for writing on glass is a solution of gum arabic in strong hydrofluoric acid coloured with some matter which can withstand the acid: cudbear is used for this purpose.

For enamelled cards ordinary printing ink is mixed with a few drops of equal parts of copal varnish and mastic varnish.

Lithographic ink ought to conform to the following requirements. It should be flowing on the pen, not spreading on the stone; capable of forming delicate tracings, and very black to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to reproduce the most delicate outlines of the drawing and to afford a great many impressions. It must therefore be able to resist the acid with which the stone is moistened in the preparation without letting any of its greasy matter escape.

Lithographic ink may be prepared as follows:—Mastic (in tears) 8 oz., shellac 12 oz., Venice turpentine, 1 oz.: melt together; add of wax 1 lb., tallow 6 oz.; when dissolved, add further of hard tallow soap in shavings 6 oz.; and when the whole is perfectly incorporated, add of lampblack 4 oz.; lastly, mix well, cut in moulds, and when cold cut it into square pieces.

Another recipe is as follows:—Fuse together wax, 18 parts; soap, 18 parts; shellac, 14 parts; resin 6 parts; and tallow, 10 parts. Then stir in 2 parts of india-rubber dissolved in 5 parts of oil of turpentine, and 6 parts of lampblack. The whole is heated till the smell of turpentine has nearly disappeared and is then cast into sticks.

Autography is the operation by which a writing or a drawing is transferred from paper to stone. For autographic ink:—White wax 8 oz., white soap 2 oz. to 3 oz.; melt, and add lampblack 1 oz.; mix well, heat strongly, and add shellac 2 oz.; again heat strongly and stir well together. On the mixture cooling pour it out as before. With this ink lines may be drawn of the finest and fullest class, without danger of its spreading; and the copy may be kept for years before being transferred. These inks are rubbed down with a little water in the same way as Indian ink.

Printing ink. Ink prepared for use with type, copper-plates, &c., is composed of a vehicle and pigment. The chief properties required in a good printing ink are:—

(1) A perfectly uniform syrupy consistency.

(2) Must be easily transferred from the ink-rollers to the type, and from the type to the paper.

(3) Must not smudge types, and must be easily washed off them with printer's lye.

(4) The ink must not dry so quickly as to set on types or rollers, but must not dry so slowly on the paper as to hinder folding, &c., of sheets.

(5) When dry, the ink must not set off from the paper on to anything with which it comes in contact.

(6) The printed characters should not show a greasy margin.

(7) The ink should not have a strong smell.

The ink which most nearly fulfils all these requirements is composed of the finest quality of lampblack incorporated with a pure linseed oil varnish. The demand for cheap inks for the printing of newspapers and cheap books has been met by using cheaper qualities of lampblack and substituting for the varnish various compositions of oils and resins with soap, which may or may not contain a proportion of linseed oil.

The linseed oil varnish used for good ink was formerly prepared by heating a quantity of linseed oil in a boiler until the vapour evolved could be ignited. A light was then applied and the whole allowed to burn for about half an hour, until a trial showed that the oil was of the right consistency. The practice of burning the oil gave a dark-coloured product and has now been discontinued.

The present practice is to heat the oil to about 380° to 400°, taking every precaution to avoid its ignition. The boiler is provided with a closely fitting lid or, better, with a cover of wire-gauze, which extinguishes a flame while allowing the vapours to escape.

Provision is made for lifting the boiler from the fire or withdrawing the fire from the boiler, or, in some cases, for running off the oil into a cold vessel. A gutter round the furnace above the fire-door prevents any chance of the oil reaching the fire, even should it boil over the top of the pot. In some modern plant the oil is heated by means of superheated steam. A varnish so prepared is insoluble in water or alcohol, but it mingles readily enough with fresh oil and unites with mucilages into a mass diffusible in water in an emulsive form. The oil loses from one-tenth to one-eighth of its weight by boiling into the thick varnish (Watts).

An average letterpress ink may be made by reheating a varnish produced as above and adding for each gallon of the original oil 4 lbs. resin and 1 lb. brown soap in slices. This is then mixed with the requisite quantity of pigment—rather less than $\frac{1}{4}$ of its weight in the case of lampblack—and the whole thoroughly ground and incorporated in a suitable machine, usually between rollers of polished granite or steel, as in Lehmann's apparatus. The presence of soap in the ink causes it to ' lift ' well, *i.e.* to be completely transferred from the type to the paper. The following recipes represent vehicles of a cheaper class :—

Linseed oil and resin vehicle.—Resin 50, boiled linseed oil 100, resin soap 10, partly boiled oil, 6 parts by weight.

Resin oil vehicle.—Resin oil 50, resin 50, boiled linseed oil 50, resin soap 5, thin boiled linseed oil 6 parts.

Cheap mineral oil vehicle.—Resin is dissolved in about an equal weight of heated mineral oil (petroleum) of sp.gr. 0·880–0·920 (Wass, Fr. Pat. 322298, 1908).

Composition vehicles. 5 kilos. Venice turpentine, 15 kilos. castor oil, and 1 kilo. white wax, mixed at 100° (Knecht). 9 kilos. thick turpentine, 10 kilos. soft soap, and 4 kilos. oleine, mixed hot (Rösl).

The lampblack used is of various qualities according to the price of the ink. The proportion used is just sufficient to give a full black impression, and this is less with the better qualities of lampblack. The ink for rotary machines contains about 28 p.c. of lampblack, that for high-speed newspaper printing about 24 p.c., that for book-printing about 21 p.c., and and that for illustration work about 19 p.c. with 2 p.c. of Prussian blue and 1 p.c. of indigo.

Brackenbusch's inks consist of 25 parts paraffin oil, 45 parts of fine colophony, and 15 parts of lampblack. The amount of colophony is reduced in soft inks for high-speed work.

It has been proposed to use oxides of iron or manganese as black pigments for printing inks, in which case the paper could be bleached and subsequently re-made into white paper. This cannot be done with the lamp-black inks now used (*see e.g.* Fireman, U.S. Pat. 802928, 1905).

It is said that so marvellously thin is the layer of ink on small type that one pound weight even of cheap newspaper ink will cover no less than 7000 square feet of type matter.

Coloured printing inks. These inks are made from the varnishes above described by the addition of dry colours, taking great care that the colours are thoroughly well ground and assimilated with the varnish, since lumps of any kind not only clog the type but alter the tint. Some tints which are exceedingly light will require an admixture of white powder to give the necessary body to the ink.

The following pigments are eligible for incorporation in printing inks :—

White.—Heavy spar (barium sulphate) and zinc white.

Red.—Orange lead, vermilion, burnt sienna, Venetian red, Indian red, lake vermilion, orange mineral, rose pink, and rose lead.

Yellow.—Yellow ochre, gamboge, and lead chromate.

Blue.—Cobalt, Prussian blue, indigo, Antwerp blue, Chinese blue, French ultramarine, and German ultramarine.

Green.—Usually mixtures of yellow and blue, but sometimes chrome green, cobalt green, emerald green, or *terre verte.*

Purple.—A mixture of those used for red and blue.

Deep brown.—Burnt umber with a little scarlet lake.

Pale brown.—Burnt sienna : a rich shade is obtained by using a little scarlet lake.

Lilac.—Cobalt blue with a little carmine added.

Pale lilac.—Carmine with a little cobalt blue.

Amber.—Pale chrome with a little carmine.

Pink.—Carmine or crimson lake.

Shades and tints.—A bright red is best got from pale vermilion with a little carmine added ; dark vermilion when mixed with the varnish produces a dull colour. Orange red and vermilion ground together also produce a very bright tint, and one that is more permanent than an entire vermilion colour. Cheaper substitutes are orange mineral, rose pink, and red lead. Lead chromate makes the brightest colour. For dull yellow, use yellow ochre. Indigo is excessively dark, and requires a good deal of trouble to lighten it. It makes a fine showy colour when brightness is not required. Prussian blue is useful, but it dries very quickly, hence the roller must be frequently cleaned. The objection to Prussian, Antwerp, and Chinese blues, is that they are hard to grind and likely to turn greenish with the varnish when used thin. For green any of the yellows and blues may be mixed. The varnish itself having a yellow tinge will produce a decidedly greenish tint with a small quantity of Antwerp blue. Emerald green is got by mixing pale chrome with a little Chinese blue, and then adding the mixture to the varnish until the tint is satisfactory.

In using painter's colours it is advisable to avoid as much as possible the heavy ones. Some colours require less oil in the varnish than others. For the comparative permanence of colouring matters, *v.* PIGMENTS.

A bronze of changeable hue may be given to inks with the following mixture (Southward):—Gum shellac 1½ lbs. dissolved in one gallon of 0·95 p.c. alcohol or Cologne spirits for 24 hours. Then add 14 oz. aniline red. Let the mixture stand for a few hours longer, when it will be ready for use. When added to good blue, black, or other dark ink, it gives a rich hue to it. The quantity must be carefully apportioned.

Bronzing, the production of printed matter having the colour and lustre of gold or silver, is carried out by printing with a varnish which remains 'tacky' for a time, and then dusting over the whole surface with bronze powder or aluminium powder or similar substances. The powder adheres only to the varnish and thus produces the desired effect.

Such a varnish may be produced by melting into a good linseed oil varnish sufficient beeswax to give it the consistency of lard or tallow. (*See* Ure's Dict. of Arts, Manufactures, &c.; Cooley's Cyclop. of Practical Receipts; Lehner's Ink Manufacture; Southward's Practical Printing; Noble's Principles and Practice of Colour Printing; L. E. Andés' Oil Colours and Printer's Inks; and Seymour's Modern Printing Inks.)

INKANI FAT. A fat obtained from the seeds of the East African tallow tree, *Stearodendron Stuhlmannii* (Engl.).

INOSIC ACID, INOSINE *v.* CARNINE.

INOSITOL (*Inosite*). A number of natural substances having the composition of cyclic polyalcohols, *e.g.* hexahydroxy*cyclo*hexanes $C_6H_6(OH)_6$, are often classed with the carbohydrates since they have the same formula, taste sweet, occur along with them in nature, and possibly have been formed from them by the junction of the ends of the six carbon chain, although such transformation has never been realised in the laboratory. Typical of the class is inositol. No less than nine stereoisomeric inositols:

$$(OH)CH\begin{array}{l}\diagup CH(OH)CH(OH)\diagdown\\ \diagdown CH(OH)CH(OH)\diagup\end{array}CH(OH)$$

are possible, of which seven are inactive and two optically active and enantiomorphic. Five of these have been described, viz. optically active *d*- and *l*-inositol, and inactive inositol, cocositol and scyllitol. Similar pentahydroxy*cyclo*hexanes are likewise found in plants. These are *d*- and *l*-quercitol.

The formation of furfural on distillation of *meso*inositol with phosphoric anhydride in a copper vessel (Neuberg, Biochem. Zeitsch. 1908, 9, 551) is the only instance in which a complex substance has been obtained common to both the carbohydrates and inositol.

d-**Inositol** (*matezodambose*) is prepared by demethylation (boiling with concentrated hydriodic acid) of the naturally occurring methyl ether, pinitol. It crystallises in anhydrous prisms, m.p. 247°–248°, $[\alpha]_D+65°$ without mutarotation and forms hexacetyl and hexabenzoyl derivatives.

Pinitol (*pinite*) $C_7H_{14}O_6$, also called *matezite* and *sennite* was discovered in the resin of the Californian *Pinus lambertiana* (Dougl.) (Berthelot, Compt. rend. 1856, 41, 392). It occurs in the residues of the manufacture of coniferin, in senna leaves, and in the liana of Madagascar rubber (*mateza roritina*). It crystallises in colourless rhombs, m.p. 186° $[\alpha]_D+65{\cdot}5°$. The structure of pinitol was established by Maquenne (Compt. rend. 1889, 109, 812).

l-**Inositol** was obtained by Tanret (Compt. rend. 1889, 109, 908) by demethylation of quebrachitol. It crystallises in needles; m.p. 247° $[\alpha]_D-65°$.

Quebrachitol (quebrachite) occurs in quebracho bark. It crystallises in prisms; m.p. 186° $[\alpha]_D-80°$.

r-**Inositol**, obtained by mixing the *d*- and *l*-isomerides in equal quantities, is optically inactive, m.p. 253°. Tanret (Compt. rend. 1907, 145, 1196) has obtained both racemic- and meso-inositol from fresh ripe berries of mistletoe.

Meso- or *i*-**Inositol** (*dambose, nucite*) is widely distributed in both plants and animals. It occurs in muscles, in the heart, lungs, and liver, in beef and horse flesh, and in the urine in cases of Bright's disease. In plants, it is found in beans, peas, &c., in the leaves of asparagus, oak, ash, walnut, &c., in all parts of the grape vine and hence in wines and in fungi. The chief source is the leaves of the walnut tree (Tanret and Villiers, Compt. rend. 1877, 84, 393; 1878, 86, 486), but very much larger quantities are afforded by mistletoe. It may also be prepared from cochineal mother liquors. It crystallises in bunches of needles, m.p. 225°, and does not reduce Fehling's solution. Yeast is without action, but certain fungi decompose it. The hexacetate forms monoclinic plates, m.p. 212°. Hugo Müller (Chem. Soc. Trans. 1907, 91, 1780) has described and measured the crystals of the monobromopentacetate, minute crystals, m.p. 240°, the dibromotetracetate broad transparent prisms, m.p. 140°, and scaly crystals, m.p. 235°; also of inositoldibromohydrin, m.p. 210°.

When inositol is evaporated with nitric acid almost to dryness and then again carefully evaporated with ammoniacal calcium chloride, a rose red colouration is obtained which enables 0·0005 gram to be detected with certainty (Scherer, Annalen, 1850, 73, 322). With ammoniacal strontium acetate, a still more delicate violet colouration is obtained.

Bornesitol, the monomethyl ether, occurs in Borneo rubber: it forms rhombic prisms, m.p. 199°–203°.

Dambonitol, the dimethyl ether, is found in Gabon rubber: it crystallises in hexagonal prisms, m.p. 195°.

Phytin, which is present in many plant seeds and has been isolated from rice bran, is inositol phosphoric acid (Winterstein, Zeitsch. physiol. Chem. 1908, 58, 118).

Cocositol (cocosite) $C_6H_{12}O_6$, was discovered by Hugo Müller in the leaves of *Cocos nucifera* (Linn.) and *Cocos plumosa* (Hook.) (Chem. Soc. Trans. 1907, 91, 1767). It crystallises from water in large transparent lustrous monoclinic crystals, m.p. about 345°–350°, and is optically inactive. It forms a hexacetate, giving prismatic crystals, m.p. about 300°, also a benzoate and nitrate. It gives the red colouration characteristic of inositol (Scherer's reaction). H. Müller (private communication) regards it as identical with scyllitol: the occurrence of this substance in two such different organisms as the cocoa-nut palm and the dog-fish is most remarkable.

Scyllitol (scyllite) $C_6H_{12}O_6$, discovered by Staedeler and Friedrichs (J. pr. Chem. 1858, (i.) 73, 48) in various organs of the *Plagiostomi* (dog-fish) has been investigated by J. Müller. It is inactive, crystallises in hard lustrous monoclinic prisms, m.p. above 339° and is sparingly soluble in water. It gives Scherer's reaction and forms a hexacetyl derivative.

d-**Quercitol** $C_6H_{12}O_5$ is found in the acorn and in minute quantity in the cork and bark of the oak. Hugo Müller (Chem. Soc. Trans. 1907, 91, 1766) has also obtained it from the leaves of *Chamærops humilis* (Linn.), the only Eurpoean representative of the palm family, which was formerly used like esparto for making paper. The leaves contain 1·35 p.c. of quercitol. They are crushed, extracted with boiling water, and the extract precipitated first with neutral and then with basic lead acetate. The lead in solution is removed and the filtrate evaporated until crystals appear. It crystallises in prisms, m.p. 234° $[\alpha]_D + 20{\cdot}16°$. It is not fermentable and forms acetyl and similar esters, showing that it contains five hydroxyl groups. Potassium permanganate oxidises it to malonic acid and other products, confirming the structural formula as

$$CH_2<\begin{matrix}CH(OH)CH(OH)\\CH(OH)CH(OH)\end{matrix}>CH(OH).$$

l-**Quercitol** was obtained by Power and Tutin (Chem. Soc. Trans. 1904, 85, 624) from the leaves of *Gymnema sylvestre* (R.Br.). It crystallises in prisms from water or needles from alcohol, m.p. 174° $[\alpha]_D - 73{\cdot}9°$, and forms penta-acetyl and pentabenzoyl derivatives. On oxidation with potassium permanganate, malonic acid is formed; with sodium hypobromite, the product is diketotrihydroxyhexahydrobenzene $C_6H_5O_2(OH)_3$. It is not the optical antipode of *d*-quercitol.

Quercitol contains 4 asymmetric groupings and therefore 8 optically active and two unresolvable inactive modifications are possible.

E. F. A.

INSECTICIDES *v.* Plant-sprays.

INSECT WAX *v.* Waxes.

INTENSIFIERS *v.* Photography.

INULA CAMPHOR *v.* Camphors.

INULIN *v.* Carbohydrates.

INVERTASE (*Sucrase*). Invertase is the enzyme which hydrolyses or inverts sucrose to dextrose and lævulose. It is present in all yeasts except *S. octosporus*, *S. capsularis*, and *S. membranæfaciens* (Hans.), and is extremely active. According to O'Sullivan and Thomson (Chem. Soc. Trans. 1890, 57, 834), whose contribution to the subject is still a classic, it can hydrolyse 200,000 times its weight of sucrose, and probably this figure is much understated, as is the case with other enzymes, but little is known of its nature.

O'Sullivan purified invertase by fractional precipitation so long as it remained active, and found that the proportion of carbohydrate increased. He identified this as mannose, as was also done by Koelle (Zeitsch. physiol. Chem. 1900, 29, 429). A very pure preparation was obtained by Osborne (*ibid.* 1899, 28, 399) which gave none of the protein reactions, except precipitation by copper sulphate, lead acetate, and phosphotungstic acid; it gave the biuret, xanthoprotein, and Millon's test faintly, and could not be freed completely from carbohydrate. It also always contained nitrogen and ash. Salkowski (Zeitsch. physiol. Chem. 1909, 61, 124) considers that invertase does not contain carbohydrates and that the yeast gum which accompanies it is an impurity.

According to Mathews and Glenn (Bio-Chem. J. 1911, 9, 29), the most active preparation contains about 2 p.c. of ash and 2·2 p.c. of nitrogen. It consists of a gum and a nitrogenous portion yielding 70–76 p.c. of mannose on hydrolysis. These authors consider invertase to consist of a union of an inactive colloidal gum with an active protein ferment: by the action of acid, the ferment is freed from the carrier and rendered active.

Invertase appears to be effective in all cases where dextrose and lævulose are united, even when a third sugar molecule is attached to these. Thus it hydrolyses raffinose, gentianose, melicitose, and stachyose, splitting off lævulose in each case.

Invertase is of common occurrence in the vegetable kingdom: it is present in buds, flowers, and leaves of the higher plants and in numerous mould fungi. It is not so widespread in the animal body as maltase, being practically limited to the mucous membranes of the alimentary canal.

The laws regulating the velocity of invertase action are dealt with elsewhere (*v.* Fermentation and Hydrolysis).

It is very sensitive to the minutest quantities of alkali, which retards or stops its action, and for this reason its action is accelerated by dilute acids or acid salts, although probably, like diastase, it is most active in truly neutral solution. Quantitative work with invertase must be carried out in hard glass vessels and with solutions which have been stored and measured in such vessels. It is the neglect to avoid alkaline impurity which has occasioned many of the controversial statements in the extensive literature relating to this subject.

The rate of action is much influenced by temperature: 55°–60° being that of maximum activity, beyond which it becomes weakened by heat (*see* also papers by Euler, Zeitsch. physiol. Chem. 1910 and 1911). It is destroyed between 65° and 70°. The power of the enzyme to resist heat is considerably increased by the presence of sucrose: according to O'Sullivan, it will withstand a temperature 25° higher.

An active solution of invertase is readily obtained by extracting dried yeast with water or by shaking up living yeast with chloroform water. A very active permanent preparation may be prepared by setting aside washed pressed yeast with a little water to autolyse at 37° for a few days. The liquid is filtered and alcohol added a few cub. cm. at a time to the filtrate so as to keep the precipitate in a granular form. The liquid is decanted, the precipitate washed first with a little 60 p.c. and then with 80 p.c. alcohol and at once dissolved in a minimum quantity of water. The precipitation process may be repeated and the final product dissolved clear in the smallest quantity of water and bottled with a little toluene. This solution, which is of very high activity, may be kept for years without its activity materially changing (*v.* Fermentation).

IODGLIDIN, IODIN, *v.* Synthetic drugs.

IODINE. Symbol I. At.wt. 126·92. This element was discovered in 1812 by Courtois in the mother liquor of kelp. The discovery was first announced to the French Institute in 1813. The properties of the new element were further investigated by Clement and Desormes, Gay-Lussac, and Davy.

Iodine is a crystalline solid of greyish-black colour and bright metallic lustre resembling plumbago. Its sp.gr. is 4·948. It is obtained by sublimation in brilliant rhomboidal plates, or in elongated octahedrons belonging to the trimetric system. In very thin plates it transmits light of a red colour. It melts at 114·15°, and boils at 184·35° (Ramsay). It volatilises at ordinary temperatures spontaneously in the air, diffusing an odour resembling chlorine. It is sometimes employed in this way in hospitals as a disinfectant. The vapour has an intense rich violet colour, and is one of the heaviest of all known gases, having a sp.gr. of 8·801. A stratum 4 inches thick presents a black mass quite impervious to light. It is very slightly soluble in water, requiring about 7000 parts for solution. It is soluble in chloroform, bromoform, carbon disulphide, light petroleum, and benzene, forming violet solutions; also in ethyl, methyl, and amyl alcohols, and in ether and glycerol, forming brown solutions. It is very soluble in potassium iodide, of which 1 part in 2 parts of water will dissolve 2 parts of iodine. In reactions it resembles chlorine and bromine, but is less energetic, and is displaced by these elements from its compounds with hydrogen and the metals. It has a strong affinity for most of the metals, and in the presence of water, attacks and dissolves gold. The most characteristic reaction of free iodine is the dark blue compound formed with starch; this test is extremely sensitive, and will reveal the presence of one-millionth part in any liquid containing it. Another characteristic reaction is to liberate the iodine from a solution by nitrosulphuric acid, and dissolve it out by carbon disulphide; this affords an accurate and easy method of estimating it by the depth of the crimson colour of the solution; it is also extremely sensitive, and well adapted to estimate small quantities of the element.

Iodine in minute quantities is very largely distributed throughout the animal, vegetable, and mineral kingdoms. As a mineral it occurs in combination with silver, mercury, and lead, in ores from Mexico, Chile, and Spain, with zinc in Silesia, and with lead in South America. It is also found in dolomite from Saxony, in limestone from Montpellier, in shale from Sweden, and in calcium phosphate from France. It exists also in the 'caliche' of Chile in the form of sodium iodate. This is the only mineral source from which it is manufactured, and has been for many years the most important of all the commercial sources.

Many mineral waters contain iodine, notably those of Carlsbad in Bavaria, Hall in Austria, Marienbad in Bohemia, Holberg in Pomerania, Halle in Saxony, Sales in Piedmont, Nix in Savoy, Kreuznach in Galicia, Halse in Java, and Jallien in France. It is also found in the waters of Friedrichshall, Castellamare, Heilbrun, Homburg, Seidchutz, and Vichy; and in this country in those of Leamington, Bonington, Bath, Cheltenham, and Woodhall. It is a valuable remedy in skin diseases. The sea is an abundant source of it. Iodine is always present in sea-water, but in such a very minute proportion that it is difficult of detection except by operating on large quantities. It has been estimated in the Atlantic at 1 part in 280,000,000 (Stanford); all fishes and all animal products from the sea appear to contain iodine, but in very minute quantity. The following table shows a few of the marine products in which it has been estimated:—

Cod-liver oil	0·000322	p.c. iodine.
Cod-liver	0·000817	,,
Codfish	0·000160	,,
Herring, salt	0·000650	,,
Whale oil	0·000100	,,
Seal oil	0·000050	,,
Oysters (Portuguese)	0·000040	,,
Prawns	0·000440	,,
Limpets	0·003200	,,
Cockles	0·002140	,,
Whelks	0·008920	,,
Mussels	0·035720	,,
Sponge (Turkey)	0·200000	,,
Sponge (Honeycomb)	0·054000	,,

Nearly all seaweeds or marine algæ contain it. It is present even in the *Zostera marina* (L.) or grass wrack, natural order *Naiadaceæ*, a flowering plant growing only in the sea; but there are some remarkable exceptions. The gelatinous species of algæ, the *Chondrus crispus* (L.) (or Irish moss), and *Gelidium corneum* (Lam.) of British species, and the *Eucheuma spinosum* [(L.) J.Ag.], or *Agar agar* of foreign species, do not contain iodine. The *Enteromorpha compressa* [(L.) Grev.], or common sea grass, when dry has a strong odour of the sea, but does not contain iodine. The salsola or salt wort, *Salsola Kali* (L.), natural order *Chenopodiaceæ*, growing on the seashore, and from which barilla was made, contains no iodine. Some of the algæ are comparatively rich in iodine, and the ash of these plants, known as kelp, for many years formed the only commercial source of this important element.

Manufacture.—By far the greater bulk of all the iodine produced is now extracted from the mother liquors of the nitrate works in Chile, but the manufacture of iodine from kelp has for long been carried on in Scotland and in France, and within recent years has been started in Norway and in Japan. Courtois, a saltpetre maker in Paris, who discovered iodine, obtained it from the kelp liquors which were used to furnish the salts of potash required in his manufacture, and this was for many years the only commercial source of iodine. The manufacture was unsuccessful commercially in the hands of the discoverer, and he died in poverty. It was afterwards successfully carried out by MM. Cournerie, of Cherbourg, and has continued to be an important manufacture on the Normandy coasts. In this country it was first made on the small scale by Dr. Ure of Glasgow, and the manufacture has since been almost exclusively confined to that city, where it has assumed considerable importance. It was first made there in quantity in 1841, and the imports of kelp into the Clyde in that year amounted to 2,565 tons. In 1845, there were four small works engaged in the manufacture of iodine. Kelp was then used for soap making on account of the sodium carbonate it contained, and the iodine was extracted from the lyes of the soapboilers. In 1846 there were twenty makers of iodine in Glasgow, who then treated the kelp directly, extracting also the potash salts which had a high value in the market. The fall in the price of potash salts owing to the discovery of the Stassfurt mineral, which reduced the price to one-third, the very variable character of the kelp used, and the extreme fluctuations in the price of iodine, ranging from 4*s.* to 34*s.* per lb., soon reduced the number of makers, and now there are only three works in Scotland. The produce of iodine from kelp was so limited that it offered unusual temptations to speculators, who derived most of the benefit from the high prices, the manufacturers suffering the losses during the low prices.

The history of kelp, or *varec* as it is called in France, is extremely interesting. It is a crude rough slag made by burning seaweed in long shallow pits. For many years it was a large and valuable article of commerce, and greatly enriched the proprietors of the West Highland estates where it was principally made. It was then the only source of soda. At the beginning of last century it realised 20*l.* to 22*l.* per ton, and the Hebrides alone yielded 20,000 tons per annum, worth upwards of 400,000*l.*; and as the burners only received 35*s.* to 40*s.* per ton for their share, the profit to the Highland lairds was enormous, and it induced an amount of extravagance which ruined most of them. It was largely used in soap making and in glass making, and within the last hundred years there were glass works at Dumbarton using this material, which were celebrated for the quality of their glass. At a glass works in Drontheim in Norway, it was still used for this purpose up to about forty years ago. The importation of barilla gave the first blow to kelp, and it fell in price, and for the twenty-two years ending 1822, the average price was 10*l.* 10*s.* The duty was then taken off barilla, and the price of kelp again fell to 8*l.* 10*s.*; in 1823, the salt duty was repealed and kelp fell again to 3*l.*, and in 1831 to 2*l.*, at which price there was no further profit on the manufacture. In the meantime soda was being largely made by the Leblanc process, and kelp was superseded altogether as a source of soda. It must have been a most expensive source, as it yielded only about 4 p.c. of alkali and often less than 1 p.c.; and at one time must have cost the soap makers what would have been equal to 100*l.* per ton for soda ash, worth now about 5*l.* 10*s.*

The manufacture of iodine and potash salts then began to assume some importance, but the kelp required was not the same, that which contained the most soda containing the least potash and iodine. Moreover the kelpers had been taught to burn at a high temperature, which improves the yield of sodium carbonate but volatilises much of the potash and some of the iodine. The seaweed employed by the kelpers was of a kind containing little iodine, and not very rich in potash. They used almost exclusively the black wrack, cut in large quantities in the Highland lochs, and consisting of the three fuci, *Fucus vesiculosus* (L.), *Ascophyllum nodosum* (Le Jol.), and *F. serratus* (L.), which are all uncovered at low tide. This is now entirely unutilised: the kelp made from it was known as *cut-weed kelp.* The following is the average analysis from numerous cargoes of the kelp:

Potassium sulphate	23·08
Potassium chloride	1·45
Sodium chloride	19·13
Sodium carbonate	6·48
Insoluble	43·71
Water	6·22
	100·07
Total potash, K_2O	13·40
Iodine, lbs. per ton	4·18 =0·18 p.c.

Drift kelp is the only variety now employed as a source of iodine. It is made from the red wracks, the *Laminaria digitata* [(L.) Lamx.], or tangle, and the *L. stenophylla*, which are always submerged by the tide, and contain about ten times as much iodine as the fuci. These seaweeds are torn up by the storms from the rocks on which they grow, and cast ashore; unlike the black wrack, these plants suffer much from rain, the more valuable salts being completely washed away, and are often after drying quite valueless, the kelper losing all his labour. From the time of its discovery, the iodine was the most important product, but the potash salts were also very remunerative at first. Potassium chloride, or 'muriate,' as it is technically called, was worth 25*l.* per ton. The discovery of the Stassfurt mineral reduced its value to about one-third, and the further discovery of bromine in the same mineral reduced the price of that element from 38*s.* to 1*s.* 3*d.* per lb., the present value. The amount of bromine in kelp is small, only about one-tenth of the iodine, and it has not been extracted from this source for the last forty years. It is remarkable that the algæ should select iodine, as bromine is a much larger constituent of sea-water, which usually contains about 6 parts in 100,000, and according to Dittmar appears to bear the constant relation to the chlorine of 0·34 to 100, whereas iodine exists only as a minute trace, difficult even of detection, although the aggregate amount in the ocean must be enormous.

The algæ differ considerably in the proportion of iodine which they take up from the sea-water, and only two species, the *Laminaria digitata*, and the *L. stenophylla* are worth burning for kelp.

It is remarkable that the giant algæ of the Falkland Islands contain very little iodine, although these are the largest sea-plants in the world. The *Duvillœa utilis* (Bory.), a marine tree with a stem a foot in diameter, and the *Macrocystis pyrifera* (Turn.) which grows to the length of 1500 feet, contain only traces of iodine; in some samples it can scarcely be detected.

The following table shows the average yield of the most important varieties. The kelp plant figures are taken from a large number of analyses, from seaweed gathered all around the shores of Great Britain and Ireland; also Denmark, Norway, and Iceland.

Dry weeds	Per cent.	lbs. per ton.
Drift Kelp:		
Laminaria digitata [(L.) Lamx.], Tangle, stem	0·4535	10·158
„ *stenophylla*	0·4777	10·702
„ *saccharina* (Lamx.), Sugar Wrack	0·2794	6·258
Cut Kelp:		
Fucus serratus (L.), Black Wrack	0·0856	1·807
Ascophyllum nodosum (Le Jol.), Knobbed wrack	0·0572	1·281
Fucus vesiculosus (L.), Bladder Wrack	0·0297	0·665
Various:		
Halidrys siliquosa [(L.) Lyngb.], Sea Oak	0·2131	4·773
Japanese Seaweed, edible	0·3171	7·102
Himanthalia lorea [(L.) Lyngb.], Sea Laces	0·0892	1·998
Rhodymenia palmata [(L.) Grev.], Dulse, edible	0·0712	1·594
Chorda Filum [(L.) Stackh.], Sea Twine	0·1200	2·688
Zostera marina (L.), Grass Wrack	0·0457	1·023
Duvillœa utilis (Borg.), Falkland Islands	0·0075	0·179
Macrocystis pyrifera (Turn.), Falkland Islands	0·0308	0·690

The seaweeds chiefly used in Japan for the extraction of iodine are *Laminaria, sp. Ecklonia cava, E. bicyclis* (Kjellm.), and *Sargassum sp.* The iodine content varies with the age of the algæ and also with the time of year, being greatest during June to September; the following figures give the iodine content of some of the raw seaweeds: *Ecklonia cava*, 0·23 p.c.; *E. bicyclis*, 0·27 p.c.; *Sargassum sp.*, 0·05 p.c.; *Laminaria angustata*, (Kjellm.), 0·18 p.c.; *L. longissima*, 0·17 p.c.; *L. ochotensis*, 0·19 p.c.

It will be seen that even in the drift weeds the quantity of iodine is inconsiderable, but if the plants are properly burnt to a loose ash at a low temperature, they ought to yield a kelp containing 25 to 30 lbs. of iodine to the ton. 12 lbs. per ton is, however, above the average yield from ordinary drift kelp. The kelpers often neglect to protect the seaweed from the action of rain, which washes out the soluble iodides, and moreover it is difficult to prevent them from burning it into a hard slag by working it up, when molten, with iron clauts. Sand and stones are thus mixed up with it, and the great heat employed drives off some of the iodine. The result is a hard slag of great density, and this density forms one of the difficulties in inducing the kelpers to burn the weed to a loose ash, which they imagine, from the lightness, will not give them the weight they expect. As an actual fact, of course, the total weight of the ash so produced is considerably more, from the same quantity of weed used; but old fallacies die hard, especially amongst the poor and ignorant people who do this work. There is the further disadvantage that the sulphates are reduced to sulphides or oxysulphides, and a considerable extra expenditure of oil of vitriol to decompose these is entailed; sulphur is thus obtained as one of the by-products of the lixiviation of kelp, in which it ought not to exist at all. The presence of silica as sand greatly assists the volatilisation of the iodine.

The table at top of next column shows the analyses of very good samples of Irish and Scotch kelp, and also of the latter burnt into loose ash, and the comparison of these indicates clearly the effect of the heat of burning.

—	Kelp		Ash
	Irish	Scotch	Scotch
Potassium sulphate	11·14	13·95	12·71

Iodine, lbs. per ton	15½	14½	28
Carbon in insoluble part	Nil	Nil	9·00

A different method of manufacture was introduced by Stanford in 1863, when works were erected in the outer Hebrides for the carbonisation of the stems of tangle (*L. digitata*) in closed retorts, thus converting the tangle into charcoal and collecting the products of destructive distillation, consisting principally of tar and ammoniacal liquor, in suitable condensers. A very porous charcoal is thus produced which contains all the iodine present in the seaweed employed; when lixiviated it gives very white salts containing no sulphides. The residual charcoal, after lixiviation, does not resemble that from wood, which is principally carbon with a small percentage of ash, but in its composition and general character approaches animal charcoal obtained from bone. The following table shows the comparison:—

—	Seaweed	Bone
Carbon	52·54	11·77
Calcium phosphate	10·92	77·70
„ carbonate	15·56	1·43
„ sulphate	—	0·35
Magnesium carbonate	11·34	—
Alkaline salts	5·70	1·09
Silica, &c.	3·94	0·66
	100·00	100·00

The presence of magnesium carbonate is a peculiar characteristic of this charcoal, as all seaweeds are rich in magnesium salts. Seaweed charcoal, as might be expected from its composition, is an excellent decoloriser and deodoriser. As compared with animal charcoal it is much lighter and more bulky, and therefore has not replaced it as a decoloriser, although from its high percentage of carbon it would well stand the constant re-burning required in sugar works, and be improved by this treatment.

This process by carbonisation was in use in the islands of Tyree and North and South Uist for a number of years, with great benefit to the crofters and cottars of these islands. It required, however, the erection of separate carbonising works in each island, and, as the winter tangle only was used, it was difficult to secure sufficient supplies except from a large area. Moreover, it was found in practice very troublesome to completely extract the soluble iodides from the charcoal, and ultimately the process was abandoned in favour of the older and simpler method of kelp burning. A wet process of extracting iodine from seaweeds has also been tried. It had been noticed by Stanford that the whole of the alkaline salts present in the seaweed, and a considerable quantity of extractive matter containing dextrin and mannite, could be extracted from the fronds of the *Laminaria* or red seaweeds by simple maceration in cold water. The residue, which is the plant apparently unaltered, consists of a nitrogenous substance resembling albumen, to which the name of 'algin' has been given, and the algic cellulose or algulose, which represents the cellular fabric of the plant. The algin or alginic acid is removed by digesting it with solution of sodium carbonate, which dissolves it as sodium alginate, leaving the algulose. The solution can be effected in the cold, but it is necessary to employ heat, otherwise it is impossible to filter off the algulose. A Taylor filter is the only one that can be employed, the filtration being extremely difficult on account of the great viscosity of the algin or sodium alginate and the extreme fineness of the cellular algulose. The process adopted is to boil the seaweed with sodium carbonate, and filter; the algulose is separated by filtration, and the filtrate is mixed with hydrochloric acid, and the alginic acid is then easily filtered off; the solution is neutralised with caustic soda, evaporated to dryness, and carbonised, the residue forming the 'kelp substitute.' The alginic acid, which has a slight amber colour, is washed, bleached, and redissolved in sodium carbonate; the resulting liquor, evaporated in a vacuum pan, forms the commercial alginate of soda or 'soluble algin.' By evaporation on glass plates or porcelain slabs, the algin is obtained in the form of a transparent flexible sheet, which, however, tends to crack as it approaches dryness, and by immersing this in a very dilute solution of hydrochloric acid it is converted into alginic acid or 'insoluble algin,' which, without altering its appearance, renders the sheet perfectly insoluble in water. The soluble algin is a definite salt of sodium, having the composition, when pure, $C_{76}H_{75}O_{22}N_2Na_5$.

Commercial algin or sodium alginate resembles gum arabic, and in the sheet form can scarcely be distinguished from gelatin from which it differs by the solution not gelatinising, and by giving no reaction with tannin. It is distinguished from albumen by not coagulating on heating; from starch by giving no colour with iodine; from dextrin and gum arabic by its insolubility in dilute acids. All mineral acids, and citric, tartaric, lactic, oxalic, and picric amongst the organic acids, precipitate alginic acid in a gelatinous form.

It precipitates all the alkaline earths as alginates, with the exception of magnesium, the alginate of which is soluble. It precipitates nearly all the heavy metals as alginates, but gives no precipitate with mercuric chloride, nor with potassium silicate. The following analyses show the usual composition of the commercial algin :—

——	No. 1		No. 2		Average	
Water	17·13		19·30		18·22	
Organic matter . . .	59·97		58·13		59·05	
Sodium carbonate . .	18·32	per cent. ash 22·90	17·78	per cent. ash 22·57	18·05	per cent. ash 22·73
Neutral salts . . .	2·98		2·77		2·87	
Insoluble ash . . .	1·60		2·02		1·81	
	100·00		100·00		100·00	
Soda, Na_2O	10·71		10·40		10·55	

This substance, known as soluble algin, is sodium alginate, but potassium, ammonium, lithium, or magnesium alginate are all soluble algins, and scarcely distinguishable in appearance. These all present the form of thin flexible sheets, resembling gelatin, and having the same colour, but none are gelatinous. The solution of algin resembles that of gum arabic, which in many of its applications it may be expected to replace; it is quite soluble in cold water, but the solution takes about 12 hours to complete. It is so extremely viscous that a 2 p.c. solution is as thick as a 50 p.c. solution of gum arabic, and a 5 p.c. solution is poured with difficulty out of a wide-mouthed bottle. Nearly all the mineral acids precipitate alginic acid ($C_{76}H_{80}O_{22}N_2$) from the solution as a very gelatinous precipitate; a 2 p.c. solution becomes semi-solid when thus treated. In this respect, it resembles a strong solution of egg albumen, and it can be employed for thickening colours in printing, or as a mordant in the same manner. Alginic acid is insoluble in water, so that in dressing fabrics the soluble algin forms a flexible varnish, which can be converted into a lustrous hard glaze by passing it through a weak mineral acid. This process, which would destroy the ordinary starch and gum dressings, renders it also permanent and insoluble in water, the fabric becoming waterproof. As the alginates of calcium, aluminium, iron, &c., are all insoluble, the same effect is obtained by the use of solutions of these metals for the final wash. Alginic acid when dry resembles albumen, but it can be obtained also in thin transparent sheets, and readily coloured like gelatin, from which, however, it differs in being insoluble in hot water. It can also be obtained in blocks. Calcium alginate ($C_{76}H_{74}Ca_3N_2O_{22}$) resembles it, but is whiter, like bone.

Aluminium alginate is very soluble in ammonia, and the aluminium ammonio-alginate is insoluble when dry, so that it makes a cheap waterproof varnish. It forms a good mordant or dung substitute in dyeing. Copper alginate is soluble in ammonia, forming a beautiful blue copper ammonio-alginate, which is also insoluble when dry, and makes a varnish useful for waterproofing fabrics which are liable to decomposition or to attacks of insects.

Ferric alginate is also soluble in ammonia, forming a bright red ferro-ammonio-alginate; insoluble when dry, and proposed as a styptic, and for administering iron internally. These metals are most completely precipitated from solution by sodium alginate.

Nickel, cobalt, zinc, cadmium, manganese, chromium, uranium, silver, platinum, tin, arsenic, and antimony all form soluble ammonio-alginates some of which are beautiful salts. Sodium alginate, mixed with a dichromate, is sensitive to light in the same way as gelatin, the mixture becoming insoluble in water after exposure to light.

Alginic acid is a moderately strong acid, liberating carbon dioxide in the cold from the alkaline carbonates and from magnesium carbonate; in the latter case, the two insoluble substances in the presence of water form soluble magnesium alginate. The use of algin requires a thorough knowledge of its properties, on account of the numerous metallic salts which precipitate it, and with which it is therefore incompatible; these reactions limit to a great extent the application of the substance in solution as a substitute for gum and other bodies used for thickening purposes.

Algulose or algic cellulose contains no fibre, but consists of fine cellular tissue, which makes a transparent and very tough paper. It dries to a hard mass resembling ebony, but denser.

The kelp substitute in this wet process was obtained by evaporating and carbonising the acid liquor from which the alginic acid has been precipitated, after neutralising it with caustic soda. It should contain all the iodine and potash salts of the weed but no sulphides, and should yield about 30 lbs. of iodine to the ton. At the same time, in spite of the advantages which apparently would attend the adoption of this process, the manufacturing costs are so high and the demand for the products, other than iodine and potash salts, is so limited, that the process has not met with success on the commercial scale.

Lixiviation of kelp.—Little improvement has taken place in this process; the same simple method which has been in use for many years is still adopted in the Scotch works.

The kelp reaches the factory in large masses; these are first broken up into pieces about the size of road metal. The lixiviation is effected in rectangular iron vats with false bottoms; the vats are coupled together and heated by steam, and treated exhaustively. The whole arrangement is similar in every respect to that adopted in the lixiviation of black ash in the Leblanc process of soda manufacture. The solution is run off at about 40° to 45°Tw. This is evaporated in open hemispherical cast-iron boiling pans, about 9 feet in diameter, and the salts which deposit are fished out. In some works this boiling down is effected in cylindrical wrought-iron closed pans, heated by a coil of steam pipes round the inside of the pan, and provided with mechanical stirrers to keep the deposited salts in suspension. When the liquor is concentrated to 62°Tw., the whole is run out into a settler to allow the salts to deposit, and the supernatant liquor is run off hot into the crystallisers. In both cases the salt fished out or deposited is a crude potassium sulphate, which adheres a good deal to the pan and contains 50 to 60 p.c. of potassium sulphate, mixed with sodium sulphate and chloride. The liquid is run into cylindrical iron coolers, and a crop of potassium chloride crystallises out in two or three days. The mother liquor is again boiled down, and the salt deposited is fished out; this salt is known as 'kelp salt,' and consists of sodium chloride, containing sodium carbonate equal to 8 to 10 p.c. of alkali (Na_2O). The hot liquor is again run into the cooler, and another crop of potassium chloride is obtained. This process is repeated several times, kelp salt being fished out in the boiling pan, and potassium chloride crystallised out in the cooler. These successive crops of 'muriate,' as it is technically called, range in strength from 80 to 95 p.c. of potassium chloride.

The mother liquor is now rich in iodine, and is treated for its extraction. The several salts all contain iodine, and require careful washing to obtain it. These salts are known as 'Kelp salt,' which was formerly used for reducing the strength of soda ash, but is now unsaleable, 'Sulphate,' which is sold at a low price for manurial purposes, and 'Muriate,' which is largely used for the manufacture of saltpetre, potassium carbonate, chlorate, and dichromate, and the prussiates. The residual kelp waste formerly realised about 5*s.* per ton, and was employed in the common bottle glass manufacture; it consists principally of the carbonates of lime and magnesia, and some phosphates. It is all used as a manure in France, but in this country the farmers have always rejected it.

The following is the analysis of an average sample:

Salts of sodium and potassium .	1·50
Carbon	3·09
Calcium sulphate . . .	3·06
,, sulphide . . .	1·70
,, carbonate . . .	20·50
*Calcium and magnesium phosphates	6·72
Magnesium carbonate . .	6·89
Magnesia	2·22
Silicic acid and sand . . .	20·82
Water	33·50
Total	100·00
*Containing phosphoric acid . .	2·70

The mother liquor, containing the iodides and bromides, also contains considerable quantities of sulphides, sulphites, and thiosulphates of sodium and potassium; it is mixed with about one-seventh of its volume of sulphuric acid, free from arsenic, about 145°Tw. (sp.gr. 1·725), and allowed to settle for 24 hours. This is effected in a closed lead-lined wooden vessel, provided with means to collect any sulphuretted hydrogen which may be given off. The sulphur compounds are decomposed, and a considerable deposit of sulphur takes place. This is known as 'Sulphur waste'; when dry it contains about 70 p.c. of sulphur, and is used in vitriol making. It also obstinately retains iodine, and long steaming is required to extract it. The liquor is strained off from the sulphur and run into the iodine still. This was formerly made of lead, but it now assumes the form of a deep hemispherical iron pot, heated by an open fire, and covered with a strong leaden lid, to which are luted two earthenware arms; these are connected with two series of stoneware udells, about ten in each set. These udells have stone stoppers beneath to allow any water containing chlorine, bromine, and iodine to drain off. The apparatus is shown in Fig. 1. Manganese dioxide is added at intervals to the contents of the still, and the iodine is carried over with the steam. The reaction is as follows:

$$2NaI+3H_2SO_4+MnO_2 \\ =I_2+2NaHSO_4+MnSO_4+2H_2O.$$

Repeated distillations go on, without changing the udells, until these are full of iodine, the bulk of which, and the best, is found in the udells forming the centre of the series. The deposition of the iodine in successive layers squeezes much of the moisture out, and it is obtained in a firm, well crystallised form. The iodine on removal from the udells still contains moisture, and requires further treatment before the state of purity now demanded by consumers is attained. This old-fashioned process is the only one adopted in this country; many others have been proposed and tried, but have not been commercially successful. Commercial iodine is always sent out in 1 cwt. kegs; the consumption is usually reckoned in kegs, which means 1 cwt. It improves by keeping, becoming perfectly dry; and as it can be stored in a small compass, and often represents considerable value, it has been a favourite commodity for small speculative buyers. Bromine does not pay for the collection, but if it were required the arms would be changed and a simple worm-condensing arrangement of lead or earthenware, or a series of stoneware Woulff bottles attached: a further quantity of manganese dioxide would be added to the still, and the bromine distilled over. The liquor remaining in the still, and known as 'waste still liquor,' is a dense acid liquid of sp.gr. 1·235 to 1·500, containing sulphates of iron, manganese, potassium, and sodium; it is very troublesome to deal with and is run away as useless.

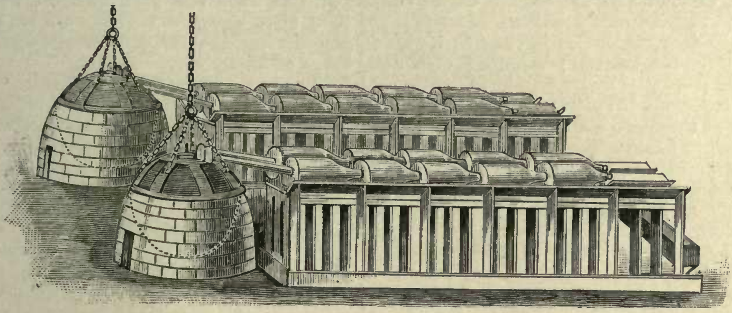

Fig. 1.

The following is the analysis of an ordinary average sample. One gallon contained 3·327 lbs. of dry salts:—

—	Liquor per cent.	Dry salts per cent.
Potassium sulphate .	5·13	15·42
Sodium sulphate .	9·10	27·36
Sodium chloride .	6·80	20·43
Manganous sulphate .	3·75	11·27
Ferric sulphate . .	3·00	9·02
Calcium sulphate .	0·19	0·57
Magnesium sulphate .	0·04	0·12
Sulphuric acid, free .	5·26	15·81
	33·27	100·00

The iodine used for medicine is resublimed in small earthen or porcelain covered pans, and is then known as 'resublimed iodine'; it is obtained in large brilliant plates, and is anhydrous. The pans employed must be shallow, as the vapour is very dense.

When iodine is badly made it may contain white needles, which consist of iodine cyanide; it is now a rare impurity, but a very poisonous one.

In France a different method is adopted. After the precipitation of the sulphur in the mother liquor by addition of hydrochloric acid in slight excess, and boiling for some time, the clear liquor is drawn off and diluted with water to 40°Tw. Chlorine is then passed into the solution, until saturated, and the iodine is precipitated in a pulverulent form. Sometimes, instead of passing in chlorine, the calculated quantity of potassium chlorate is added to the solution; by interaction with the hydrochloric acid this salt yields the chlorine necessary for the liberation of the iodine. Great care must be taken that too much chlorine is not added, as iodine chloride may be formed, and go off as vapour. The clear liquor is then drawn off, and the iodine repeatedly washed by decantation to remove the salts. It is drained in earthen vessels with perforated bottoms, and finally dried on porous tiles. It is then resublimed. This is effected in ordinary earthenware retorts with short necks, and heated in a sand-bath in which they are completely immersed, the iodine being sublimed into earthen receivers. To recover the bromine from the liquor after extraction of the iodine, it is evaporated to dryness, and the residue is distilled in a leaden retort with sulphuric acid and manganese dioxide; it is collected in a receiver under strong sulphuric acid. The production of iodine in France has fallen off considerably; it is all used locally, either resublimed or made into potassium or other iodide, for which purpose the precipitated damp iodine suffices.

In Norway there are now nine or ten works engaged in the extraction of iodine from kelp. In Japan the chief kelp-producing districts are the province of Shima and the island of Hokkaido, but nearly all fishery districts yield a little. The industry is more or less scattered along the coast of Japan and is in the hands of many small producers, from whom the firms of iodine makers procure their supplies.

Iodine from caliche. This mineral, the crude sodium nitrate of Peru and Chile, now forms by far the most important source of iodine. It contains iodine in the form of sodium iodate, which accumulates in the mother liquors from which the sodium nitrate has been crystallised. The proportion of iodine in the caliche varies considerably in the different deposits; in some it is absent altogether, in others it runs as high as 0·17 p.c. or 3·8 lbs. per ton; usually it does not exceed 0·02 p.c.

There are about 157 nitrate factories in Chile, but many of these are old and well worked out, and some are so badly situated as regards position and the raw material is of such a low grade, that they cannot work at a profit, and consequently are closed. At present about 101 factories are in operation, and their production of nitrate amounts to from 2,400,000 to 2,500,000 tons annually. Most of the factories are provided with plant for the extraction of iodine from the mother liquor, but, as their power of production of iodine is largely in excess of the world's power of consumption, the manufacturers have combined to restrict the output. The basis of the power of production of these factories is put down at 115,000 Spanish quintals (about 5,100 tons) per annum, whilst the total quantity consumed is only a fraction of this amount. A certain percentage of the iodine sold in Chile year by year is allotted to each factory, and consequently there are rarely more than a few months in each year during which iodine is made, and there is always a very large stock in hand. The exports are naturally kept as nearly as possible equal to the requirements, but if any large increase in consumption took place there is no doubt that Chile could supply four or five times the quantity at present exported annually. The cost of recovering iodine as a by-product of the sodium nitrate industry is, in many cases, not more than from 1½*d.* to 2*d.* per oz.

It first came over in quantity in 1874, about 497 kegs. In the following year, 900 kegs were exported, and since then the export has continually increased. It was at first a very crude article, containing little over 50 p.c. of iodine, and a good deal was exported in the form of copper iodide. It is now, however, sent over in a pure state.

The following is the analysis of one of the samples of iodine sent from Peru in 1874:

Iodine	52·53
Sodium iodate	1·26
,, nitrate	11·62
Potassium nitrate	2·49
,, sulphate	1·78
Iodine chloride	3·34
Magnesium chloride	0·36
Insoluble matter	1·52
Water	25·20
	100·10

In 1877 the total production of iodine in Scotland was estimated at 1200 kegs; in France at 800 kegs. The present output does not reach these figures.

Japan began to export iodine in 1902, when 35 cwt. were sold. In 1904 the quantity exported was 612 cwt., in 1906 (consequent upon a fall in the price of iodine) only 196 cwt., and in 1907, 305 cwt.

In 1882, the export of iodine from Chile was 4116 cwt., in 1901 it had risen to 5280 cwt., and last year it amounted to 7900 cwt., of a value of about 350,000*l.* This is about four times the present total production of the rest of the world.

The quantity of iodine sold throughout the world in 1887 was 6375 cwt., of which about 1000 cwt. were used in colour making. The present average annual consumption may be taken at nearly 10,000 cwt.

The final mother liquor, or 'aqua vieja,' from which the sodium nitrate has been crystallised, contains sodium iodate, nitrate, chloride, and sulphate, and magnesium sulphate. A good liquor contains about 0·3 p.c. of iodine.

It is run into wooden vats and the iodine is precipitated; the agent employed is sodium bisulphite in solution. The exact amount of iodine in the mother liquor is estimated, and a definite quantity of the solution is added to completely precipitate the iodine. As the bisulphite solution is run into the 'aqua vieja,' the liquid is stirred either by wooden paddle-wheels or by air forced up from perforated pipes at the bottom of the tanks. The latter method is quicker and more efficient, but the air carries away some of the iodine from the solution. The solution is then neutralised by addition of 'sal natron' liquor and again well stirred. After some time, most of the iodine settles to the bottom of the tank; any little that remains floating is removed by a calico bag at the end of a stick. The supernatant liquid is drawn off and used over again with the nitrate liquors.

The iodine is washed with water, and pressed into thick cakes. It then contains 80 to 85 p.c. of iodine and 6 to 10 p.c. of mineral matter, and requires to be purified by resublimation. This is effected in a cast-iron retort, to which eight earthenware condensers or udells are attached in series. The retort is heated by a slow fire, and when the operation is completed the retort is allowed to cool, and the iodine removed from the udells. It is thus obtained pure. The complete plant is shown in the descriptive plans Figs. 2 and 3.

The sodium bisulphite is prepared by passing the fumes of burning native sulphur into a solution of 'sal natron' or sodium carbonate. The sulphur, which is one of the many minerals found in this interesting region, is burned on an iron plate in a plain iron oven, and the fumes drawn by a steam injector into perforated pipes in the solution of sal natron. The manufacture of this substance is also peculiar to the district. It is obtained by burning together 85 parts of crude sodium nitrate, obtained from the 'aqua vieja' tanks, and 15 parts of coal. The mixture is made in the form of a cone 5 feet high, with a space of 2 feet dug out round the base. It is saturated with water and ignited; the sodium carbonate thus formed fuses and runs out into the pit. It is dissolved in water, and the solution is pure enough for use in this process, the impurities consisting of sodium sulphate and chloride, the unburnt coal being left in the residue undissolved.

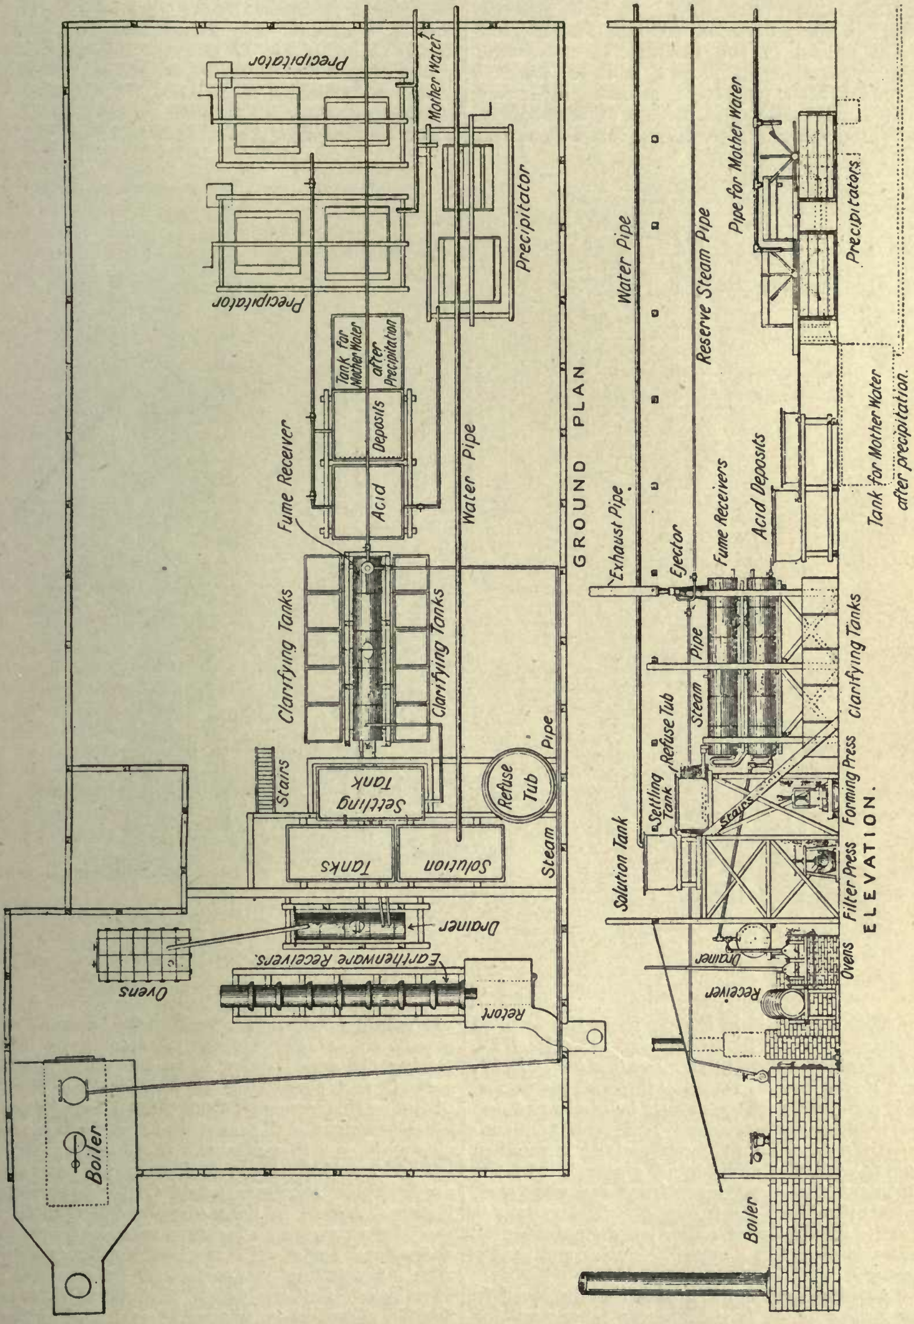

Fig. 2.

Uses of iodine.—About one-fifth of the total consumption of iodine is employed in the manufacture of aniline colours; a good deal of this is recovered and used again. It is principally used in the manufacture of Hofmann violet, and aniline green in the form of methyl iodide; also for making erythrosin and the blue shade eosins, in which iodine is made to react upon fluorescein. Some substitution products are occasionally made, such as the ethylated chrysaniline. A small quantity is used in photography, but the bulk of the iodine of commerce is employed in medicine. Iodine, iodoform, and the iodides of arsenic, iron, lead, mercury (red iodide), potassium, sodium, and sulphur are all official in the British Pharmacopœia; the preparations employed will be referred to under their respective names. Hydriodic acid, ethyl iodide, and iodides of ammonium, cadmium, mercury (green iodide), and starch are also used in medicine, and each will therefore be noticed. Iodine, if pure, should sublime without residue, and the portion subliming first should not include any slender colourless prisms emitting a pungent odour (cyanide). The British Pharmacopœia directs that one gram dissolved in 50 c.c. of water, containing two grams of potassium iodide, should require for complete decolouration at least 78·4 c.c. of the volumetric solution of sodium thiosulphate, which contains 24·8 grams of the salt in 1000 c.c.

FIG. 3.

It is employed in the B. P. in the form of *Tinctura iodi*, 1 in 40, *Liquor iodi*, 1 in 24, *Linimentum iodi*, 1 in 8, *Unguentum iodi*, 1 in 31, and *Vapor iodi*. In the tincture and the liquor, it is dissolved with potassium iodide in rectified spirit and water respectively. The liniment contains the same ingredients dissolved in rectified spirit, with the addition of glycerol. In the ointment the same ingredients are employed, substituting lard for the spirit. The vapour is for the inhalation of iodine; the tincture with water is placed in a suitable inhaler and gently heated.

A volumetric solution of iodine dissolved in potassium iodide is used in the laboratory for titrating solutions of arsenious acid, of sulphurous acid, and sodium thiosulphate. It contains 12·7 grams of iodine in 1000 c.c., and corresponds to 1·7 gram of sulphuretted hydrogen, 3·2 grams of sulphur dioxide, and 4·95 grams of arsenious oxide. Iodine is also used for testing oils, which differ as to the amount absorbed, and some can be distinguished from others by this means (*v.* OILS, FIXED AND FATS).

Other unofficial preparations of iodine are also employed in medicine. *Glycerinum iodi* is iodine dissolved in glycerol, used for external application. *Pigmentum iodi*, Coster's paste, is iodine dissolved in light oil of wood tar, and used for ringworm. *Tinctura iodi decolorata* is a tincture made with rectified spirit, and in which the iodine is decolorised by ammonia. It is used for chilblains. *Collodium iodi* is flexible collodion containing 30 grains of iodine to the ounce, and is very useful for painting on wounds. Carbolised iodine solution is a colourless mixture of tincture of iodine, phenol, and glycerol in hot water; it is used as a gargle or pigment in diphtheria, and internally for Asiatic cholera.

Medicinal properties of iodine.—Iodine was first employed in medicine in the form of burnt sponge, a remedy long used in treating goître. When administered internally it is usually in combination with an alkali; taken alone it is an irritant poison. It is a most powerful alterative, impoverishing the blood and stimulating the absorbents. It is antisyphilitic and antiscrofulic. In syphilis, scrofula, and chronic rheumatism it is largely used, and especially in swellings of the joints and enlarged glands, which are also treated by painting externally with tincture of iodine, in which it acts as a counter-irritant. It has a remarkable power in expelling both mercury and lead from the system. The vapour mixed with steam from hot water is useful in inhalation for many affections of the air passages. Long-continued use may give rise to the depressing nervous train of symptoms known as iodism, and for which belladonna is employed as an antidote. Copious drinks of solution of starch form the antidote in cases of poisoning. Used alone, iodine is a powerful disinfectant and decoloriser, acting in the same way as chlorine. It may be allowed to evaporate spontaneously, but is very apt to colour the sheets, blinds, or anything dressed with starch; it is also used in candles, the burning of which volatilises it.

Hydrogen iodide HI is a colourless gas, very soluble in water and resembling hydrogen chloride; it forms dense white fumes in the air; its sp.gr. is 4·3737. It liquefies under pressure, and solidifies at −55°. It is composed of equal volumes of iodine and hydrogen, and contains 99·2 p.c. of its weight of iodine. The aqueous solution is colourless, but on exposure to air it becomes coloured by the deposition of iodine from oxidation. It is decomposed by sulphuric and nitric acids, and by chlorine and bromine, which set the iodine free.

The following table shows the relative percentage of hydriodic acid at different specific gravities:—

Sp.gr. at 15°	Per cent. of acid
1·708	51·9
1·551	47·2
1·442	39·2
1·297	30·3
1·175	18·5
1·083	5·9

It is usually prepared in solution by passing sulphuretted hydrogen into water in the presence of iodine: $H_2S+I_2=2HI+S$. At first the action is slow on account of the deposition of sulphur covering up the iodine and preventing its solution; the hydriodic acid when formed, however, dissolves an increasing proportion of iodine, and by the gradual addition of iodine and water as the action progresses, large quantities of hydriodic acid may thus be obtained up to a sp.gr. of 1·56.

A modification of this process for very pure acid has been proposed by Winkler. The iodine is dissolved in carbon disulphide, and the solution covered with a stratum of water; when the sulphuretted hydrogen passed into the mixture, the hydriodic acid dissolves in the water, and the sulphur in the carbon disulphide. The aqueous solution only requires boiling for a few minutes to expel the sulphuretted hydrogen, and to obtain the hydriodic acid quite pure. Hydriodic acid is employed in the manufacture of some of the iodides, and is used in medicine in the form of syrup.

Another method was suggested by Kolbe. One part of amorphous phosphorus is added to 15 parts of water in a tubulated retort filled with carbon dioxide, and 20 parts of iodine gradually added. The resulting liquid is allowed to stand and then heated for a short time, cooled, mixed with 4 parts of water and distilled. It yields a colourless acid free from uncombined iodine: $P+5I+4H_2O=5HI+H_3PO_4$.

Iodic acid HIO_3. This acid is usually prepared by boiling iodine in strong nitric acid, free from nitrous acid. Iodic acid is deposited in crystals. When heated it gives off water, and iodine pentoxide I_2O_5 is obtained in small white crystals. It is very soluble in water, and easily decomposed by reducing agents forming hydriodic acid and free iodine.

The iodates have the general formula MIO_3.

Potassium iodate KIO_3 forms small white cubic crystals. Sodium iodate $NaIO_3$ crystallises in small eight-sided prisms. Both salts are poisonous. Both are obtained in considerable quantity in the manufacture of the respective iodides by No. 2 process as described below. The iodates can easily be separated by taking out the first salts deposited on evaporation, as these are less soluble than the iodides. If iodic acid were required on the large scale, it could be easily made as a by-product of the iodide manufacture by crystallising out the iodate before fusion, and precipitating it with barium chloride as barium iodate. This is then decomposed by sulphuric acid. It has, however, no commercial application.

Iodine trichloride ICl_3 is obtained in orange-yellow crystals by passing chlorine into a flask containing iodine vapour sublimed from a small retort. It is a very active disinfectant and germicide in solution of 1 to 1000. It has been used in medicine internally. In contact with organic matter, chlorine and iodine are liberated in a nascent state.

Iodine cyanide, or *Iodide of cyanogen*, CNI. This very poisonous substance is interesting as forming an occasional impurity in commercial iodine; it is very seldom met with now, and ought never to be present if the manufacture is properly carried out. Its occurrence is probably due to an insufficient addition of oil of vitriol to the saturating vat or to the iodine still. It is usually prepared in the laboratory by the distillation of iodine with mercuric cyanide. When present in iodine it presents the appearance of exceedingly fine silky needles, colourless, and very volatile, even at ordinary temperatures, and with a penetrating pungent odour which excites tears. It sublimes without change. It is sparingly soluble in water, easily so in alcohol, and in ether, and also in fixed and volatile oils. The aqueous solution does not give the starch reaction of iodine, nor does it precipitate silver nitrate.

Sulphur iodide S_2I_2 is a dark crystalline substance, obtained by gently heating in a glass flask 1 part of sulphur with 4 parts of iodine until the mixture liquefies; the flask is then broken, and the crystalline mass removed. It is insoluble in water, but soluble in glycerol. It has the odour and staining properties of iodine. It is used in medicine externally in skin diseases applied in an ointment. The official preparation is *Unguentum sulphuris iodidi*, containing 30 grains to 1 ounce.

Arsenious iodide, or *Iodide of arsenic*, AsI_3. This salt forms small orange-coloured crystals, soluble in water and in alcohol; it has a neutral reaction, and gives a yellow precipitate with sulphuretted hydrogen. Heated in a test-tube it almost entirely volatilises, violet vapours of iodine being set free.

It is prepared by direct combination of metallic arsenic and iodine, or by evaporating together to dryness solutions of arsenious and hydriodic acids. The dose is $\frac{1}{30}$ of a grain; and the Pharmacopœia preparation is *Liquor arsenii et hydrargyri iodidi*, about 1 grain in 100.

Nitrogen iodide $N_2H_3I_3$ or $NH_3{\cdot}NI_3$ is a dark brown powder, obtained by adding iodine to excess of solution of ammonia. It is a most violent explosive, but its action is uncontrollable, and it is impossible to keep it in safety. It has therefore found no commercial application, but has been proposed as a chemical photometer on account of the ease with which it is decomposed by light in presence of excess of ammonia (*v.* Guyard, Ann. Chim. Phys. [vi.] 1, 368).

Ammonium iodide NH_4I. This is a white crystalline salt, very deliquescent and becoming yellow on exposure to air. It is prepared by saturating hydriodic acid with ammonia, or by decomposing iodide of iron with ammonium carbonate and filtering off the iron precipitate. The solution in either case is evaporated and set aside to crystallise. It is used in photography, and also in medicine instead of potassium iodide, especially in rheumatism, as causing less depression than the potassium salt. It must be kept from the access of light and air, as iodine is freely given off. It is soluble in alcohol.

Potassium iodide, or '*Hydriodate of potash*,' KI. This is the most important of the iodides, and forms a considerable article of manufacture, as the greater portion of the iodine of commerce goes into consumption in this form. It is a white, colourless, and odourless salt crystallising in large cubes, and permanent in the air. It contains no water of crystallisation, and is very soluble in water, dissolving in two-thirds of its weight. It is also soluble in alcohol. There are three methods employed in the manufacture.

1st. Hydriodic acid is saturated with potassium carbonate, and the solution evaporated and crystallised. This is the most direct method, and there is no loss; it gives a pure product, but it is expensive and tedious.

2nd. Iodine is dissolved in solution of caustic potash. This produces a mixture of potassium iodide and potassium iodate; the reaction is $3I_2+6KOH=5KI+KIO_3+3H_2O$. The solution is evaporated to dryness, a little charcoal is added, and the product fused in an iron pot at a red heat until all the iodate is decomposed, and potassium iodide alone remains. The mass is dissolved in water, the solution filtered and crystallised.

3rd. Iodide of iron is first prepared by the addition of iron borings and iodine to water; the latter must be added gradually to keep down the temperature; the solution is filtered, mixed with potassium carbonate and the iron precipitate washed and filter-pressed. The solution is then evaporated to dryness and the residue redissolved and crystallised.

This process is that most commonly adopted by manufacturers. The crystallisation is performed in enamelled iron pans, surrounded by a steam jacket in brickwork, and very gradually cooled. The best crystals are obtained on fluted glass rods suspended in the liquid.

The second process is that directed by the British Pharmacopœia.

Potassium iodide or '*Hydriodate*,' as it is often called, is used in photography, but medicine is the principal outlet, and requires a large consumption. It is a powerful alterative, diuretic, and absorbent; and is much administered internally, especially in rheumatism and syphilis; the dose is 5 to 10 grains, but doses of 100 grains have been given in some cases. Its properties are similar to those of iodine. As iodine is freely soluble in potassium iodide solution, it presents an excellent form for its internal administration.

It must contain no iodate; this is easily detected by the addition of tartaric acid and starch solution, which sets free hydriodic acid, and if there be any trace of iodate present, free iodine is liberated, as shown by the blue colour of the iodide of starch. Potassium iodide should not contain water, and therefore should not lose weight when heated; it should contain no sulphate, and therefore give no precipitate with barium chloride insoluble in nitric acid. A feeble alkaline reaction from the presence of a slight trace of carbonate, indicated by cloudiness with lime or baryta water, soluble in nitric acid, is allowed by the London Pharmacopœia (but not by the German) as tending to retain the colour of the iodide when long kept. Chlorides of potassium or sodium are a common impurity; the presence of a chloride is shown by precipitating with silver nitrate, and agitating the precipitate with ammonia. The ammonia solution should give no precipitate with nitric acid. One gram requires for complete precipitation 60·2 c.c. of a volumetric solution of silver nitrate containing 17 grams of the salt in 1000 c.c. It is almost impossible to obtain this salt, when made on the large scale, quite free from chloride (the B. P. allows a 'very little') as potassium carbonate cannot be prepared in quantity without it; a good iodide contains:

Potassium iodide . . .	99·4
" chloride . . .	0·2
Water	0·4
	100·0

This salt is officinal in the following preparations; the number of grains in one fluid ounce is given in each case. *Linimentum iodi* 22 grains; *Linimentum potassii iodidi cum Sapone* 54½ grains; *Liquor iodi* 33 grains; *Tinctura iodii* 11 grains; *Unguentum iodi* 16 grains; *Unguentum potassii iodi* 54 grains.

Potassium iodide is sometimes administered in large doses, and it is important medicinally that it should contain no iodate, as this salt is poisonous: it must not be prescribed in mixtures containing potassium chlorate, for this salt decomposes it, forming iodate.

Sodium iodide NaI. This salt is obtained as a deliquescent white crystalline powder, soluble in two-thirds of its weight of water. It may be prepared by the same methods as the corresponding potassium salt; that from ferrous iodide is usually employed, and the solution is simply evaporated to dryness. It crystallises in anhydrous cubes and also in hexagonal plates, having the formula $NaI,2H_2O$. It is used in medicine for the same purposes as potassium iodide, but the principal application is as a precipitant of silver and gold from the weak copper ores of the Tharsis and other copper-extracting companies. The same tests as with the potassium salt may be used for its purity; 1 gram requires 66 c.c. of the volumetric solution of silver nitrate for complete precipitation.

Ferrous iodide, or *Iodide of iron*, FeI_2. This is a crystalline green deliquescent mass. It is only employed in medicine, and more particularly in the form of syrup of iodide of iron, in which it can be better preserved. The official preparations are *Pilula ferri iodidi*, and *Syrupus ferri iodidi*, containing 34·4 grains of the salt in one fluid ounce. It is a tonic alterative useful in anæmia of scrofulous patients, especially children.

A similar syrup of manganese iodide is also sometimes used in medicine.

Zinc iodide ZnI_2. An easily fusible compound which sublimes in needles. It is prepared in the same way as the iron salt, and obtained by evaporation as a white crystalline deliquescent salt. It is sometimes used in photography.

Lead iodide, or *Plumbic iodide*, PbI_2. This is a brilliant yellow powder, made by precipitating a solution of lead nitrate with potassium iodide, and washing and drying the precipitate. By boiling the powder in water, and allowing the solution to cool, it is obtained in bright yellow crystalline scales. It is employed in medicine externally in the form of ointment and plaster. The official preparations are *Emplastrum plumbi iodidi*, 1 part in 9; and *Unguentum plumbi iodidi*, 1 part in 8.

Mercurous iodide HgI, or *Green iodide of mercury*, is a green insoluble powder, which darkens on exposure to light. It is prepared by rubbing together in a porcelain mortar the equivalent proportions of mercury and iodine, and moistening the mixture with alcohol until the metallic globules cease to appear and a green powder is obtained. This must be dried in the air in a dark room, and preserved in a bottle put away from the light. It can be obtained in yellow crystals by sublimation. It is insoluble in water and alcohol. It is employed in medicine in doses of 1 to 3 grains. It is an irritant poison and is used in syphilis.

Mercuric iodide, or *Red iodide of mercury*, HgI_2. This is a brilliant scarlet powder, known as Chinese vermilion. It may be prepared in the same manner as the green iodide, using double the equivalent of iodine; but a better product is obtained by precipitation. A solution of mercuric chloride, or corrosive sublimate, is precipitated with potassium iodide, both salts being dissolved in boiling water; the precipitate is washed and dried over the water-bath. By sublimation it may be obtained in large and beautiful crystals, which when hot are yellow, but reassume their scarlet colour on cooling. It is insoluble in water, but very soluble in solution of potassium iodide. This solution contains a double iodide of mercury and potassium and is used in analysis as a precipitant for alkaloids. It forms a pigment more brilliant than vermilion, but it is not much used for this purpose, as it is easily altered by exposure. It is employed in medicine, especially in syphilis, in doses of a thirty-second to an eighth of a grain, and also externally as an ointment. The official preparations are *Liquor arsenii et hydrargyri iodidi*, containing 1 grain in 100 grain measures, and *Unguentum hydrargyri iodidi rubri*, containing 1 part in 28. It has been recently introduced as a germicide for washing wounds, instead of corrosive sublimate, which is not so effective and is more poisonous. It has also been used as an antifermentive in tanning.

Bismuth iodide BI_3 is a red powder obtained by precipitation from bismuth nitrate by potassium iodide. It has been introduced into medicine as a substitute for iodoform in treating wounds. It has no odour. This iodide is soluble in potassium iodide, forming a double iodide employed in analysis as a precipitant for alkaloids.

Silver iodide AgI. This salt occurs native, in hexagonal crystals, as *iodargyrite* or *iodyrite*. It is obtained by precipitation from a solution of silver nitrate and any soluble iodide. This salt is not employed commercially in this form. It is the active salt of iodine which is used in photography, but it is always produced on the plate or the paper. It is the form in which iodine is often precipitated and weighed. It is almost insoluble in ammonia, but soluble in potassium iodide and cyanide, and in sodium thiosulphate.

Palladium iodide PdI_2. This is a dark-brown powder, interesting as the most insoluble salt of hydriodic acid, and as a form in which it is estimated in analysis.

Cuprous iodide, or *Iodide of copper*, Cu_2I_2. When solutions of potassium iodide and cupric sulphate are mixed, only half the iodine is precipitated as cuprous iodide, the other half being set free, according to the following equation: $2CuSO_4 + 4KI = Cu_2I_2 + I_2 + 2K_2SO_4$. It is necessary, therefore, to add a reducing agent as sulphurous acid or sodium hyposulphite, but ferrous sulphate is usually employed; the whole of the iodine is then thrown down as cuprous iodide

$$2CuSO_4+2FeSO_4+2KI = Cu_2I_2+K_2SO_4+Fe_2(SO_4)_3.$$

The former reaction was proposed by Soubeiran as a method of obtaining iodine from kelp liquors, but it has not been much used.

Cuprous iodide is a white crystalline solid, insoluble in water; on exposure to a red heat it fuses to a brown mass. The iodine can be separated from it by heating it with manganese dioxide or strong sulphuric acid. Or it may be decomposed by boiling with water and zinc, which yields zinc iodide and metallic copper. Or it may be treated with potassium or sodium hydroxides or carbonates, which decompose it, forming cuprous oxide and potassium or sodium iodide. With ammonia it combines, forming ammonio-cuprous iodide $CuI,2NH_3$; a white crystalline powder.

Iodide of starch, or *Iodised starch*, is a dark blue powder obtained by triturating iodine with a little water and adding gradually starch in powder until it assumes a deep and uniform colour, and drying at a low temperature. It is decolorised at 100°. It is used in medicine as a mild form of administering iodine internally, in doses of half a drachm to four drachms. In the form of a paste it is employed to cleanse and heal foul sores and ulcers.

Estimation of iodine.—The violet vapour of free iodine is characteristic, and there are also four very sensitive tests for iodine and iodides: for the former the blue colour test with starch, and the crimson solution in chloroform, benzene, or carbon disulphide; for the latter the precipitation as silver or palladium iodide. All these can be employed in estimating iodine, the colour tests by comparison with standard solutions, and the gravimetric tests by weighing the iodine as silver iodide or palladium iodide. Insoluble iodides must be converted into alkaline iodides before precipitation by silver nitrate or palladium chloride. This may be effected by fusing with sodium carbonate, or preferably by a mixture of this and potassium carbonate. Another method for a metallic iodide is to suspend it in water and pass sulphuretted hydrogen through the mixture; the metal is precipitated as a sulphide, and hydriodic acid formed. Silver iodide is generally heated with zinc and dilute sulphuric acid, the silver is reduced to the metallic state, and zinc iodide remains in solution.

If the iodine exists in the form of a soluble iodate it must be reduced to an iodide by sulphurous acid. With organic iodides it is usual to ignite with pure sodium hydroxide.

In the colour tests, the iodine must be set free by bromine, chlorine, or, preferably, nitro-sulphuric acid. The starch method, owing to the easy decomposition of the iodide of starch, is not generally available, but the separation of the iodine from solution by a solvent forms a process of great accuracy, of easy and rapid execution, and of general application. In estimating the iodine in kelp or seaweed ash, or kelp substitute, the following process is adopted. Kelp is not an easy cargo to sample. There is often great difference in the value of the large masses forming the cargo. Stones and sand are a frequent cause of annoyance; stones are often found fused into the centre of a block of kelp, and forming most of the block. These can only be detected by breaking up all the large pieces. With seaweed ash, or charcoal, or kelp substitute there is no difficulty. Where there is much sand the kelp is more friable. The sand is generally composed of shells, and is mostly carbonate of lime; but it is sometimes quartz, flint, or other form of silica. To insure an accurate sample, about 100 lbs. are carefully picked from a cargo of, say, 100 tons, and ground up. A portion of this is finely powdered and kept as a sample for reference. Of this, 5 grams are taken to estimate the moisture, another 5 grams are taken to estimate the soluble matter, the carbon, and the ash, also the potash and the iodine in the soluble matter. The kelp is treated with about 75 c.c. of hot water, which dissolves little or none of the oxysulphides. This operation is repeated and the residue washed, and the solution made up to 250 c.c. In a portion of this the potash is estimated by platinum tetrachloride. For estimating the iodine, one-tenth part or 25 c.c., equal to 0·5 gram of kelp, is taken. This will not contain more than 5 milligrams of iodine, generally about 2 milligrams, often only 0·5 milligram. If the amount exceeds 5 milligrams, it is advisable to dilute the solution with an equal bulk of water. Five c.c. of carbon disulphide are then added and a few drops (one to three) of nitro-sulphuric acid dropped in. This reagent is prepared by treating starch with nitric acid, and passing the nitrous fumes into sulphuric acid of 1·843 sp.gr. to saturation. The mixture keeps perfectly well. The testings are performed in large even test tubes, and compared with graduated standard solutions of potassium iodide treated in precisely the same manner. By this method $\frac{1}{250000}$th part of iodine is easily detected and measured, and up to $\frac{1}{100000}$th part the estimation is very accurate. It has several advantages over the use of starch, as besides the introduction of an organic substance liable to change, the blue colour of the iodide of starch is distributed over the whole liquid, and when dilute can only be seen by looking down the length of the tube. Moreover, the solution is not transparent, and the indications are not sharp enough for accurate quantitative work, though useful often in testing. The carbon disulphide method is quite as sensitive, and the iodine is removed from the solution and concentrated in a sixth of the volume at the bottom of the tube. The maximum effect, which takes time with the starch, is immediate in this case. The carbon disulphide solution of iodine can be removed, and the iodine recovered from it by an alkali for further experiment if desired, but it is quite unnecessary for accurate results. It is usual to remove it from the disulphide by zinc in the presence of water, so that the reagent can be used over and over again. Many years of experience of this and other processes have shown that this is the only one to be relied on where many such estimations have to be performed daily, especially in kelp and its products, which contain such a small proportion of iodine. If the iodine is to be determined in a seaweed or other organic material, the sample must always be carbonised in a small iron retort or close crucible, and not burnt to ash in an open crucible. The salts are washed out from the charcoal, and the carbon and ash estimated by burning the residue. If this be not done, it is almost impossible to completely burn away the carbon in the presence of so much alkaline salts which at a high temperature fuse and cover it over. If, moreover, a long time is taken, as it must be, over an ordinary Bunsen burner, a large portion of the potash and all the iodine may be easily burnt off. If the salts contain magnesium, as all those from seaweeds do, it is necessary to make sure that there is an excess of alkali present, or the iodine will be rapidly burnt off. In kelp and seaweed there always is sufficient alkali, and this precaution is unnecessary, but where the object is to estimate iodine in organic substances containing it in minute traces, more caustic soda should always be added before carbonising. As all seaweeds also contain soluble sulphates which become reduced to sulphides and oxysulphides when burnt to ash, carbonisation presents another advantage, as it prevents this change.

Palladium chloride is the only reagent which can be relied on for the direct gravimetric estimation of iodine in mixed liquors containing chlorides and bromides. The kelp liquor must be mixed with hydrochloric acid and set aside in a warm place till the sulphur compounds are decomposed, it is then filtered off and precipitated with palladium chloride, and allowed to stand for some time. The black precipitate of palladium iodide may be washed with hot water, and lastly with a little alcohol, dried at a gentle heat, and weighed on a tared filter; 100 parts contain 70·45 parts of iodine. Or it may be ignited in a platinum crucible, and the iodine calculated from the weight of the palladium left; 100 parts of palladium are equal to 238·5 parts of iodine. If chlorine is also to be estimated in the same liquid, palladium nitrate must be substituted for the chloride. If bromine is also present the chloride must be used, or a soluble chloride must be added, or the bromine will be precipitated with the palladium iodide. This method gives discordant results with kelp, on account of the cyanides often present. Free alkalis, chlorine, and bromine also prevent the precipitation.

In 'caliche' the iodine exists as an iodate, and this must be first reduced to an iodide by sulphurous acid or sodium bisulphite. There are several methods of estimating iodine, bromine, and chlorine, directly and indirectly, when present together. A very simple method of separating these elements directly is to distil over the iodine first by boiling with ferric sulphate; it may be condensed in solution of potassium iodide and titrated with sodium thiosulphate. The bromine is then separated from the residue in the retort, which has been allowed to cool, by gently warming the solution after addition of potassium permanganate, and distilling it into solution of ammonia in excess, in which it is titrated with an acid; or estimated gravimetrically by precipitation as silver bromide. The chlorine can be estimated in the residue or by difference from a determination of the total quantity of chlorine, bromine, and iodine in the original substance by precipitation as silver salts. Another method is to distil over the iodine with a concentrated solution of potassium dichromate; after the iodine is removed the addition of a little sulphuric acid to the retort will set free the bromine, the chlorine can then be determined as in the last process.

Field's method of separating these three halogens is to divide a solution into three equal parts; each portion is precipitated by silver nitrate. No. 1 is washed, dried, and weighed. No. 2 is digested with potassium bromide, then washed, dried, and weighed. No. 3 is digested with potassium iodide, then washed, dried, and weighed. No. 1 contains the silver chloride, bromide, and iodide. No. 2 contains only silver bromide and iodide, the chloride having been by this process converted into bromide. No. 3 contains silver iodide only, the chloride and bromide having been both converted into iodide. The exact quantities of each in the solution can therefore be easily calculated. The valuation of commercial iodine has been alluded to already; the sodium thiosulphate is usually standardised by titrating it with a potassium iodide solution of pure iodine. 100 c.c.=2·48 grams ($\frac{1}{100}$th of $Na_2S_2O_3,5H_2O$) and is equal to 1·27 grams of iodine ($\frac{1}{100}$th of atomic weight in grams). Another method of volumetrically estimating the strength of an iodine solution is to pass sulphuretted hydrogen into it until decolorised; the hydriodic acid formed is then titrated with decinormal soda, using methyl orange as an indicator.

Commercial iodine seldom contains any impurity but moisture; it is almost impossible to estimate the water by drying in the ordinary way. An easy method is to rub it up with five times its weight of pure dry mercury, adding a little alcohol. It is then dried for 12 hours, or until it ceases to lose weight, over sulphuric acid in a desiccator. This process is accurate to about 0·1 p.c., but most suitable for very damp iodine. Another method is to add a weighed quantity (about double the weight of the iodine) of zinc sheet in small pieces in a tared capsule, along with a little water, when the iodine is all converted into zinc iodide; the contents of the capsule are gradually evaporated to dryness and weighed, the weight then includes that of the dry iodine. It is better, however, in all cases to estimate the iodine by titration. The same may be said of the valuation of potassium iodide; but in this case it is often also necessary to estimate a small quantity of chloride which is always present; and silver nitrate is the best reagent for this purpose, as the chloride ought to represent so small a percentage as to be difficult of detection. Bromine as a rule need not be looked for. Should it be present, however, some other process must be employed. It is necessary to take at least 3 grams of the potassium iodide, and add to it not less than 3·1 grams of pure silver nitrate, the precipitate is digested in strong ammonia, then filtered off, washed, dried, and fused with the usual precautions. The solution is concentrated by evaporation, and the silver chloride precipitated by nitric acid. This gives accurate results, even when the potassium chloride is under 0·5 p.c.

For the determination of small proportions of chlorine and bromine in iodine, the following process is recommended by Tatlock and Thomson (J. Soc. Chem. Ind. 1905, 24, 187). 10 grams of the sample are triturated with 100 c.c. of water, and finely granulated zinc, or zinc dust, is added in small portions, with agitation, until all the iodine is converted into zinc iodide. The temperature of the solution must not be allowed to rise sensibly during the process. The solution is now filtered, the residue washed two or three times, and to the filtrate 7 grams of pure sodium nitrite are added. The solution is carefully acidified with dilute sulphuric acid, the precipitated iodine is collected and washed two or three times with cold water, and the filtrate is agitated with benzene in a small separator. The aqueous layer is run into another small separator, mixed with a little more sodium nitrite and dilute sulphuric acid, and again shaken with benzene. To the aqueous solution excess of silver nitrate and some nitric acid are added, the liquid is heated to boiling, and the precipitate is collected on a weighed filter and well washed with hot water. A solution containing 2 grams of silver nitrate, 90 c.c. of water, and 10 c.c. of ammonia of sp.gr. 0·88 is prepared. About 60 c.c. of this solution are poured back and forward through the filter containing the precipitate, and the latter is finally washed with the remaining 40 c.c. The silver bromide on the filter is now washed with warm dilute nitric acid and with hot water, dried, and weighed. The ammoniacal filtrate is acidified with dilute nitric acid, and the precipitate of silver chloride is collected as usual. G. G. H.

IODIPIN, IODIVAL, IODLECITHIN, *v.* SYNTHETIC DRUGS.

IODOCAFFEIN *v.* SYNTHETIC DRUGS.

IODOETHYLFORMIN $C_6H_{12}N_4(C_2H_5I)_2$ is obtained by the action of ethyl iodide on a weak alcoholic solution of hexamethylene-tetramine. Crystallises in long needles, tasteless, soluble in water, sparingly soluble in alcohol, insoluble in ether and chloroform. Decomposed by sodium carbonate and strong acids with liberation of formaldehyde; used internally as a substitute for alkaline iodide.

IODOFORM *Tri-iodomethane* CHI_3. Iodoform was discovered in 1822 by Serullas (Ann. Chim. Phys. [ii.] 20, 165; 22, 172; 25, 311; 29, 225; 39, 230), and Dumas in 1834 (*ibid.* [ii.] 56, 122) determined its exact composition. Serullas obtained it by acting on alcohol with iodine in presence of caustic or carbonated alkalis. The reaction may be stated thus:

$$CH_3{\cdot}CH_2{\cdot}OH+4I_2+6KOH$$
$$=CHI_3+HCOOK+5KI+5H_2O.$$

Numerous other compounds have been suggested as substitutes for alcohol in this reaction, by Serullas, Bouchardat (J. Pharm. Chim. [ii.] 23, 1; [iii.] 3, 18), Lefort (Compt. rend. 23, 229), Millon (*ibid.* 21, 828), and others; but Lieben (Annalen Suppl. 7, 218 and 377) has shown that many of these, such as ether, chloroform, methyl alcohol, formic and acetic acids, phenol and probably the carbohydrates, when properly purified, do not yield iodoform. The reaction, however, takes place with ethyl ethers, which first break up by the action of water into alcohol and acid; with aldehyde, acetone, and generally with the higher normal alcohols of the fatty series and their corresponding aldehydes; also with lactic acid, turpentine, methyl benzene, and some other compounds. This reaction serves in many instances as a very delicate and reliable test for the presence of alcohol. It may be obtained in dilute solutions (Lieben, Annalen Suppl. 7, 236). In the reaction with turpentine, Guyot (J. Pharm. Chim. [iv.] 13, 313) and Chautaud (*ibid.* [iv.] 14, 19) employ iodated lime. When iodine is made to act on sodium ethoxide, instead of on alcohol and alkali, methylene iodide is formed together with only small proportions of iodoform (Butlerow, Annalen, 107, 110; Mulder, Rec. trav. chim. 7, 310). Iodoform was observed by Erlenmeyer (J. 1861, 668) among the products of the action of hydriodic acid on glycerol, and Rice (Pharm. J. [iii.] 6, 765) notes that a mixture of 'white precipitate,' alcohol, and iodine does not explode from the formation of nitrogen iodide when phenol is present, but that nitrogen and iodoform are formed. Iodoform may also be extracted from the product of the action of coal gas on iodine (Johnston, Phil. Mag. 17, 1). Acetylene mercuric chloride, silver and cuprous acetylides, and a solution of acetylene in concentrated sulphuric acid all yield iodoform when treated with iodine and dilute sodium hydroxide solution (Le Comte, J. Pharm. Chim. [vi.] 16, 297).

To prepare iodoform, Filhol (J. Pharm. Chim. [iii.] 7, 267) adds 1 part of alcohol to a solution of 2 parts of crystallised sodium carbonate in 10 parts of water and raises the temperature to 60°–80°. 1 part of iodine is then gradually added, and when the liquid has become colourless, iodoform slowly forms and sinks to the bottom and may be removed by filtration. The filtrate is heated as before, another portion of sodium carbonate and alcohol added, and chlorine is led into the mixture to liberate iodine which has combined with the alkali. Another deposit of iodoform occurs, and the process may be repeated until the product represents nearly half the iodine employed. Another plan, suggested by Rother (Pharm. J. [iii.] 4, 594), is to warm the following mixture until it becomes colourless: iodine 32 parts, potassium carbonate 32 parts, 95 p.c. alcohol 16 parts, water 80 parts. The iodoform which is deposited is removed, and to the clear solution a mixture of potassium dichromate 2 to 3 parts, and hydrochloric acid 16 to 24 parts, is added to liberate iodine. After neutralising the solution with potassium carbonate, 32 parts more of that salt are added, together with 6 parts of iodine and 16 parts of alcohol, and the heat being maintained a second quantity of iodoform precipitates. This may be removed and the operation repeated several times (*cf.* Cornelius and Gille, J. Pharm. Chim. [iii.] 22, 196; Smith, Pharm. J. [iii.] 5, 211; Bell, *ibid.* [iii.] 12, 786; Günther, Arch. Pharm. [iii.] 25, 373). Iodoform can be prepared by the electrolysis of a solution of an iodide in the presence of alcohol, aldehyde, or acetone (Dingl. poly. J. 255, 88; J. Soc. Chem. Ind. 1885, 243; Foerster and Meyes, J. pr. Chem. [ii.] 56, 353; Elbs and Herz, Zeitsch. Elektrochem. 4, 113; Abbot, J. Phys. Chem. 1903, 84; Teeple, Amer. Chem. J. 26, 170). According to Suilliot and Raynaud (Bull. Soc. chim. [iii.] 1, 3) almost the whole of the iodine employed is obtained as iodoform when acetone is acted upon by what is possibly nascent potassium hypoiodite produced by treating potassium iodide with sodium hypochlorite. A slight excess of dilute solution of sodium hypochlorite is added to a mixture of potassium iodide 50 parts, acetone 6 parts, and sodium hydroxide 2 parts, dissolved in 1 to 2 parts of water. The reaction probably takes place thus:

$$(1)\ KI+NaClO=KIO+NaCl.$$

$$(2)\ CH_3{\cdot}CO{\cdot}CH_3+3KIO$$
$$=CHI_3+CH_3COOK+2KHO.$$

This process has been applied to the working of kelp, and is said to produce iodoform of a very high degree of purity (Pharm. J. [iii.] 20, 423).

Iodoform crystallises in lemon-yellow hexagonal plates (Rammelsberg and Kokscharow, J. 1857, 431) which melt at 119°, volatilise when heated (*cf.* Dott, Pharm. J. [iii.] 16, 299; 17, 282), or better in a current of steam. It has a persistent and disagreeable odour. It is nearly insoluble in water, benzene, or light petroleum, but dissolves in ether, alcohol, and volatile oils (*cf.* Vulpius, Arch. Pharm. [iii.] 20, 44). Crystalline form (Pope, Chem. Soc. Trans. 75, 46). Lowering of the freezing-point in benzene solution (Paternò, Ber. 22, 465). In the dry state iodoform is not acted on by sunlight; but in solution, with access of oxygen, it rapidly liberates free iodine (Humbert, J. Pharm. Chim. [iii.] 29, 352; Hebeler, Pharm. J. [iii.] 16, 1088; Daccomo, Gazz. chim. ital. 16, 247; Neuss and Schmidt, Pharm. J. [iii.] 19, 247; Fischer, Pharm. Zeit. 34, 31; Bougault, J. Pharm. Chim. [vi.] 8, 213). Iodoform has been much used in medicine and surgery as an antiseptic, but its value in this respect has often been questioned. It would appear, however, that while outside the system it exerts no antiseptic power, it acts differently in presence of pus at the temperature of the body. Iodine is, in this case, liberated which combines with ptomaïnes to render them innocuous (De Ruyter, Med. Press Cir. 1887, 403; *cf.* Riedlin, Arch. Hygiene, 7, 309, and Ber. 22, Ref. 66; also Altenberg, Chem. Zentr. 1901, ii. 1212; Mulzer, *ibid.* 1905, i. 1174). Numerous attempts have been made to mask the odour of iodoform in its pharmaceutical preparations (Pharm. J. [iii.] 8, 439; 11, 111 and 895; 12, 439 and 703; 16, 288; 17, 556; 18, 249). For iodoform gauze *v.* Daux, J. Pharm. Chim. [5] 16, 201.

When iodoform is heated in closed tubes to 150°, methylene iodide is formed (Hofmann, Chem. Soc. Trans. 13, 65). The zinc-copper couple reduces it to acetylene (Gladstone and Tribe, *ibid.* 28, 512). Bromine converts it into bromoform (Löscher, Ber. 21, 410), and phosphorus pentachloride into chloroform. Finely divided silver, even in the cold, reduces iodoform, acetylene and silver iodide being formed. Other metals act in the same way, but in the case of iron in the presence of water the products are methyl and methylene iodides (Cazeneuve, Compt. rend. 97, 1371; 98, 369). With sodium ethoxide, methylene iodide, acrylic acid, and ethyl lactic acid are produced (Butlerow, Annalen, 107, 110; 114, 204; 118, 325). Methylene iodide is also formed by the action of potassium hydroxide on a solution of iodoform in acetone (Willgerodt and Muller, Chem. Zentr. 1884, 808). Iodoform reacts with certain mercury and silver salts. Mercuric acetate is reduced to mercurous acetate with evolution of carbon dioxide (Cotton, J. Pharm. Chim. [v.] 16, 481); mercurous chloride is converted into mercurous iodide and chloroform (Drescher, Pharm. J. [iii.] 17, 882), the reaction being similar to that between iodoform and phosphorus pentachloride; and dry silver nitrate is decomposed with explosive violence, silver iodide, nitrogen peroxide, nitric acid, and carbonic acid being probably formed (Pharm. J. [iii.] 20, 62). The last-mentioned reaction has been made the basis of a method for the volumetric estimation of iodoform (Greshoff, Rec. trav. chim. 7, 342). A crystalline but unstable compound of iodoform with strychnine is described by Lextrait (Compt. rend. 92, 1057). A reaction, which has been employed as a test, is obtained when a few drops of an alcoholic solution of iodoform are added to a small quantity of a mixture of phenol and solution of caustic potash, and the mixture gently warmed. A red precipitate is formed which, dissolved in a small quantity of alcohol, exhibits a carmine red colour (Lustgarten, Monatsh. 3, 717). Detection of adulteration (Kremel, Ph. Post, 21, 213). Assay of iodoform (Meillère, Chem. Zentr. 1898, ii. 140). A. S.

IODOFORMAL *v.* Synthetic drugs.

IODOFORMIN $C_8H_{12}N_4I_4$ is prepared by adding an alcoholic solution of iodine to ammonia and formaldehyde mixed in molecular proportions when iodoformin falls as a brown pulverulent precipitate (*v.* Synthetic drugs).

IODOFORMOGEN *v.* Synthetic drugs.

IODOKOL *v.* Synthetic drugs.

IODOLE *Tetraiodopyrrole* C_4I_4NH. Iodole is an antiseptic, similar in its action to iodoform. It is less energetic, but is free from the disagreeable smell which characterises that compound. References to communications on the physiological action of iodole and its application in therapeutics are given by Ciamician (Gazz. chim. ital. 16, 543). *Cf.* Trousseau (Pharm. J. [iii.] 17, 265); and Robinson (Chem. Zeit. 1887, 222).

Ciamician and Dennstedt, who first prepared iodole, obtained it by acting on potassium pyrrole, C_4H_4NK, with iodine in ethereal solution (Ber. 15, 2582). It is formed, even in the cold, when iodine is brought in contact with pyrrole, in presence of such indifferent solvents as alcohol, wood spirit, chloroform, acetone, carbon disulphide, or ethyl acetate. The reaction may be explained thus: $C_4H_4NH+8I=C_4I_4NH+4HI$. It is, however, better to add some agent to remove the hydriodic acid as it is formed, such as alkalis or their carbonates; or to oxidise it with such substances as ferric chloride, cupric sulphate, chlorine or bromine, oxide of manganese, &c., and thereby utilise the whole of the iodine (Ciamician and Silber, Ber. 18, 1766, 19, Ref. 327). Iodole may also be obtained from the corresponding chlorine or bromine derivatives of pyrrole by the action of metallic iodides (Patent, Ber. 20, Ref. 123).

Iodole crystallises from alcohol in light yellow microscopic needles. Heated at 140°–150° it decomposes without melting. It is insoluble in water but easily dissolves in ether, in hot alcohol or glacial acetic acid, or in alcoholic potash. The alcoholic solution with nitric acid gives an intense red colour, and a green colour is obtained when the crystals are heated with sulphuric acid. Acted upon by zinc-dust and potassium hydroxide, iodole is converted into pyrrole (Ciamician and Silber, Ber. 19, 3027) (*v.* Synthetic drugs). A. S.

IODOTHION *v.* Synthetic drugs.

IODYRITE, or Iodargyrite. A mineral composed of silver iodide (AgI) crystallising in the rhombohedral system. Distinctly developed crystals are small and comparatively rare; they possess a perfect cleavage parallel to the basal plane, on which the lustre is pearly, and are very soft (H. = 1) and readily distorted. Their pale sulphur-yellow is not darkened by exposure to sunlight. Sp.gr. 5·51. At a temperature of 146°, the material becomes optically isotropic and cubic, reverting on cooling into the birefringent rhombohedral form.

The mineral occurs in the upper oxidised zones of certain silver-bearing veins, and when found in quantity, as at Broken Hill in New South Wales, in Chile and Mexico, it is an important ore of silver (Ag, 45·97 p.c.). Some of the silver-ore formerly mined at Broken Hill consisted of white kaolin enclosing films and specks of iodyrite.

Miersite is a rare cubic form of silver iodide with copper iodide (4AgI·CuI) from Broken Hill, New South Wales (L. J. Spencer, Min. Mag. 1901, 13, 41; G. T. Prior, *l.c.* 188). L. J. S.

IONIUM. A radioactive element, discovered by Boltwood in uranium minerals (Boltwood, Amer. J. Sci. 1907, 24, 370; *cf.* Hahn, Ber. 1907, 40, 4415). The results obtained by Boltwood and Hahn were confirmed by Marckwald and Keetman (Ber. 1908, 41, 49), who were unable to separate ionium from thorium, an element which it closely resembles. Ionium occurs, however, associated with actinium, in many of the uranium group of minerals in the absence of thorium (Szilárd, Le Radium, 1909, 6, 80).

Highly active preparations of ionium may be obtained from carnotite as follows (Boltwood, Amer. J. Sci. 1908, 25, 365). The ore is dissolved in hydrochloric acid and several grams of the chlorides of the cerite earths added. The earths are separated as oxalates, converted into chlorides, and precipitated with sodium thiosulphate. The latter procedure is repeated several times, when a product is obtained having a radioactivity several thousand times as great as that of an equal weight of pure uranium.

The residues obtained in working up uranium ores containing little thorium may be precipitated in strongly acid solution with hydrofluoric acid. The precipitated fluorides are converted into sulphates, and from the aqueous solution of these, ionium and thorium are quantitatively precipitated by adding zinc hydroxide. The precipitate is dissolved in hydrochloric acid and the solution precipitated with oxalic acid. The oxalate thus obtained contains the ionium, and has an activity 200 times as large as that of metallic uranium (Keetman, Jahrb. Radioaktiv. Elektronik. 1909, 6, 265).

Ionium emits α-rays, which have a range in air of only 2·8 cms.; it also emits β-rays. It produces no emanation. The life of ionium is at least as long as that of radium.

According to Boltwood, ionium is the direct parent of radium, and according to Keetman (*l.c.*), does not change directly into actinium.

Thorium-ionium oxalate has a very high and constant activity, and may with advantage be utilised in testing the constancy of electrometers and for determining capacities (Keetman, *l.c.*).

IONONES *v.* KETONES.

IPECACUANHA. *Ipecacuanha Root. Racine d'Ipecacuanha*, Fr.; *Brechwurzel*, Ger. Ipecacuanha occurs in commerce as a dusky grey root, with a thick bark, transversely corrugated or ringed, the corrugations often penetrating to the woody interior, and minutely wrinkled longitudinally. The root attains a diameter in some cases of $\frac{2}{10}$ to $\frac{3}{10}$ of an inch, and as many as twenty rings may be counted to the inch in length. It has a short friable, not fibrous, fracture, and the bark, which constitutes some three-fourths of the root, separates easily from the wood. (*Cf.* Flück. a. Hanb. 373; Tschirch and Lüdtke, Arch. Pharm. 1888, 432.)

The drug was first introduced into Europe from Brazil about the close of the 17th century as a remedy for dysentery, and since that period it has always retained a place among articles of *materia medica.* Its employment has, however, been mainly as an expectorant and emetic, but it has frequently been used in the treatment of intestinal diseases, and its historic reputation as a remedy for dysentery has been somewhat revived in India. Applied locally the powdered root is an irritant, and in large doses it is poisonous. (*Cf.* Pereira, Mat. Med. 1853, 2, 1591; Flück. a. Hanb. 370.) It is administered either in the state of powder—for instance, admixed with opium and potassium sulphate in the well-known Dover's Powder—or made into pills, or in vinous solution. The mode of preparation of the drug for use in medicine has been much studied by pharmacists (*v.* indexes Ph. and Year-Bk. Ph.).

The root is derived from the *Uragoga Ipecacuanha* [Willd. (Baill.)], a low shrub found for the most part between 8° and 22° S. latitude, in Brazil and also to some extent in the adjoining portions of New Granada and Bolivia. The plant grows in shady forests, in valleys, but not actually in swamps. According to Balfour the plant exists in two varieties, one having a woody and the other an herbaceous stem (*cf.* Bentl. a. Trim. 145; Flück. a. Hanb. 374; Pocklington, Pharm. J. [iii.] 2, 841, 921).

The most important constituent of ipecacuanha is the alkaloid *emetine*, first obtained in an impure state by Pelletier and Magendie in 1817 (Ann. Chim. Phys. [ii.] 4, 172), and further studied by Pelletier (J. Pharm. Chim. [ii.] 3, 145; 14, 200), Pelletier and Dumas (Ann. Chim. Phys. [2] 24, 180), Merck (Neues Jour. Trommsdorf. 20, 1, 134), Buchner (Rep. Pharm. 7, 289), Landerer (*ibid.* 52, 211), Reich (Arch. Pharm. [2] 113, 193), Lefort (J. Pharm. Chim. [iv.] 9, 241), Pander (J. 1871, 373), Glénard (J. Pharm. Chim. 22, 178; Compt. rend. 81, 100), Lefort and F. Würtz (*ibid.* 84, 1299), Power (Pharm. J. [iii.] 8, 344), Kunz-Krause (Arch. Pharm. [3] 25, 461; 232, 466) and Podwyssotzky (Pharm. J. [iii.] 10, 642); Kremel (Arch. Pharm. [iii.] 26, 419).

The emetine of the earlier investigators has been shown by Paul and Cownley (Pharm. J. 53, 61; [iii.] 25, 111) to be a mixture of at least two different alkaloids; one, a base insoluble in caustic alkalis, for which it is proposed to retain the name of *emetine*; the other, *cephæline*, is soluble in caustic alkalis. These were separated from ipecacuanha by extraction with alcohol, precipitation with basic lead acetate, evaporation of the filtrate to dryness, and treatment of the residue with dilute acid; the solution was mixed with ether, ammonia added in slight excess, and shaken, and from the separated ethereal solution, dilute sulphuric acid took up the emetine, which was precipitated by adding caustic soda solution and treated further in order to entirely remove the other base. The alkaline solution when acidified and then shaken with ether and ammonia yielded cephæline. Emetine $C_{15}H_{22}NO_2$ melts at 68°, is amorphous, strongly alkaline and colourless, but turns yellow when exposed to light. It is soluble in alcohol, ether, chloroform, or benzene, but only sparingly so in hot light petroleum or in water. Cephæline $C_{14}H_{22}NO_2$ is colourless, but, like emetine, is turned yellow by exposure to light. It is less soluble in ether than emetine. It melts at 119° when all the solvent has been driven off (Frerichs and Tapis, Arch. Pharm. 240, 390).

A third alkaloid, *psychotrine*, has been isolated from ipecacuanha (Paul and Cownley, Pharm. J. [iii.] 25, 690). It exists in relatively small proportion, is characterised by its very sparing solubility in ether, and remains in the ammoniacal liquor from which emetine and cephæline have been extracted by ether. Psychotrine forms pale yellow crystals which melt at about 138°. The proportions of these alkaloids in Brazilian, Columbian, and Indian ipecacuanha are given by Paul and Cownley (Pharm. J. [iv.] 2, 321; 15, 256). Allen and Scott-Smith (Analyst, 27, 345) give a table comparing the colour reactions of emetine, cephæline, and psychotrine.

To determine the value of ipecacuanha or its pharmaceutical preparations, an estimation of the alkaloidal content is made. This is done either by a process similar to one of those given for the extraction of the alkaloid (*v.* Kremel, Pharm. Post, 21, 151) or, having obtained a suitable solution, by titration with Mayer's reagent (*cf.* Zinoffsky, Pharm. J. [iii.] 3, 342; Dragendorff, Werthbestimmung einiger starkwirkender Droguen, 1874, 37; Stewart, Amer. J. Pharm. 1876, 359; Naylor, Pharm. J. [iii.] 16, 507; Lyons, *ibid.* [iii.] 16, 627; Zeitsch. anal. Chem. 28, 258; Flückiger, Pharm. J. [iii.] 16, 643; Jones, *ibid.* [iii.] 17, 277; Alcock, *ibid.* [iii.] 16, 680; Ransom, *ibid.* [iii.] 18, 241, 400; Cripps and Whitby, *ibid.* [iii.] 19, 721; Braithwaite and J. C. Umney, *ibid.* [iii.] 20, 252, 253; Arndt, Pharm. Zeit. 1889, 585; Keller, Chem. Zentr. 1893, i. 235, 322; 1894, i. 236; J. Pharm. Chim. [v.] 27, 465; Frerichs and Tapis, Arch. Pharm. 240, 390).

Besides emetine, ipecacuanha contains a compound *ipecacuanhic acid* $C_{14}H_{18}O_7$ (Willigt, Sitz. Ber. K. Akad. Wien. 5, 192) which was thought by Pelletier (Ann. Chim. Phys. [ii.] 4, 172) to be gallic acid. It is a reddish-brown amorphous mass, with a bitter taste and very hygroscopic. It is soluble in water or alcohol, but less so in ether. With ferric chloride it gives a green colour. It reduces salts of silver and mercury, and is not precipitated by neutral lead acetate. Kunz found the root to contain *choline*. The colouring matter of ipecacuanha was examined by Podwyssotzky. It forms purple-red compounds with alkalis. From its combination with barium an acid was obtained, *erythrocephaleïn*, which crystallises from chloroform in straw-coloured needles. When the root is distilled with sodium carbonate and a little ferric chloride, a distillate is obtained from which a crystalline fluorescent *volatile alkaloid* may be isolated (Arndt, Chem. Zentr. 1889, 433; Pharm. Zeit. 1889, 585). It is present to the extent of 0·3 p.c. It forms compounds with most alkaloidal reagents, and gives a *hydrochloride* which crystallises in fluorescent octahedrons. No trace of this volatile alkaloid, however, could be found by Cripps (Pharm. J. [iv.] i. 159). Ipecacuanha also contains *gum* (Willigt), *starch*, 30 p.c. in the cortica and 7 p.c. in the woody portion (Flück. a. Hanb.), and other constituents usually found in plants. It yields about 3 p.c. of ash (Mumms, Pharm. J. [iii.] 17, 898).

For characters of allied plants, such as striated ipecacuanha, *Psychotria emetica* (Linn.), and undulated ipecacuanha, *Richardsonia grandiflora* (Cham. et Schlecht.), and others sometimes substituted for *Uragoga*, *cf.* Flück. a. Hanb. 375; Attfield (Pharm. J. [ii.] 11, 140); Planchon (J. Pharm. Chim. [iv.] 16, 404; 17, 19); Power (Pharm. J. [iii.] 8, 344); Kirkby (*ibid.* [iii.] 16, 126); Hooper (*ibid.* [iii.] 18, 317); and Ransom (*ibid.* [iii.] 18, 787). A. S.

IRETOL *v.* PHENOL AND ITS HOMOLOGUES.

IRIDIN *v.* GLUCOSIDES.

IRIDIUM. Sym. Ir. At.wt. 193·1.

The occurrence of this metal and the properties of its principal alloys with platinum will be described under PLATINUM. Its principal source is the osmiridium which is left after treatment of crude platinum with *aqua regia.*

The osmiridium is first freed from sand and certain other admixed metals by lixiviation with water, after which it is brought into a fine state of division by melting it with its own weight of lead, and once or twice its own weight of oxide of lead. The mixture is kept at red heat for half an hour, treated successively with nitric acid, and with *aqua regia*, and then sifted through fine silk. The division of the mineral may also be brought about by melting it with zinc and then removing the latter by means of hydrochloric acid or by volatilisation.

The finely-divided mineral may now be fused with barium or sodium peroxide, with sodium chloride, or with a mixture of nitre and potash, after which the mass is taken up with water containing alcohol, then with hydrochloric acid which converts the metals into chlorides. These are transformed into double chlorides by the potassium chloride, and the metals are finally separated as nitrites.

The solution of the chlorides, after standing for 24 hours, is filtered, and the filtrate treated with sodium nitrite, iron is precipitated as sesquioxide and gold (if present) as metal; on addition of soda any remaining lead, copper, and bismuth are precipitated. The solution is now made alkaline with soda and treated with chlorine at 50°–60°, whereby osmium and ruthenium oxides are volatilised. The residue is acidified with hydrochloric acid, and the iridium and rhodium are precipitated as ammonium double nitrites by means of sodium nitrite and ammonium chloride. The precipitate is filtered off, dissolved in warm hydrochloric acid, and again treated with ammonium chloride, whereupon iridium separates as ammonium iridochloride, whilst the rhodium remains in solution (Deville and Debray, Compt. rend. 1874, 78, 1502; Leidié, *ibid.* 1899, 129, 214; *ibid.* 1900, 131, 888; Quenessen, *ibid.* 1905, 141, 258; Leidié, Bull. Soc. chim. 1901, [iii.] 25, 9; *ibid.* 1902, [iii.] 27, 179; *ibid.* 1903, [iii.] 29, 801; Gibbs, J. pr. Chem. 1864, 91, 175).

The mineral may also be fused with potash and potassium chlorate; on treating the mass with water, the osmium and ruthenium are dissolved, whilst the iridium mixed with some platinum remains as a blue-black powder, which is attacked by acids, and from which the platinum may be removed by means of sulphuretted hydrogen, the iridium remaining behind as a sesquichloride.

Iridium may be separated from gold by heating the mixture in a clay crucible. The fused gold is poured off and the iridium silicate remaining is reduced (Mietzschki, J. Pharm. Chim. 1902, 15, 68).

The metal may be isolated by heating iridium ammonium chloride with reducing agents at a dull red heat (U.S. Pat. 805316, 1905).

Another method of separating iridium sometimes employed, is to mix the finely-divided osmiridium with sodium chloride in a porcelain tube and pass a current of chlorine through it. This converts the metals into chloride, and the iridium can then be separated by means of sulphuretted hydrogen (Schneider, Annalen, 1867, Suppl. 5, 267).

On account of their extreme hardness, the native grains of osmiridium are employed as such for tipping the points of gold nibs, but only a small proportion even of the few grains which occur with ordinary crude platinum are suitable for the purpose. A small quantity of osmiridium is used for pivots, &c., of watches and scientific instruments, but practically the whole is worked up for the production of iridium, which is mainly employed in alloy with platinum for the manufacture of crucibles and for many other purposes. Owing to its extreme hardness and to its power of retaining its temper and edge under conditions where steel requires constant sharpening, iridium has been employed in preference to that metal, for wire-drawing, jewellers' tools, points for compasses and watches, and for edging cutters for rubber, celluloid, &c. If the metal could be produced in quantity, it would find extended use in place of platinum for crucibles. Such crucibles possess the hardness of steel and show no alteration in weight on strong ignition, although they become bluish at a red heat from superficial oxidation, which disappears on stronger heating. With a badly regulated gas flame, a deposit of carbon is produced upon the crucible, but this readily burns off and leaves no ill effect as regards weight, appearance, or brittleness. Boiling with *aqua regia*, fusion of phosphates in presence of carbon, the heating of silica or silicates with a reducing agent, or even fusion of metallic lead or zinc in the crucibles, is without apparent action. Prolonged fusion of copper in iridium makes it brittle when hot, but if the heat be raised sufficiently to volatilise the copper, the iridium shows no ill effect.

Iridium is a white metal as bright as steel, having a sp.gr. of 22·39 (G. Matthey), and melting at about 1950°; 2150°–2250° (J. Ind. Eng. Chem. 1911, 3, 354).

Under ordinary conditions, iridium is not attacked by any acid, not even by *aqua regia*.

At a dull red heat it combines with fluorine, chlorine, or oxygen. It also combines with sulphur when heated, and gives a readily fusible compound with phosphorus, which is decomposed at a white heat.

Colloidal iridium may be obtained by mixing iridium chloride with lysalbic acid and concentrated soda, and subsequently dialysing the mixture (Paal and Amberger, Ber. 1904, 37, 124); or by reducing iridium chloride with hydrazine hydrate in the presence of gum arabic solution (Gutbier and Hoffmeier, J. pr. Chem. 1905, [ii.] 71, 452). It is a catalyst, but is not as powerful as colloidal platinum.

Iridium black is a complex mixture containing varying proportions of the metal and its oxides, obtained by reducing iridium salts with alcohol, formic acid, or formaldehyde. The black powder thus formed is washed with water and dried *in vacuô* (Böttger, J. pr. Chem. 1834, 3, 276).

It has properties similar to, but more powerful than, those of platinum black. It absorbs gases and has the property of inducing chemical action, as, for instance, the combustion of hydrogen and of alcohol, the transformation of chlorine, iodine, or bromine water into halogen acid and oxygen, the decomposition of hypochlorites, and so forth (Schönbein, Ann. Chim. Phys. 1866, [iv.] 7, 103, 113). It dissolves in *aqua regia*, as does also iridium in alloy with platinum.

Although the black iridium oxide is a valued pigment for china, the commercial use of iridium for that or other purposes other than as metal or in alloys, is practically *nil*, as the demand for the metal as such exceeds the supply. For the same reason, none of the large variety of salts which iridium forms, are of technological interest.

Iridium Compounds.

According to Wöhler and Witzmann (Zeitsch. anorg. Chem. 1908, 57, 323; *see* also Zeitsch. Elektrochem. 1908, 14, 97), the oxide IrO does not exist under ordinary conditions.

Iridium dioxide IrO_2 is best prepared by the action of alkali on a hot solution of sodium iridichloride Na_2IrCl_6, the sesquioxide first formed being oxidised to dioxide by a current of oxygen. The oxide is then dried in a current of carbon dioxide at 200°, after which it is boiled with alkali and then with sulphuric acid. The anhydrous dioxide and also the one containing 2 mols. H_2O is black. When freshly precipitated it is more readily soluble in acids and alkalis than when dried.

The solution obtained by the action of potash or sodium iridichloride in the cold, ultimately becomes violet in colour and contains the dioxide in colloidal form; after a time a violet modification of the dioxide separates, and on boiling, the solution becomes blue. The blue and green solutions of the dioxide in hydrochloric acid also contain the dioxide in colloidal solution.

Iridium sesquioxide Ir_2O_3 is obtained by mixing air-free hot solutions of sodium iridium sesquichloride $Ir_2Cl_6,6NaCl,24H_2O$, and potash in a current of carbon dioxide. The mixture is evaporated to dryness and heated to redness in a current of the same gas, after which it is purified in the same way as the dioxide. With hydrochloric acid this oxide also gives a colloidal solution. Like the dioxide, its properties depend on the proportion of water it contains. The sesquioxide imparts a fine black colour to porcelain after firing, and when mixed with zinc oxide it yields a grey tint.

Iridium trioxide is so unstable that it has not been obtained pure.

Iridium trihydroxide $Ir(OH)_3$ is a yellowish-green substance which dissolves in alkalis and oxidises rapidly in the air, forming

Iridium tetrahydroxide $Ir(OH)_4$, a heavy indigo blue powder, which becomes green, then brown on heating (Joly and Leidié, Compt. rend. 1895, 120, 1341; Gutbier and Riess, Ber. 1909, 42, 3905).

Iridous chloride $IrCl_2$ is a green, insoluble mass, formed when chlorine is passed over spongy iridium or when the tetrachloride is heated.

Iridium trichloride $IrCl_3$ is a light, insoluble, olive-green powder prepared by heating one of its double salts with sulphuric acid, and also by other methods (Antony, Gazz. chim. ital. 1893, 23, i. 184). It forms complex compounds with the chlorides of phosphorus and arsenic (Geisenheimer, Compt. rend. 1890, 110, 1004, 1336), and double salts with metallic chlorides of the type $M_3IrCl_69H_2O$.

Iridium tetrachloride $IrCl_4$ may be obtained by heating ammonium iridichloride in chlorine, or by dissolving the finely-divided metal in *aqua regia*, or the blue hydroxide in hydrochloric acid. It forms double chlorides of the type M_2IrCl_6 and with alkyl amines (Rimbach and Korten, Zeitsch. anorg. Chem. 1907, 52, 406; Delépine, Compt. rend. 1909, 149, 1072; *ibid.* 1908, 146, 1267; Vézes, *ibid.* 1392; Gutbier, Zeitsch. physikal. Chem. 1909, 69, 304; Gutbier and Riess, *l.c.*). The iridichlorides, when reduced, yield the iridiochlorides. Similar bromides and iodides of iridium also exist.

Iridium forms ammonium or ammine derivatives similar in constitution to the platinum compounds and corresponding to the chlorides $IrCl_2$, $IrCl_4$; also a series of compounds corresponding to $IrCl_3$, and analogous to the cobaltic, chromic, and rhodic compounds, thus:

When iridium chloride is treated with ammonia, double salts $Ir(NH_3)_3Cl_3$,

$$Ir(NH_3)_4,Cl_3,H_2O,$$

and $Ir(NH_3)_5Cl_3,H_2O$ are formed. Iridium ammonia chlorohydroxide, sulphate, thionate, oxalate, nitrate, and a number of halide derivatives are also known (Palmaer, Zeitsch. anorg. Chem. 1895, 10, 320; *ibid.* 1896, 13, 211; *see* also Mylius and Dietz, Ber. 1898, 31, 3187).

Complex iridium nitrites and their chloro and oxalic acid derivatives have been prepared (Joly and Leidié, Compt. rend. 1895, 120, 1341; Leidié, *ibid.* 1902, 134, 1582; Bull. Soc. chim. 1902, [iii.] 27, 936; Vézes and Duffour, *ibid.* 1910, [iv.] 7, 507, 512; Miolati and Gialdini, Atti. R. Accad. Lincei, 1902, [v.] 11, ii. 151; Werner and Vries, Annalen, 1908, 364, 77).

Iridicyanides resemble the ferricyanides and are described by Martius (*ibid.* 1861, 117, 357; *see* also Rimbach and Korten, Zeitsch. anorg. Chem. 1907, 52, 406).

Iridium sulphides IrS, Ir_2S_3, IrS_2 (Antony, Gazz. chim. ital. 1893, 23, i. 184, 190), and the ammonium pentadecasulphide $(NH_4)_3IrS_{15}$ (Hofmann and Höchtlen, Ber. 1904, 37, 245) are known.

Iridium sulphate $Ir(SO_4)_2$ is a yellow-brown mass which when warmed with sulphuric acid is reduced, giving a green solution of the sesquisulphate $Ir_2(SO_4)_3,6H_2O$ (Rimbach and Korten, *l.c.*).

Iridium sesquisulphate forms alums with ammonium, thallium, and the alkali metals, of the type $Ir_2(SO_4)_3\cdot M_2SO_4,24H_2O$ (Marino, Zeitsch. anorg. Chem. 1904, 42, 213; Rimbach and Korten, *l.c.*; Delépine, Compt. rend. 1906, 142, 631). It also forms sulphates of the type

$$Ir(SO_4M')_3,H_2O\ (?)\ \text{or}\ Ir_2(SO_4)_3\cdot 3M_2SO_4,H_2O$$

which are bluish-green in colour, and are decomposed by ammonia and alkali hydroxides with precipitation of a violet oxide of iridium. The contained sulphuric acid is not precipitated by barium (Delépine, Compt. rend. 1906, 142, 1525).

According to Delépine iridium forms two series of disulphates: (1) green salts, generally acidic, derived from the acid

$$H_2[Ir(SO_4)_2(OH)H_2O];$$

(2) reddish-brown basic salts derived from the acid $H_3[Ir(SO_4)_2(OH)_2]$ (Compt. rend. 1909, 149, 785).

He has also obtained green pyridine derivatives (*ibid.* 1910, 151, 878).

Double salts of *iridous sulphite* have been described by Seubert (Ber. 1898, 11, 1761).

Iridium selenide (Chabrié and Bouchonnet, Compt. rend. 1903, 137, 1059); *oxalates* (Gialdini, Atti. R. Accad. Lincei, 1907, [v.] 16, ii. 551, 648; Vézes and Duffour, Bull. Soc. chim. 1907, [iv.] 5, 869, 872); *phosphor halides* (Strecker and Schurigin, Ber. 1909, 42, 1768); and *mercaptide* (Hofmann and Rabe, Zeitsch. anorg. Chem. 1897, 14, 293) are known.

IRIS BLUE *v.* OXAZINE COLOURING MATTERS.

IRISH MOSS GUM *v.* GUMS.

IRON. Sym. Fe. At.wt. 55·84. *History.*—Iron has been known and prized from the very earliest historical period, articles of the metal having been found among the contents of the Great Pryamid of Egypt, where they are believed to have remained for 5000 years. Iron was also used in Nineveh in considerable quantities, and in the British Museum are picks, hammers, and saws made of iron, found by Layard in the ruins of Nineveh, and which are believed to be of a date not later than 880 B.C. Iron is frequently mentioned in the earlier books of the Bible; it was much prized by the Greeks, and was discovered by Schliemann in the ruins of Mycenæ, which was destroyed B.C. 561. The Chinese were acquainted with the use of iron at a very early period, and it was also highly valued and much worked by the Romans. The metal employed in all the above instances was obtained by direct reduction from the ore, by methods very closely resembling those still in use by semi-barbarous peoples in various parts of the world. In England iron was largely worked by the Romans, and in the Forest of Dean there are still to be seen remains of these old Roman workings, whilst the partly reduced slags left by the Romans were in more modern times employed for many years in the blast furnaces of that district as a source of iron. At the Norman invasion Gloucester possessed a considerable trade in iron, but until the introduction of coal Sussex was the chief seat of the manufacture in this country. The exact date at which the blast furnace was introduced is not known, and it was probably the result of a gradual development of the more primitive hearths formerly in use. Cast iron was, however, known to Agricola, who died in 1555, and it was employed for cannon in this country in the year 1516. At this period small blast furnaces were employed which were capable of producing about 7–10 tons of metal per week, the fuel used being charcoal. The resulting pig iron was afterwards converted into wrought iron in a finery, or small hearth, not unlike the smith's fire. The large quantities of wood employed for the production of charcoal for this manufacture led to the introduction of various Acts of Parliament during the 16th century, which had for their object the restriction of the industry to certain districts, and a diminution of the waste of valuable timber. In the early part of the 17th century Dud Dudley succeeded in 'charring' coal or producing a coke suitable for use in the blast furnace, but the use of coal did not become general until after Abraham Darby had again succeeded in the manufacture of coke at Colebrook Dale about 1730. The introduction of the steam engine by Watt led to the use of more powerful blowing machinery, and gave increased yields, which again were much improved upon by the application of hot blast in 1829, by subsequent alteration in the shape of the interior, and by the considerable increase in the size and the capacity of the furnaces. Various other improvements have from time to time been adopted, such as the utilisation of the gases from the furnace, the use of regenerative hot blast stoves, and the introduction of improved methods of calcining the ore, so that the present output of the best furnaces is about 400 times that of the blast furnaces of 200 years ago, whilst the consumption of fuel has been reduced to about one-fifth of that formerly employed. In connection with the manufacture of steel, the cementation process is in various forms of very great antiquity, but a notable improvement was effected by Huntsman, about 1740, by the introduction of cast steel, while a further advance was made in 1839, when Heath introduced the use of manganese in steel melting. As before mentioned, wrought iron was originally prepared directly from the ore, and at a subsequent date was obtained from cast iron by the use of the open-hearth finery. In 1784 Cort patented the puddling process, and in so doing laid the foundation of much of the prosperity of England during the century that followed. But in recent years the whole system of the manufacture of wrought iron has been revolutionised by the magnificent inventions of Bessemer and Siemens, by which the decarburised iron is obtained in the fluid condition. The metal then is commonly known as 'mild steel,' and has met with such a variety of applications that for rails, girders, guns, shipbuilding, bridge construction, and many other uses, it has gradually replaced the iron obtained by the puddling process.

Chief iron ores. Iron is occasionally found native, either in the form of meteorites also containing nickel, or as metal which, by the action of heat and reducing agents, has been naturally separated from the ore. These sources are, however, unimportant, except for savage tribes, who are in some instances largely dependent upon such methods of supply. Iron is very widely distributed throughout the crust of the earth in various forms. On account of its cheapness, and the readiness with which it combines with various elements, such as sulphur, phosphorus, or arsenic, which, if present in the metal, would injuriously affect its mechanical properties, comparatively few ferruginous compounds are practically available as sources of iron. It is necessary if an iron ore is to be profitably employed that the working expenses and carriage should be small, that the ore should be rich and readily reduced, and that it should be free from sulphur, phosphorus, arsenic, or other impurities which seriously deteriorate the quality of the iron. Such ores are practically either oxides or carbonates.

Oxides of iron. These may be divided into three classes.

1. *Magnetites.* Magnetic oxide of iron (Fe_3O_4) is the richest oxide of iron which occurs in nature; if pure, it would contain 72·4 p.c. of metallic iron. Its colour varies from brownish-grey to iron-black; it is brittle, magnetic, and produces a black streak. It crystallises in the cubic system, but is generally found massive. It occurs in immense quantities of remarkable purity in Sweden and on the shores of Lake Superior. The Swedish iron, which has so long been famed, is made from this ore. *Ilmenite* is an impure magnetite containing titanium, which occurs in Norway. *Franklinite*, which occurs in New Jersey, may be regarded as a magnetite in which the ferrous oxide is more or less replaced by oxide of zinc; and *Chrome Iron Ore* is a magnetite in which the ferric oxide is replaced by oxide of chromium.

2. *Red hæmatites.* Ferric oxide (Fe_2O_3) occurs in a number of forms which possess different physical characters, such as *Micaceous iron ore*, *Specular iron ore*, *Kidney iron stone*, &c. These forms differ in hardness, density, and colour, but each gives a red streak. Red hæmatite is generally very free from phosphorus, and is found in Cumberland, where it is employed in the preparation of a pig iron low in phosphorus, suitable for the ordinary, or acid, Bessemer process. In the United States a deposit of phosphoric red fossil (hæmatite) ore runs from Clinton in the State of New York to Birmingham in Alabama. Many of the ores of Spain and of the Lake Superior district, such as those of Vermillion, are also red hæmatites.

3. *Brown hæmatites.* Ferric oxide occurs associated with a variable amount of combined water in the different varieties of brown hæmatites. In colour these vary from light to dark brown, and they give a brown streak. A specially rich, pure, and easily reducible variety is now imported in large quantities from Spain, and a pure variety was formerly worked in the Forest of Dean. In Northamptonshire, Lincolnshire, &c., a brown hæmatite is employed which contains about 10 p.c. of silica and over 0·5 p.c. of phosphorus. The *minette* ores of

France and Northern Germany, in the vicinity of the Rhine, although phosphoric, and containing only about 30 p.c. of iron, are of this class, and are among the most important iron ore deposits of the world. Brown ores are also met with in considerable quantities in the United States. *Limonite, Bog iron ores,* and *Lake ores* are other examples of hydrated oxides of iron occurring in various localities.

Carbonates. These consist essentially of ferrous carbonate ($FeCO_3$), the important differences in character observed in various ores depending chiefly upon the amount and character of the impurities present. These ores are widely distributed and of great importance.

Spathic iron ore is the purest form in which ferrous carbonate occurs; it has a pearly lustre, and is generally light brown in colour. There are very extensive deposits of this ore in various parts of Europe, notably at Erzberg in Styria; the ore is usually free from phosphorus, but contains much manganese.

Clay iron stone is a less pure variety of ferrous carbonate which contains clayey matter, and was for many years the most important ore of this country; it usually occurs in the coal measures. The ore is generally dark in colour, and contains from 30 to 40 p.c. of metallic iron, associated with less manganese and more phosphorus than in the purer spathic ores.

Cleveland iron stone is a variety of clay iron stone met with in the North Riding of Yorkshire. It is generally uniform in character and contains about 33 p.c. of metallic iron; it contains little manganese, but the percentage of phosphorus is higher than in either of the ores previously mentioned, except, perhaps, in the case of the impure brown hæmatites.

Black band iron stone is an ore which occurs chiefly in Scotland and North Staffordshire. It contains a variable amount of bituminous matter which imparts a characteristic black colour, and which frequently enables the ore to be calcined without the addition of any extra fuel. In other respects black band very closely resembles clay iron stone.

In addition to the ores previously enumerated, several other materials are employed for the production of iron, such as 'tap-cinder,' which is essentially ferrous silicate, and is produced in the puddling process. In this case the product obtained is a common variety of iron known as cinder pig. Tap-cinder is only met with in quantities suitable for the requirements of blast furnaces in those districts where puddling has been conducted for a considerable period. The residue from Spanish pyrites, after the extraction of sulphur and copper, is commonly known as 'purple ore,' and has been made into bricks and used in the blast furnace. It is often used as a fettling in the puddling process.

The following table will illustrate the approximate composition of the various ores of iron. It will be understood, of course, that such materials are subject to considerable variations in character, and it has been thought better to give approximate values deduced from a number of analyses, than to introduce a mass of figures detailing actual results obtained.

APPROXIMATE COMPOSITION OF IRON ORES.

—	Magnetite	Red hæmatite	Brown hæmatite		Carbonate ores

Preparation of iron ores.—The greater part of the iron ores now raised are charged into the blast furnace without any special preparation. Anhydrous oxides, such as Lake Superior ores, do not require calcination, except in some cases, to remove sulphur. The chief European ores are, however, treated before smelting. The mechanical preparation of iron ores is very simple, and consists of a rough assortment of the size of the materials to be employed. In some cases the larger pieces are broken by hand or suitable crushing machinery, whilst in other instances the very fine ore is separated by riddles and used for other purposes, as it would be apt to choke up the blast furnace. Poor ores, such as those of Cleveland, are charged in larger pieces than the richer hæmatities or magnetites. Non-calcareous ores, which contain iron pyrites, are frequently weathered for a few months, and the sulphur becoming oxidised, passes away in solution as ferrous sulphate. Shale is also removed by weathering.

Calcination.—Many iron ores are calcined before being used in the blast furnace, the object being to remove volatile substances such as sulphur, water, carbon dioxide, arsenic, &c., and to concentrate the iron in the residue. Two other important objects are also gained by calcination; in the first place the iron is oxidised from the ferrous to the ferric condition, which prevents the formation of scouring slags, rich in ferrous silicate, during reduction in the blast furnace; and further, the material is rendered much more porous so that it is more readily acted upon by the gases of the furnace. From the above remarks it will be evident that some ores, such as red hæmatites, do not require calcination. Ores which are in a state of fine division, such as much of the ore from the Lake Superior district, are not calcined. Fine ores are frequently briquetted, and the briquettes are generally calcined before use in the blast furnace. When calcining, it is necessary to regulate the temperature as carefully as possible; with low temperatures the ore is insufficiently calcined, whilst if the heat be too great, or too much fuel is employed, the materials clot together and much of the benefit otherwise obtained is thus lost. Calcination is often conducted in open heaps, or between rectangular walls, exactly as in the case of many ores of other metals; but these methods are costly in fuel, space, and labour, and are apt to give irregular results, so are chiefly used for roasting tap-cinder in Staffordshire, or the black bands of North Staffordshire and Scotland, in which latter case the ore itself contains the necessary fuel. Kilns are now very generally employed for calcining, and in the Cleveland district the use of large circular kilns, constructed of iron lined with firebrick, is almost universal. In such kilns the ore and fuel are charged in at the top, and the calcined material removed from the bottom, the operation being continuous; in such kilns calcination is well under control, fuel is economised, and labour is saved. Rectangular kilns, fired with surplus gas from the blast furnace, have been introduced both in the United Kingdom and elsewhere.

Production of pig iron.—The ore, having if necessary been prepared as before described, is now *smelted* in the *blast furnace* to produce pig iron. For this purpose it is introduced at the top of the furnace together with the *flux* necessary to form a fluid slag (or 'cinder') with the gangue of the ore; *fuel* is also added in sufficient quantity to melt the materials and to reduce the iron. The air necessary for combustion is introduced near the bottom of the furnace, having been blown, and usually also heated, by suitable appliances. The operation is continuous, a furnace frequently working without any important stoppage for a number of years. The whole of the materials introduced into the furnace have either to be melted and flow off from the bottom as iron and cinder, or to be converted into vapour and pass off as 'waste gases' from the top.

The blast furnace.—The earliest form of blast furnace is shown in Fig. 1, which represents a form employed on the Continent for the production of wrought iron about 500 years ago. After the furnace had been heated, ore and fuel were introduced at the top, and blast from below; the result was the production of a bloom of wrought iron, which, owing to the low temperatures of such furnaces, was never melted, but was removed by taking down the brickwork at the front of the furnace. Doubtless in some of the larger furnaces of this description cast iron would sometimes be accidentally obtained, and as the value of this material for castings, and for the direct production of wrought iron by means of the finery came to be recognised, cast iron would be regularly made. This change was probably introduced early in the 16th century, and the furnaces gradually increased in size until they were capable of producing about 20 tons of pig iron per week, using charcoal for fuel. About 180 years ago coke was introduced as fuel in the blast furnace, and the size and production were slightly increased. Since this period enormous changes have been introduced, commencing with the use of coke about 1735; of hot blast in Scotland in 1829; the adoption of round and larger hearths in South Staffordshire about 1835; the utilisation of the waste gases; the largely increased height and capacity adopted in the Cleveland district shortly after 1860, and the use of hot blast stoves on the regenerative principle. A remarkable development took place in West Pennsylvania about 1890, and as a result of easily reducible ores, smaller and steeper furnaces, higher blast pressure, and increased engine power, a weekly production of nearly 5000 tons of pig iron per furnace has been attained. Fig. 2 represents a Cleveland blast furnace, the height of which would be about 80 feet, its capacity about 25,500 cub. ft., and the weekly production of pig iron varying from 500 to about 1000 tons, according to the character of the ore used, the temperature and pressure of the blast, and other circumstances. Such a furnace is closed at the top by means of the 'cup and cone' arrangement, into which the materials are charged, and delivered into the furnace at suitable intervals by lowering the moveable cone. The combustible gases are conducted by means of suitable pipes to the regenerative stoves employed for heating the blast, or to the boilers required for raising steam for the works. A portion of the gases is carefully cleaned from dust and used for power purposes in gas engines. The furnace itself is very light in construction for so large an erection, which

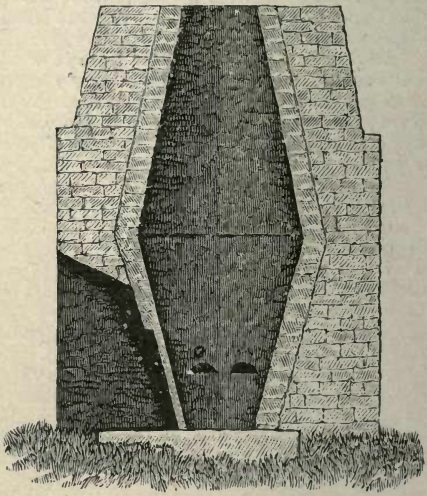

FIG. 1.

is intended to contain a great weight and to resist a very high temperature. The outer casing is of iron plates riveted together, and the furnace is lined with refractory firebrick. The blast is delivered into the furnace by about six twyers, which are connected with the hot blast main, and which are water-jacketed where they enter the furnace to prevent them being rapidly destroyed by the high temperature. The following summary will illustrate the nature of the products, and the approximate weight of the charges employed for the production of 1 ton of No. 3 Ormesby (Cleveland) hot blast pig iron :

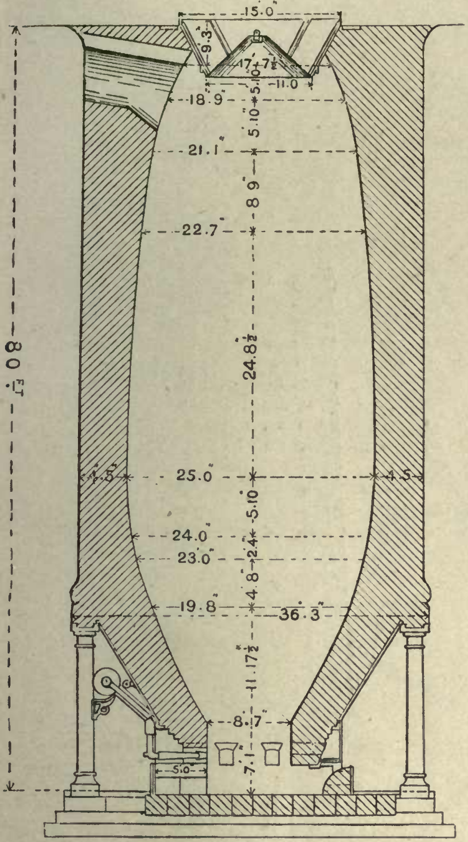

FIG. 2.

Charge	cwt.	Products	cwt.
Calcined iron stone	48	Iron . . .	20
Limestone . .	12	Slag . . .	30
Hard Durham coke	20		
Blast . .	100	Waste gases .	130
	9 tons		9 tons

In working richer ores, such as hæmatites the amount of limestone and ore employed would be less than the quantities required in the Cleveland district, and the weight of slag would be proportionately diminished. To prepare a No. 1 pig iron the quantity of fuel used would be somewhat greater, whilst with a No. 4, or a white iron, rather less fuel would be required ; the weight of the blast and of the waste gases would vary correspondingly. Usually the only material added as a flux is limestone, which is sometimes burnt before being charged into the furnace. Other fluxes are often indirectly added in the form of iron ores rich in argillaceous or aluminous matter, as mixtures of ore are frequently made to obtain a more fusible cinder. The fuel most generally used is hard coke, free from sulphur, and with as little ash as possible. Raw bituminous coal is used in Scotland and North Staffordshire and in parts of the United States, though lower furnaces are necessary as the fuel is more friable. Mixtures of coal and coke are not uncommon, and anthracite is employed in Eastern Pennyslvania. Charcoal is still used on the Continent in Sweden and in some parts of America (particularly Michigan) for the production of a superior class of iron where coal is scarce.

Any moisture which is present in the blast is decomposed in the furnace hearth, with the formation of hydrogen and carbon monoxide, and absorption of heat. Hence blast furnaces work better and more economically in cold dry weather. Gayley has successfully introduced a method of drying the blast, by refrigeration, before it is passed into the hot blast stoves. With large installations this leads to greater regularity of composition, increased output, and lower fuel consumption.

The chief changes which take place in the blast furnace may be briefly summarised as follows. The ore in the first part of its descent is rapidly heated to low redness, at which temperature the carbon monoxide, which at this point forms about 36 p.c. of the furnace gases, reduces the ferric oxide to metallic iron ; thus

$$Fe_2O_3+3CO=Fe_2+3CO_2.$$

The iron is not melted at this low temperature, but remains as a metallic sponge, which if brought in contact with the air would rapidly burn, and so reproduce ferric oxide. At a part of the furnace slightly lower than that at which reduction is chiefly accomplished the limestone is decomposed, carbon dioxide being evolved and lime produced ; thus $CaCO_3=CaO+CO_2$. During the next stage of the process, which occupies more time than either of the others, the materials gradually descend to the boshes of the furnace, and in so doing absorb heat from the ascending gases. Carbon in a state of minute subdivision produced by the reduction of carbon monoxide, is also deposited in the pores of the spongy iron, which becomes more and more carburised as it descends to the hotter parts of the furnace where fusion takes place. In passing from the boshes to the hearth the temperature is sufficiently high to cause the combination of the silica in the gangue with the lime, alumina, and other bases in the charge, and thus to form a fluid cinder, which separates from the now molten iron, the latter sinking to the bottom of the hearth, while the slag, on account of its relative lightness, floats on the top. The cinder is either tapped off at intervals, or is allowed to flow regularly off through what is known as the 'slagging hole.' The iron is allowed to accumulate, and is then tapped off from a lower point, usually at intervals of about 12 hours, into moulds roughly made in sand. The product is cast iron, but on account of its being cast in long pieces of section, which are called 'pigs,' and which generally weigh about 1 cwt. each, this variety of cast iron is commercially known as pig iron.

Chemical Properties of Cast Iron.

The metal obtained as just described is by no means pure metallic iron, but usually contains at least 5 p.c. of other materials, such as carbon, silicon, sulphur, phosphorus, manganese, chromium, &c., &c. The element which imparts the characteristic properties to cast iron is *carbon*, which is present to the extent of at least 1·5 p.c. Under ordinary conditions the maximum amount of carbon found in pig iron is 4·25 p.c., but in the presence of much manganese this amount may be considerably exceeded. The carbon is present in cast iron in two distinct conditions, known respectively as 'graphitic' and 'combined.'

Iron and carbon unite to form a definite carbide Fe_3C, and it is probable that in molten cast iron the carbon exists in solution in this form. This carbide is retained in solution if the metal is rapidly cooled, but on slow cooling, or conversely by long heating to a temperature of 900°, the carbide decomposes into the more stable condition of iron and graphite. Silicon assists the decomposition of the carbide. The graphite is of two kinds, primary and secondary. Primary graphite is formed at about 1050°, and occurs in relatively large flakes; it causes the iron to be soft and weak. Secondary graphite or 'temper carbon' is produced by decomposition of the residue of the carbide at a lower temperature (700°–800°). It is smaller, more evenly distributed, and the metal is soft but strong. The carbide may exist in solid cast iron in two forms, one of which separates at about 680° (the recalescence point), and can be seen by the microscope. The other is retained in solution at the ordinary temperature, and hence cannot be seen in micro-sections. The latter is sometimes called 'missing' carbon, as it is not determined in the ordinary Eggertz colour test.

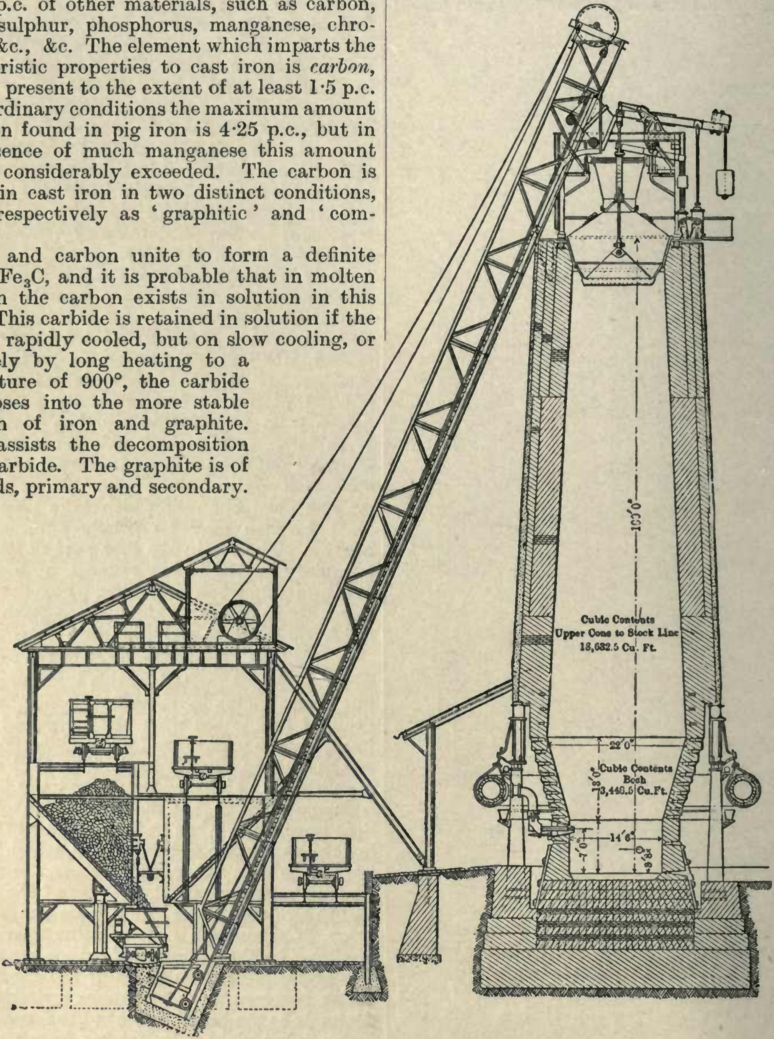

Fig. 3.—Modern American Blast Furnace with Mechanical Charging.

Graphitic carbon renders the iron *grey* in fracture, soft to the tool, and capable of taking a sharp impression of a mould. Combined carbon gives a *white* fracture, the metal is very hard, it melts at a lower temperature, but is never so fluid as in the case of grey iron. Graphitic carbon may be separated from the metal either by mechanical or chemical processes, and may be obtained in either of these ways in a state of great purity. Combined carbon, on the other hand, cannot be mechanically separated from cast iron; whilst if white iron be treated with an acid, such as hydrochloric or sulphuric, the carbon passes off in the gaseous condition, with the hydrogen evolved, in the form of badly smelling hydrocarbons. The graphitic carbon, on the other hand, would in a similar case be left behind in the insoluble residue. Iron which contains combined and graphitic carbon in nearly equal proportions has a characteristic fracture, and on this account is called 'mottled' iron. Slow cooling produces grey iron, while rapid cooling, or 'chilling,' produces white iron.

Silicon is always present in cast iron, the amount varying from about 0·2 p.c. in specially pure Swedish iron, to upwards of 18 p.c. in some varieties of 'silicon pig,' which are specially prepared for certain purposes. The average is probably from 1 to 4 p.c. When present in large proportions silicon renders the pig hard, weak, and brittle; it is also quite unsuitable for use in the puddling furnace on account of the waste of time and the injury to the lining of the furnace. Silicon, however, renders cast iron soft, strong, and grey when present in suitable proportions; and silicious irons have been largely used in the foundry on this account, as they allow of the use of larger quantities of foundry scrap, which is white and hard. They also allow in many cases of the employment of cheaper irons in foundry mixtures (Turner, Chem. Soc. Trans. 1885, 577, 902; 1886, 130). For such purposes the amount of silicon should vary from about 0·8 to 3·5 p.c., according to the size and character of the work; the lower value would be employed for chilled rolls or other purposes where crushing strength is desired, whilst the higher value would be preferred where fluidity and softness are necessary. In the blast furnace high temperatures and silicious slags favour the absorption of silicon.

Sulphur is generally present only in very small quantities in good cast iron. With much sulphur the metal is white, hard, and unsound in the foundry; and if converted into wrought iron or steel the product is red-short, and useless. In the blast furnace hot working, a slag rich in lime, and the presence of either silicon or manganese in the metal, prevents the absorption of sulphur.

Manganese is always present in pig iron; its reduction is favoured by hot working and basic slags. *Spiegel-eisen* is a white iron, containing upwards of 5 p.c. of manganese. With 20 p.c. of manganese or upwards, the metal is known as *ferro-manganese*; it frequently contains as much as 86 p.c. of metallic manganese. Both spiegel-eisen and ferro-manganese are used in steel-making, as additions at the end of the operation, the object being to add a little manganese to the bath of metal to prevent red-shortness.

Pig iron, which contains manganese, is generally low in sulphur; this fact has been applied to the production of a special pig for use in the basic process, where both sulphur and silicon are required to be present in small quantity.

Sulphur is removed from fluid cast iron for steel making by the use of 'metal mixers,' which are large vessels or furnaces capable of holding about 250 tons of fluid metal. If the iron does not already contain sufficient manganese that element is added, and manganese sulphide separates and passes into the slag. The desulphurised metal is drawn off as required and fresh iron added, so that the process is simple and continuous. Metal mixers also equalise the content of silicon, and this element may be considerably reduced in quantity by adding oxides of iron to the mixer slag.

Phosphorus varies from 0·02 in best Swedish or hæmatite iron to upwards of 3 p.c. in common cinder pig. In the case of each of the elements previously considered only a portion of that which is present in the blast furnace charge passes into the metal, but with phosphorus practically the whole of that which is present in the materials used passes into the pig iron. For foundry and forge purposes probably a little phosphorus is actually beneficial in cast iron; but in the case of wrought iron or steel its presence is highly prejudicial, as it produces remarkable brittleness in the metal when cold. Hence in the manufacture by the ordinary or 'acid' process, of either Bessemer or Siemens steel, only such pig iron as is free from phosphorus may be employed, since by the acid process no phosphorus is removed. For irons containing phosphorus the 'basic' process must be employed if they are to be converted into steel (*v. infra*, p. 171). A selection of representative analyses of cast iron will be found in Tables at the end of this article.

Grades of pig iron.—For a great number of uses pig iron is sold by the appearance on fracture. A pig which is very grey, with large crystals, is called No. 1; if the fracture shows smaller crystals it is called No. 2; with still closer grain it would be sold as No. 3 or 4. If white and grey are mixed it is called mottled; when graphitic carbon almost entirely disappears it is called white. On account of their softness and fluidity Nos. 1, 2, and 3 are chiefly employed for foundry purposes, and usually command a somewhat higher price. No. 4 is largely used in the puddling process, and would be called a forge or 'strong' iron. No. 4 is also employed in mixtures in the foundry when heavy castings are required, or when the metal is to be chilled —*i.e.* when the surface is to be rendered white and hard by cooling in contact with a mass of metal, technically known as a 'chill.' Mottled and white irons are chiefly used in mixtures of pig iron to give hardness, strength, or density.

Foundry practice.—The ironfounder commonly employs a mixture of irons, and it is the custom to mix not merely different grades of iron, but also metal from different localities. This originated at first from the results of practical experience, but it has since been shown in many cases to be in accordance with scientific knowledge, as the best foundry iron for any particular purpose contains a certain proportion of combined and graphitic carbon, silicon, phosphorus, &c. (Turner, Journ. Iron and Steel Inst. 1886), and these constituents can usually be best regulated by mixing together the irons obtained from different localities. If special strength is required the silicon should not exceed about 2 p.c., and the phosphorus should be somewhat less than half that quantity. But if softness and fluidity are specially desired these amounts may frequently be nearly doubled without serious injury. The metal is melted in a small blast furnace called a cupola, which is constructed of iron plates, lined with firebrick or ganister; it is circular in section, and is driven with a low-pressure cold blast, introduced through twyers near the bottom. The metal is charged from the top, the fuel used being hard coke free from sulphur; the weight of coke varies from about 5 to 15 p.c. of the metal used, being higher with smaller outputs. A small quantity of limestone is added to act as a flux. The metal on melting runs down, accumulating in the bottom of the cupola below the twyers, and is then tapped off at intervals into suitable ladles. For special qualities of castings, melting is sometimes performed in a reverberatory furnace; this is more expensive, but gives a cleaner and more uniform metal, which can, if necessary, be tested before use. For the majority of purposes 'green sand moulding' is adopted, a pattern being first prepared and an impression obtained in fine sand, which has been previously mixed with a small proportion of carbonaceous matter, such as coke dust. For special work, or intricate forms, other varieties of moulds are prepared, which are often of loam; these are supported by masonry, and braced with tie rods, &c., as may be found necessary. Such moulds are carefully dried before being used; in some cases drying is performed in stoves at a low red heat, in other instances by means of a fire which is placed inside the mould. In the latter case gaseous fuel is commonly employed. Green sand moulds are not dried before use; where they can be employed they have the advantages of rapidity and economy.

Iron, when remelted in the foundry, becomes harder, owing to the elimination of silicon and the absorption of sulphur. Hence in some cases, when the metal is originally too soft, a great improvement is noticed on remelting several times; but in other cases no improvement is observed, and frequently deterioration results. Many observers, among them Sir W. Fairbairn (Brit. Assoc. Report, 1853, 87), have stated that iron is improved by remelting a certain number of times, and that afterwards by further melting it again deteriorates. But the experiments of various observers gave very conflicting results in this direction, some recommending very few meltings, others a larger number. It has been shown by Turner (Chem. Soc. Trans. 1886, 493) that the effect formerly attributed to the operation of remelting is really due to the chemical changes which take place during that operation, and that the chemical composition of the product, when rightly understood, gives an indication of its mechanical properties.

Production of wrought iron.—It has already been mentioned that by the earlier processes wrought iron was produced directly from the ore. Similar processes are still carried on by semi-civilised races in various parts of the world, and in an improved form direct reduction is still practised in parts of America where charcoal is cheap, and where no ready means of transit exist. Many attempts in the same direction have also been made in various parts of Europe. In several instances great expectations have been raised in connection with these suggested improvements, but none of them has met with much commercial success. In these methods of reducing the iron ore the temperature employed is usually not sufficiently high to melt the metal obtained; the phosphorus present in the ore remains in a great measure in the slag, which is rich in oxide of iron, and the wrought iron obtained even from moderately phosphoric ores, is still sufficiently pure to be useful. The direct method is usually extravagant both in fuel and labour, whilst the slags produced frequently contain sufficient iron to make them valuable for use in the blast furnace.

Wrought iron is now generally prepared by an indirect process, cast iron being produced as an intermediate product between the ore and the finished metal. The impurities of the crude pig iron are then removed by oxidation, and pass away either in the form of gas, as with carbon, or, like phosphorus, silicon, and manganese, remain in the slag. This purification was originally performed in small hearths called 'fineries,' and for the production of specially selected metal these have survived in isolated places to the present day. But a most important change was introduced in 1784, when Cort patented the puddling process, in which the operation of purification is conducted in a reverberatory furnace. In Cort's original furnace the working bottom was made of sand, and white pig iron was employed; the iron never became perfectly fluid, and from the pasty character of the metal the 'puddling' process derived its name. This original form of the process has now almost entirely given way to what is known as 'pig boiling,' in distinction from the earlier 'dry process.' Pig boiling was introduced by Joseph Hall, of Tipton, Staffordshire, about 1820. In principle the operation is exactly the same in either case; in practice the chief differences are in the construction of the furnace, the materials forming the bottom, and the kind of cast iron employed. In the more modern process (which, however, is gradually being replaced by the use of 'mild steel') the furnace bottom is constructed of cast-iron plates, and the bridge is internally cooled either by air or water; the cast-iron bottom plates are covered with a layer of oxide of iron about 3 inches thick, which forms the working bottom of the furnace; the sides are formed of fettling, also consisting essentially of oxide of iron; the metal used is a grey iron, usually what is known as a No. 4 forge quality. The result of these changes is that the furnace works with fewer repairs; that, owing to the use of oxidising fettling, the operation is conducted more rapidly, and larger charges can be employed; whilst, as grey iron is used, the metal is perfectly fluid when melted, and 'boils' vigorously during the elimination of the carbon. A sketch of the furnace is given in Fig. 4.

The operation is conducted as follows. The furnace being at a red heat from the previous charge, the fettling is repaired, as necessary, by the addition of 'bull-dog,' pottery mine, hæmatite, or other forms of oxide of iron. About 4 or 4½ cwts. of pig iron are then charged on to the bed of the furnace, the door being closed and the temperature raised while melting proceeds. After about 30 minutes the iron is generally melted, and is then kept fluid and well rabbled for about 10 minutes, the length of time depending very much on the composition of the metal employed. By this time practically the whole of the silicon will have been removed, and much of the manganese. The temperature is then lowered somewhat, by regulating the damper, and a violent reaction ensues between the oxygen of the fettling and the carbon in the metal. The iron boils vigorously owing to the escape of carbon monoxide, which burns in jets at the surface, and a quantity of slag, called tap cinder, is removed, part of this being allowed to boil over the fore plate of the furnace, and the remainder being tapped out at the end of the operation. The phosphorus gradually passes out during the process, being eliminated most rapidly at this stage, and passing into the tap cinder. After the boiling stage is over the metal 'drops' and 'comes to nature'—*i.e.* granules of malleable iron gradually separate, and the whole becomes quite pasty. In this condition it is 'balled up' by the puddler into blooms, each of which is somewhat under 100 lbs. in weight. These are then hammered and rolled, forming 'puddled bar,' which is not yet fit to be sent into commerce. The whole operation of puddling usually occupies about 70 minutes. Analyses of forge irons, puddled bar, &c., are given in Tables at the end of this article. The puddled bar is cut up into lengths and made into suitable bundles called 'piles,' which are reheated in a furnace, which is larger but otherwise very similar in construction to that in which the puddling operation is conducted. The piles are withdrawn at a welding heat, and hammered or rolled to produce merchant iron, best iron, best best iron, &c., according to the quality and the amount of work expended on the material. A number of attempts have been made to introduce mechanical contrivances to replace the laborious process of puddling; but, after numerous trials, these have been almost entirely abandoned in this country, though a revolving furnace invented by Danks was successfully used in America. Wrought iron was formerly used for ship building, bridge construction, rails, armour plates, and similar purposes, for which it has since been replaced by steel. Wrought iron is now chiefly employed for purposes which require a reliable metal which can be easily welded or otherwise worked by the smith. It is also used for tubes, wire, sheets, and fittings which are exposed to atmospheric oxidation.

Steel. Steel was formerly defined as a variety of iron which contained from 0·5 to 1·5 p.c. of carbon, and which was capable of being hardened and tempered. This definition, however, has now to be extended so as to include various forms of 'mild steel' which contain under 0·5 p.c. of carbon, and which cannot be hardened. We therefore include under the designation of 'steel' all metal which, though containing under 0·5 p.c. of carbon, has been produced in the molten condition. In such a classification wrought iron is obviously excluded, as it is produced in a pasty form. The characters of steel depend largely on the proportion of carbon and other elements which enter into its composition. With low percentages of carbon the metal possesses great ductility, moderate tenacity, and very slight power of hardening. With 0·45 p.c. of carbon the ductility is somewhat less, the tenacity greater, whilst its hardening power is quite appreciable. Such a metal would be employed in the manufacture of rails and for similar purposes. With from 0·6 to 1 p.c. of carbon the ductility is still lower, whilst the tenacity reaches upwards of 40 tons per square inch of section, and a metal is obtained which can be readily hardened and tempered. This class of steel is largely used for cutting tools, drills, dies, &c., and for best purposes is still usually produced in crucibles. With carbon from 1 to 1·5 p.c. a steel is obtained which is suitable for the hardest tools, and which requires to be very skilfully hardened and tempered. As the proportion of carbon increases, the steel requires to be worked at a somewhat lower temperature. With upwards of 1·5 p.c. of carbon the metal is brittle, is no longer capable of being hardened, it is more fusible, and thus gradually passes into cast iron. Hardening increases the tenacity of steel, but diminishes its ductility. The tenacity of steel, like that of wrought iron, is also increased by the amount of work done in rolling or in drawing out the metal into wire, and certain varieties of steel wire are prepared which have a tensile strength of upwards of 100 tons per square inch. The presence of manganese in steel increases its tenacity; in suitable proportions it also very materially improves the working properties of the metal, and on this account is employed both in crucible steel making and in the Bessemer and Siemens processes. In large quantities manganese renders steel permanently harder, and also causes it to be unmagnetisable (Hadfield). 'Manganese steel' contains about 10 p.c. of manganese. It is permanently hard, and is used chiefly in the form of castings for tramway points, stamp batteries, and many similar purposes. Phosphorus renders steel cold-short, and should on this account not exceed 0·1 p.c., whilst crucible steel of special quality usually contains not more than 0·04 p.c. of phosphorus.

Sulphur renders steel red-short, and should never exceed a few hundredths per cent. Silicon in the absence of any reducing agent forms silica, which renders mild steel red-short and brittle, although the presence of manganese very much modifies these effects, so that with about 0·5 p.c. of manganese several tenths per cent. of silicon may be present without injury. In steel castings about 0·3 p.c. of silicon is frequently added to promote soundness. Arsenic renders steel both hot- and cold-short; practically the whole of the arsenic present in the blast furnace charge passes into the pig iron, and is not removed during conversion into steel (*v.* Stead, also Harbord & Tucker, Jour. Iron & Steel Inst. 1888, part 1). Chromium in small quantities gives increased tenacity, and on this account is frequently added to basic or other very mild steel so as to impart greater strength. With considerable proportions of chromium the welding power of steel is much reduced. Chromium is added to steel shells as the penetrating power is thereby greatly increased. Aluminium is frequently used for addition to fluid steel for deoxidising purposes. It assists in the production of solid ingots, and prevents segregation of the impurities. The amount of aluminium left in the steel is, however, so small as to be with difficulty estimated by analysis. Nickel is added to mild steel for shipbuilding and constructional purposes, usually to about the extent of 3·5 p.c., as it imparts increased tenacity with unusual ductility. With higher proportions of nickel hard non-magnetic alloys are obtained, which are only used for certain special purposes. In recent years tungsten has been used on a very considerable scale for the production of self-hardening and other 'special' steels. Usually about 6 or 7 p.c. of tungsten is added; the steels are made in crucibles, and contain from 1 to 2 p.c. of carbon. Vanadium is also added to mild steels with marked advantage, a very small percentage giving improved physical properties. Much attention is now being devoted to the production of special alloy steels for a variety of purposes.

Manufacture of steel.—A variety of steel, or more correctly steely iron, was obtained by the earlier processes used for the production of wrought iron directly from the ore, when the process was modified by altering the amount of blast used, and the angle at which it was introduced, together with a slight increase in the quantity of fuel employed. By these means the metal prepared contained sufficient carbon to impart steely properties, although when obtained by such methods the steel is never of uniform quality. A steely iron was also frequently prepared in the puddling furnace when the process was carried on in such a manner as to remove the metal before the carbon was completely eliminated. But for some centuries at least the best varieties of steel have been prepared by what is known as the 'cementation' process. For this purpose, bar iron of the best quality is cut up in suitable lengths and placed in charcoal in the cementation furnace. This furnace consists essentially of two rectangular chambers which are constructed of firebrick, and are arranged to contain the iron and charcoal. The charge of iron used in one operation is generally about 15 tons. A fireplace under the chambers supplies the necessary heat, whilst the whole is contained in the base of a large conical chimney stack. The iron is carefully arranged and surrounded with charcoal, the rectangular chests, which are open at the top, being covered with 'swarf' to protect the contents, as far as possible, from oxidation. The heat is continued for about 7 days, although the time will vary somewhat with the temper required and other circumstances. The progress of the operation is judged by the appearance of the fracture of trial bars, which are removed and examined from time to time. The product is known as 'blister' steel, the name being derived from the characteristic appearance of the surface. Percy has shown that this is probably due to carbon monoxide evolved at a high temperature by the action of carbon on the oxygen of the intermingled slag. In good blister steel the protuberances should be as evenly distributed as possible. When fractured, the blister steel is generally found to consist of an outer crystalline layer of steel surrounding an inner portion of less altered iron. The exact theory of cementation has not been made out with certainty, although Roberts-Austen showed that pure iron became carburised when heated with a diamond *in vacuô*; but under usual conditions carbon monoxide is known to play an important part in the process. The result is that the metal, when heated in contact with solid carbon, becomes gradually carburised on the outside, and if the heating be continued for a sufficient length of time, carburisation gradually extends throughout the whole of the mass. Blister steel, when piled and reheated, is known as 'shear' steel, and gains considerably in uniformity by the treatment. The name is derived from the fact that shears used for cutting woollen cloth were formerly made of this variety of steel. But for best steel for tools and other purposes it is usual to employ 'cast steel,' the best qualities of which are prepared by melting blister steel in clay or plumbago crucibles. The charges usually weigh somewhat less than 100 lbs., a little glass or other flux is employed, and the crucible is kept covered while melting proceeds. Heating is conducted usually in wind furnaces, using coke as fuel, though gaseous fuel has also been employed. It is contended that gaseous fuel has the advantage of being more under control; it is also economical in working, and enables the process to be carried on continuously, whilst the wind furnace 'clinkers' up and has to be stopped for cleaning. Cast steel is also prepared in crucibles from materials other than blister steel, but the product is usually of an inferior character. It is found advantageous (especially with cheaper mixtures) to introduce a little manganese in the production of crucible steel, as the metal then possesses better working qualities. The 'body,' which is so characteristic of good steel, appears to be closely connected with its chemical composition, and is associated with special freedom from phosphorus and similar impurities. Crucible steel contains a few hundredths per cent. of silicon, which is reduced from the silicious material of the crucible during the melting, and which appears to play an important part in producing solid castings. For special purposes, in recent years, considerable quantities of manganese, chromium, tungsten, and of other elements have been added to steel produced in the crucible, and the 'special' steel industry has become important both in this country and abroad.

Bessemer steel. The method of producing steel with which the name of Bessemer will always be connected, and which has done so much to revolutionise the iron trade of the world, was described and patented in 1856. At first great incredulity was manifested by ironmasters, and the product was inferior; but when it came to be recognised that only iron free from phosphorus could be employed in this process, and that the red shortness which at first had been so difficult to overcome could be removed by the addition of manganese before tapping the metal, the success of the process was assured. The iron now used in the ordinary, or as it has come to be called the 'acid' Bessemer process, is of special quality, and is made from ores of hæmatite quality. It should contain only a few hundredths p.c. of phosphorus, and about 1-3 p.c. of silicon. With rapid working, as in the large American works, the silicon is about 1 p.c. lower than is the custom where fewer charges are run in the same time as in England. The metal is either remelted in a cupola or is run in the fluid state from the blast furnace, or the metal mixer, according to circumstances, but in any case is introduced in the molten condition into an egg-shaped vessel known as a 'converter,' and which has been heated either by a previous charge or by lighting a fire inside. The converter is constructed externally of iron plates, and is arranged so as to rotate on trunnions which are fixed on either side a little below the middle of the vessel. By this arrangement the converter can be readily manipulated as required during the process. At the lower part of the vessel is a moveable bottom, fitted with a blast box into which air is admitted during the 'blow' at a pressure of about 20 lbs. to the square inch. From the blast box the air enters the vessel through a number of holes passing through a fireclay or ganister bottom lining. The sides of the converter are generally lined by means of ganister (a silicious or 'acid' material) which is generally rammed into position. At the top of the converter, a little on one side, is an opening which serves for the introduction of the metal in the first place, then for the escape of waste gases during the blow, and lastly for the tapping of the metal and slag when the operation is concluded. The charge of pig iron, which weighs from about 8 to 12 tons, is introduced while the vessel is in a horizontal position, in order to avoid closing the twyers at the bottom; the blast is then turned on and the vessel rotated so as to cause the blast to rise through the bath of metal. The silicon present is rapidly oxidised and passes into the slag, at the same time producing sufficient heat, not merely to maintain the fluidity of the metal, but actually to very much increase its temperature. After the silicon has in this manner been removed, which generally occupies about 10 minutes, the carbon is attacked, and this is rendered evident by a marked increase in the size and luminosity of the flame produced. This flame continues for rather more than 10 minutes, and then, when the carbon has been burned out, suddenly 'drops,' *i.e.* becomes much smaller and less luminous, showing that the operation is concluded. During the whole of the blow the metal remains molten, and the temperature produced by the combustion of the carbon and silicon is so great that the resulting decarburised metal can be readily poured into suitable ingot moulds. But if used in this form, when it is almost perfectly freed from carbon and manganese, the metal would be red-short, and would also be too soft for many purposes. It is usual, therefore, after the flame has dropped, to add a quantity of spiegeleisen or ferro-manganese in order to counteract this red-shortness and to introduce the required amount of carbon. After the requisite addition has been made the metal is allowed to stand a few minutes so as to some extent to mix the constituents; it is then 'teemed' into the ladle and thence cast into ingots.

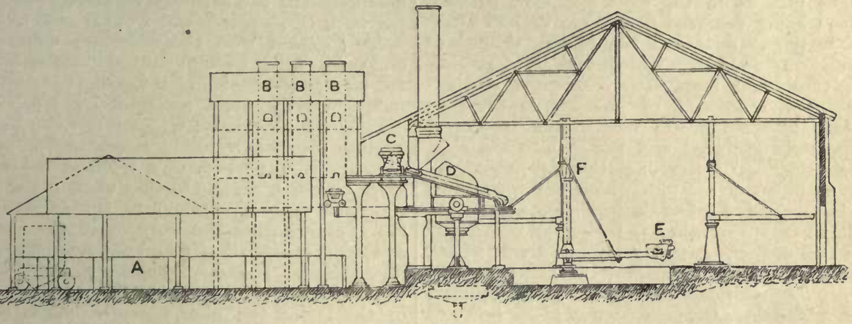

FIG. 5.

A, Shop for preparing Basic Lining; B, Cupolas for calcining Dolomite and remelting Iron; C, Ladle for Cast Iron; D, Bessemer Converter; E, Steel Ladle; F, Ladle Crane.

The basic Bessemer process.—It will be noticed that in the original Bessemer process the vessel is lined with silicious or acid materials, and only cast iron free from phosphorus can be employed, as practically none of this element is removed during the blow. But a modification of the process was introduced by Messrs. Thomas and Gilchrist, which most successfully solved the problem of the treatment of phosphoric iron. Fig. 5 (after A. Holley) shows the general arrangement of a basic Bessemer works. The mechanical arrangements of the plant and general principles involved in the two processes are exactly alike, with the exception that the lining used in the basic process is a mixture of lime and magnesia, obtained by calcining dolomite. This is mixed with dry tar in suitable proportions so as to make it bind, and is then either rammed into shape with hot tools, or pressed into bricks and baked as may be most convenient. The cast iron used should be as low in silicon as possible, on account of the injurious action of a silicious slag on the basic material of which the lining is composed. The phosphorus, on the other hand, may be as high as 3 p.c. without exerting any injurious effect on the finished product. To ensure low sulphur while the silicon is also low, about 1·5 p.c. of manganese is usually introduced into the iron. In modern works the proportions both of silicon and of sulphur are reduced and rendered more uniform by the use of a metal mixer. The 'blow' is conducted in the early stages just as in the acid Bessemer process, silicon being removed first while carbon afterwards passes out, and the flame 'drops' as before. Lime is then added, and an after-blow is given, which lasts some 5 minutes, depending on the amount of phosphorus present; during this stage the phosphorus is almost completely removed and passes into the slag. The progress of the operation is judged by means of small samples which are withdrawn and examined at intervals during the after-blow. When ready, the metal is tapped as usual, and the product is a specially mild and soft metal. The slag is used, when ground to fine powder, as a phosphatic manure; it has also been used as a material for the construction of the bottoms of reheating furnaces (Harbord and Tucker's patent). The basic Bessemer process is applied on a large scale in this country, but is used still more extensively on the Continent, especially in the large steel works in the district around Düsseldorf on the Rhine.

In Bessemer's earlier experiments small converters were employed; some of which were moveable, whilst others were fixed. Both of these forms have been recently reintroduced, and small converters have met with considerable favour for special purposes, particularly for the production of steel castings.

Siemens steel. Numerous attempts have been made to prepare steel by decarburising cast iron by some method other than that previously described; but the only successful rival to the Bessemer process was originated by the late Sir William Siemens. The invention of the Siemens furnace, with the accompanying gas producers and regenerators, placed in the hands of the practical man the successful application of a beautiful scientific principle which has been largely used in many branches of manufacture, such as the production of glass, porcelain, and pottery; for the reheating of iron and steel, and for numerous other purposes. Space will not here allow of the description of the apparatus, and it will only be necessary to mention that by this means a temperature can be easily and economically obtained, which is amply sufficient to melt wrought iron, and to enable it to be readily poured when melted. Apart from the method used in heating the furnace, the Siemens-Martin process (which was invented by Siemens, and rendered commercially successful by Martin) closely resembles in principle the original puddling process. The furnace is of the same general shape as the puddling furnace, but is capable of working a charge of from 5 to upwards of 50 tons. The external portions are of cast iron lined with very refractory silicious firebrick, while the working bottom is of refractory sand. The pig iron to be used is charged first, and the malleable iron and iron ores which are added to decarburise the pig iron are introduced at suitable intervals during the operation, which generally lasts about 8–10 hours. Several modifications of the process have been introduced, it being convenient sometimes to omit either the malleable iron or the ore, whilst in some cases malleable iron or steel scrap only has been used (Martin's process). In any case, so long as a silicious lining is employed, the materials used must be as free as possible from phosphorus. The *basic process* is also conducted in the Siemens furnace, phosphoric pig iron, or similar metal from a mixer, being used, together with the necessary steel scrap and ore or other ferruginous oxidising materials. In larger establishments hand charging has now generally been replaced by mechanical appliances. For basic working the chief modification introduced is the substitution, for the ordinary silicious bed, of a working bottom of basic material, similar to that used in the basic Bessemer process. Quicklime is also added to the charge during the working of the heat so as to ensure a basic slag and the removal of the phosphorus. The open hearth process differs from the Bessemer basic process in that while in the latter the phosphorus remains in the fluid metal until practically all the carbon has been eliminated, in the open-hearth process, on the other hand, much of the phosphorus is removed during the earlier stages of the operation. If the acid Siemens furnace may be regarded as a large puddling furnace with gaseous fuel, working on Cort's original lines, except that the temperature used is sufficiently high to melt the resulting malleable iron and so produce mild steel, then we may consider the basic Siemens process as closely resembling the 'pig boiling' of more recent times, except that, as in the previous case, the operation is on a much larger scale and the product is in a molten condition.

As compared with the Bessemer process the Siemens, or as it is frequently called, the 'open hearth' process, possesses the advantage that it is more under control, and for this reason is frequently preferred when work of a specially uniform character is required; it is also more in favour for steel castings. Further, it permits of the use of considerable quantities of scrap, which is relatively cheap, and would otherwise be a drug on the market. It also gives a greater yield per ton of metal used. This extra yield often more than pays for the cost of fuel used. The Bessemer plant, on the other hand, gives more rapid working, and hence is preferred for large outputs. There is little doubt that equally good steel may be produced by either of the processes, though the pneumatic method requires very careful attention when special uniformity is desired. In the United

Kingdom the acid Siemens process is most important; in Germany the basic Bessemer is chiefly used; in America the two processes employed are the acid Bessemer for rails, &c., and the basic open hearth for structural materials. From the metal which is slightly too phosphoric to be used in the acid process an excellent steel is made in the basic open hearth furnace.

The Talbot process. In this important modification of the open hearth basic process a large tilting furnace of cylindrical form is heated at either end by gaseous fuel and regenerators. The vessel, which holds about 150 tons of fluid metal, is basic lined and a slag rich in molten oxides of iron is maintained. Some 20 tons of metal is added to the contents of the furnace and a reaction is set up as a result of which silicon, carbon, and phosphorus are removed, and fluid steel remains. Metal is run off into the ladle as required for the rolling mills, and fresh iron poured in from time to time. The process is thus continuous, and the furnace works from week to week without stopping. The fuel consumption is low, the yield good, repairs are diminished, whilst steel of excellent quality can be produced from phosphoric ores.

Malleable cast iron. For many purposes where a complex form is necessary, and only moderate strength is required, the articles are cast in green sand in the ordinary way, but a special variety of pig iron is used, low in silicon, phosphorus, and manganese. The castings so prepared are white, hard, and brittle; but when heated, in contact with oxide of iron, in covered cast-iron boxes, to a cherry-red heat for about 48 hours, they become grey and soft. The softness so developed is accompanied with considerable malleability, so that the articles can be readily worked under the tool and punched, planed, &c., as required. Malleable cast iron, however, will not weld like ordinary malleable iron. This process is chiefly conducted in this country in the Midlands, particularly at Walsall and Birmingham, and the heating in contact with oxide of iron is known technically as 'annealing.' A portion of the graphite is removed by oxidation, and the rest, having been thrown out of solution at about 900°, exists as secondary graphite, or 'temper' carbon. In recent years the malleable cast iron industry has reached very large proportions in the United States, the output being now about ten times as great as that of the United Kingdom. The castings are generally produced from metal low in sulphur and melted in the hearth of an acid Siemens furnace. The annealing occupies a shorter time, less graphite is removed by oxidation, and the product is known as 'black heart' castings.

Tin plates. In order to protect iron from oxidation it is frequently covered with a thin layer of metallic tin. This is chiefly applied to the protection of thin plates of iron, which are first rolled in the ordinary way, and, after a preparation (including 'pickling' in dilute sulphuric acid, annealing, and cold rolling) in order to obtain a suitable surface, the plates are immersed in a bath of molten tin which is kept covered with grease. In this way a thin coating of tin adheres to the surface of the iron and protects it from oxidation so long as the iron is completely covered. In case the tin is removed from any part of the surface, however, oxidation takes place more readily than in the original metal. For this reason galvanised iron is to be

preferred for purposes where iron has to be exposed to atmospheric action, and where there is no chance of articles of food coming in contact with the zinc. Tin plates are largely manufactured in South Wales, and were formerly made from an iron possessing special malleability, and which was prepared in the old-fashioned open hearth. At present tin plates are prepared from mild steel, chiefly that produced by the Siemens process. (For details of preparation *v.* Tin plates.)

Galvanised iron. Iron which has to be exposed to the weather or other oxidising agencies is frequently galvanised, *i.e.* covered with a thin coating of metallic zinc. In this case the metal is previously cleaned from scale, &c., by being 'pickled' in hydrochloric acid, and after cleansing the article is immersed for a few moments in a bath of molten zinc, which is kept covered with a little ammonium chloride. By this means a uniform covering of zinc is obtained, which protects the iron underneath, not merely so long as the coating is perfect, but also when zinc has been partly removed. Galvanised iron, however, cannot be used in contact with either mineral or vegetable acids, and hence is not employed for cooking utensils, nor for the cans in which food is preserved.

Iron can also be coated with zinc by heating at a moderate temperature with zinc-dust; this process is known as 'sherardising.' (For further details *v.* ZINC.)

COMPOUNDS OF IRON.

Oxides. Three oxides of iron are known:—

Ferrous oxide or iron monoxide FeO;

Ferric oxide or iron sesquioxide Fe_2O_3;

Ferroso-ferric oxide or magnetic oxide of iron Fe_3O_4.

The trioxide FeO_3, which may be considered to exist in the ferrates, has not been isolated.

Iron monoxide or **ferrous oxide** FeO is a strong base. It may be prepared by the reduction of the sesquioxide in a current of hydrogen at 300°. On exposure to air it oxidises with incandescence, but loses this property when allowed to remain for 12 hours in an atmosphere of hydrogen. It is also obtained as a black, velvety powder by adding ferrous oxalate to boiling caustic potash solution; when washed with water in air it takes up oxygen. Ferrous oxide is also formed by the action of nitrous oxide on metallic iron at 200° (Sabatier and Senderens, Compt. rend. 1892, 114, 1429).

The hydrated oxide $Fe(OH)_2$ is precipitated on addition of caustic soda to a ferrous salt in absence of air. When absolutely pure the precipitate is white, but it rapidly absorbs oxygen, acquiring a greenish hue and becoming ultimately converted into the red sesquioxide. It crystallises from a strong caustic soda solution in flat, pale green prisms (de Schulten, Compt. rend. 1889, 109, 266).

Ferrous oxide absorbs carbon dioxide with avidity. It dissolves in about 150,000 parts of water. It is used to impart a green colour to glass, which at the same time becomes athermanous, transmitting but little heat (Zsigmondy, Dingl. poly. J. 287, 17 *et seq*).

Ferroso-ferric oxide, *Magnetic oxide, Black oxide* $FeO{\cdot}Fe_2O_3$ or Fe_3O_4, occurs in nature as *magnetite* (*magnetic iron ore* or *lodestone* (*q.v.*)) in most parts of the world, and constitutes one of the most important ores of iron. It is always attracted by the magnet, but does not always possess the property of attracting iron. It may be prepared by passing steam or carbon dioxide over red-hot iron. It is probably a coating of this oxide which renders iron 'passive,' or unacted upon by concentrated nitric acid or water. This property is taken advantage of in the Bower-Barff process for preventing the rusting of iron, in which the metal is heated to redness and subjected to the action of steam.

When pure this oxide is an iron-black substance having a sub-metallic lustre. Its sp.gr. is 5·18, and its melting-point is 1527° (Kohlmeyer, Metallurgie, 1909, 6, 323).

The oxide is soluble in strong acids, the solutions containing a mixture of ferrous and ferric salts. By adding caustic alkali to such a solution or to a mixture of ferrous and ferric chlorides in proper proportions, a black precipitate of *ferroso-ferric hydroxide* is obtained, which, on drying in air, yields a brown-black, brittle mass, stable in air, which is magnetic, and may thus be separated from admixed ferrous and ferric oxides. It has the composition $Fe(OH)_2{\cdot}Fe_2O_3$.

Iron-scale is a compound of ferrous and ferric oxides in varying proportions. The inner layers are not magnetic, and approximate in composition to $6FeO,Fe_2O_3$; the outer layers of the scale are magnetic, and contain a larger proportion of ferrous oxide.

Iron sesquioxide or **ferric oxide** Fe_2O_3 occurs anhydrous as *hæmatite*, sp.gr. 5·19–5·25, *specular iron ore*, *kidney ore*, and *micaceous iron ore*, and, in the hydrated condition, as the yellow or brownish *limonite* $2Fe_2O_3,3H_2O$, of which *bog iron ore*, *pea iron ore*, and certain *clay iron stones* are earthy varieties. *Göthite* Fe_2O_3,H_2O and *targite* $2Fe_2O_3,H_2O$ are other forms in which the hydrated oxide occurs. The earthy varieties of hæmatite are known as *reddle* or *raddle*, and as *red ochre*, and are used as pigments; the earthy varieties of limonite being similarly used under the names *yellow* and *brown ochre*.

The anhydrous oxide may be obtained by heating the hydrated oxide or a ferrous or ferric salt containing a volatile acid. The latter method is the one principally used for the preparation of the commercial oxide, the salts most used being the sulphate or the chloride obtained from the 'pickling' of iron in the process of galvanising.

It may be prepared in small crystals by passing the vapour of ferric chloride over heated lime. The ignited or native oxide is slowly soluble in acids, the best solvent being a mixture of 8 parts sulphuric acid and 3 parts water.

Ferric oxide crystallises in tabular rhombohedral scales of sp.gr. 5·17, having a steely lustre. At the edges the crystals transmit light of a ruby-red colour. The solidifying-point of the molten oxide is 1562°–1565° (Kohlmeyer, Metallurgie, 1909, 6, 323).

Heated in the electric furnace or in the oxyhydrogen flame it yields the magnetic oxide (Moissan, Compt. rend. 1892, 115, 1034; Read, Chem. Soc. Trans. 1894, 314). Usually it is very slightly paramagnetic, but it is more strongly magnetic if prepared by the oxidation of ferrous hydroxide (Malaguti, Compt. rend. 1862, 55, 350). Walden states that at 1350° the dissociation pressure of the oxide is about equal to that of the oxygen in the air (J. Amer. Chem. Soc. 1908, 39, 1350).

The residue obtained in the manufacture of Nordhausen sulphuric acid by distillation of ferrous sulphate consists of this oxide, and is known as *colcothar*, and is largely used as a pigment. On account of the absence of grit it is used as polishing *rouge*; the parts which are of a scarlet colour—*i.e.* which have not been strongly heated—being preferred for glass polishing and for jewellery, &c., whilst the more strongly heated parts, which possess a bluish tint, are employed under the term *crocus* for polishing metals. It has been shown that these variations in colour are due to the varying size of the grains (Wohler and Condrea, Zeitsch. angew. Chem. 1908, 21, 481).

Ferric oxide acts as a catalyst in promoting the combination of sulphur dioxide and oxygen, and a process for the preparation of sulphuric acid has been based upon this reaction (Lunge and Reinhardt, Zeitsch. angew. Chem. 1904, 17, 1041; *see* also Keppeler, d'Ans, Sundell, and Kaiser, *ibid.* 1908, 21, 532, 577; Keppeler and d'Ans, Zeitsch. physikal. Chem. 1908, 62, 89). This oxide is also used in some forms of accumulator (*see e.g.* D. R. PP. 180672 and 190236; also Peters, Chem. Zentr. 1908, i. 213).

The use of ferric oxide for standardising solutions of permanganate has been proposed by Brandt, who describes a method for the preparation of the pure substance (Chem. Zeit. 1908, 32, 812 *et seq*).

Ferric oxide is invariably present in considerable quantities in *copper paint* (*v.* COPPER OXIDES).

This oxide may be combined with the monoxides of calcium, magnesium, zinc, copper, and other metals. The resultant oxides, which are prepared usually by fusing the mixed oxides, are always magnetic, and correspond in composition with the magnetic iron oxide. The oxide containing magnesium $Fe_2O_3 \cdot MgO$ occurs naturally as *magnoferrite*, and that containing zinc and manganese is found as *Franklinite* (*see* Percy, Phil. Mag. 1873, [iv.] 45, 455; and List, Ber. 1878, 11, 1512).

Solutions of alkali ferrites are obtained by boiling solutions of the ferrates or by boiling ferric hydroxide in strong caustic alkali solution (Haber and Pick, Zeitsch. Elektrochem. 1900, 7, 215; 1901, 7, 724).

The hydrated oxide is best prepared by precipitating a solution of ferric chloride with excess of ammonia. It forms a bulky, brown, slimy precipitate, which shrinks considerably in drying. It slowly gives up its water at 320°, and if heated to dull redness when anhydrous, suddenly contracts and glows brightly, becoming much less soluble in acids; this is probably due to an allotropic change which is known to take place at 640° (Keppeler and d'Ans, Zeitsch. physikal. Chem. 1908, 62, 89; *see* also *ibid.* 641).

Freshly precipitated ferric hydroxide when heated with water under a pressure of 5000 atmospheres gives the following products:—

At 30°–42·5° limonite,

At 42·5°–62·5° göthite,

And above 62·5° targite or hydrohæmatite (Ruff, Ber. 1901, 34, 3417).

A 'yellow hydrate,' which, under these conditions is unchanged between 40° and 70°, can be obtained by the oxidation of moist ferrous hydroxide or carbonate (Muck, Zeitsch. Chem. 1868, [ii.] 4, 41; Tommasi, Ber. 1879, 12, 1299, 2334).

When the hydrated oxide is merely allowed to remain for some months under water, a crystalline powder containing $Fe_2O_3(OH)_6$ is obtained which corresponds to the native limonite. This hydrate is the colouring ingredient of yellow clays, &c., and constitutes the precipitate from chalybeate streams. It may also be obtained by precipitation from a cold solution of a ferric salt and drying, without the aid of heat, over sulphuric acid.

The freshly precipitated oxide is readily soluble in acids and in concentrated solutions of ferric salts. The solution in ferric chloride, when containing excess of oxide, may be slowly dialysed with separation of a dark red liquid in which the ratio of chlorine to iron corresponds to the composition $82Fe(OH)_3 : FeCl_3$ (Linder and Picton, Chem. Soc. Trans. 1905, 1920). A similar solution containing a small amount of acetate is prepared by dialysing ferric acetate, and is used medicinally as *dialysed iron* or *liquor ferri dialysati.*

A colloidal solution of pure ferric hydroxide may be obtained from the dialysed solution containing chlorine by electrolysis under special conditions (Tribot and Chrétien, Compt. rend. 1905, 140, 144). The solution is gelatinised by alkalis and by many acids and salts, even in very small amounts (*see* also Gilotti, Gazz. chim. ital. 1908, 38, ii. 252).

Soluble metaferric hydroxide $Fe_2O_4H_2$ is obtained by heating a solution of ferric nitrate to 100° for 3 days, and then adding a few drops of hydrochloric acid. The hydroxide is thus precipitated, and when dried on a porous tile forms black scales, which dissolve in water to a tasteless red liquid (Péan de St. Gilles, Ann. Chim. Phys. 1856, [iii.] 46, 47; Scheurer-Kestner, *ibid.* 1859, [iii.] 57, 23; Debray, Compt. rend. 1869, 68, 913).

The hydrated oxide combines with sugar, forming a soluble compound, thus lowering the percentage of crystalline sugar obtained from the pans and raising the proportion of molasses. On this account raw sugar is soon injured by contact with iron vessels, and even the clearing 'char' should be as free as possible from iron. According to Schachtrupp and Spunt (Pharm. Centralhalle, 1893, 11, 148) the hydroxide is soluble only in solutions of invert sugar, and cannot itself cause inversion, though this may be brought about by anhydrous ferric oxide.

The hydrated oxide is largely used for removing sulphuretted hydrogen from coal gas. A hydrated sulphide is thus produced with evolution of water. When the oxide ceases to absorb the gas, it is exposed to a current of air, care being taken to prevent great rise of temperature, and the oxide is reproduced with separation of free sulphur. The large quantity of Prussian blue contained in the spent 'oxide' is now used for the production of cyanides (*q.v.*).

A yellowish-brown hydrated sesquioxide, precipitated on calico by the action of caustic soda on ferrous sulphate, is known as *chamois* or *rouille.*

Iron rust when completely oxidised has a composition approximating to that of limonite, but when freshly formed contains much hydrated ferrous oxide and carbonate (Moody, Chem. Soc. Trans. 1906, 720).

Ferric acid H_2FeO_4 is only known in combination. The potassium salt is produced with evolution of considerable heat by heating the sesquioxide with potassium nitrate or hydroxide, or with a mixture of the two substances (Fremy, J. Pharm. Chim. 1841, 27, 97; Hofmann, Ber. 1869, 2, 239).

It may be prepared by the electrolytic oxidation of iron in caustic potash solution (Haber and Pick, Zeitsch. Elektrochem. 1900, 7, 215), or by passing chlorine through a suspension of ferric hydroxide in caustic potash.

Barium ferrate is the most stable salt of ferric acid, and is obtained as a dark red powder by precipitating a solution of sodium ferrate with barium chloride (Baschieri, Gazz. chim. ital. 1906, 36, ii. 282).

Ferrous sulphide FeS is found in certain meteorites. It may be considered to exist in combination with the sesquisulphide in *pyrrhotine* or *magnetic pyrites*, and in combination with other sulphides in other minerals. It is found in considerable quantities in the black deposit in cesspools, &c., being produced by the action of organic matter on ferruginous bodies or iron oxide in presence of sulphates. In meteorites it occurs as the mineral *triolite*.

It may be prepared by heating a mixture of iron filings and sulphur, or of ferrous sulphate and charcoal; by stirring a white-hot rod of wrought iron in melted sulphur; by heating other iron sulphides to bright redness in hydrogen, or by precipitating ferrous salts with alkaline sulphides or sulphuretted hydrogen. In the compact state, ferrous sulphide is a very hard, metallic-looking black, or nearly black crystalline solid of sp.gr. 4·69. It has a metallic lustre with a yellowish reflex, and sometimes occurs in hexagonal prisms. It is not magnetic, is permanent in air, and fusible at a full red heat. The precipitated sulphide, however, is readily oxidised to sulphate in air, especially when moist.

It is decomposed by acids with evolution of sulphuretted hydrogen, and is usually employed for the preparation of that gas.

Ferrous sulphide forms the main constituent of *iron lute* (*v.* LUTES).

Ferroso-ferric sulphide $FeS{\cdot}Fe_2S_3$ forms one of the varieties of *pyrrhotine*: it is obtained when iron pyrites is heated out of contact with air for the production of sulphur. *Magnetic pyrites* $5FeS{\cdot}Fe_2S_3$ or $6FeS{\cdot}Fe_2S_3$ occurs in hexagonal plates of a brassy colour. It is attracted by the magnet and has sp.gr. 4·4–4·7.

Ferric sulphide Fe_2S_3 is obtained by gently heating a mixture of iron and sulphur or by the action of sulphuretted hydrogen on the sesquioxide below 100°, and may be prepared by pouring a solution of ferric salt into excess of ammonium sulphide. By the latter reaction it is formed in the purification of coal gas (Gedel, J. Gasbel. 1905, 48, 400; Stokes, J. Amer. Chem. Soc. 1907, 29, 304). It combines with other sulphides of iron, and with the sulphides of silver, potassium, and sodium.

Potassium ferric sulphide $K_2Fe_2S_4$ is obtained when iron filings, potassium carbonate, and sulphur are heated together and the mass extracted with water. It is thus obtained in purple-coloured, needle-shaped crystals of sp.gr. 2·863, which burn when heated in air.

Sodium ferric sulphide $Na_2Fe_2S_4,4H_2O$ is obtained in a similar way and forms brown microscopic needles. It occurs in the 'black-ash liquors' of the Leblanc process.

Cuprous ferric sulphide $Cu_2S{\cdot}Fe_2S_3$ occurs native as '*copper pyrites.*'

Iron disulphide FeS_2 occurs in immense quantities as *iron pyrites* or *mundic* in hard, yellow, brassy cubes, sp.gr. 5·185; or in other forms of the regular system, and in masses of various shapes, frequently known as 'thunderbolts.' This mineral, as well as *marcasite* or *white iron pyrites* (sp.gr. 4·68–4·85), and other minerals of the same composition, but crystallising in the rhombic system, is produced in nature by the reduction of ferrous sulphate by organic matter, and is therefore often found forming fossils in peat, chalk, &c., and in clay, containing much organic matter. Marcasite may be prepared artificially by heating ferrous sulphide with sulphur; by passing hydrogen sulphide over the oxides or chlorides of iron at a red heat; by the action of carbon disulphide vapour on heated ferric oxide or by heating ferric chloride with phosphorus pentasulphide (Glatzel, Ber. 1890, 23, 37).

Pyrites is quite permanent in air, but marcasite slowly becomes oxidised and disintegrated on exposure. Iron pyrites is largely employed as a source of sulphur in the manufacture of sulphuric acid, ferrous sulphate, &c. (*v.* SULPHURIC ACID; SULPHUR; *Ferrous sulphate*).

By heating iron disulphide with aluminium powder in a stream of hydrogen sulphide the compound Al_2FeS_4 is obtained (Houdard, Compt. rend. 1907, 144, 801; *see* also Ditz, Metallurgie, 1907, 4, 786).

Iron sub-sulphide Fe_4S_3 is obtained when iron is heated in the vapour of carbon disulphide. It forms a crystalline mass of sp.gr. 6·957, and dissolves in dilute acids with evolution of hydrogen and hydrogen sulphide (Gautier and Hallopeau, Compt. rend. 1889, 108, 806).

Ferric arsenide occurs in nature as *lölingite* $FeAs_2$, and with sulphur as *mispickel* or *arsenical pyrites* Fe_2AsS, from which the greater part of the arsenic of commerce is obtained (*v.* ARSENIC). Arsenic combines directly with iron.

Compounds of carbon, phosphorus, silicon, and nitrogen with iron are also known. The effects produced on the properties of iron and steel by the three first-named elements are described under the manufacture of iron.

Iron nitride Fe_2N (Stahlschmidt, Pogg. Annalen, 1864, 125, 37) is obtained by the action of excess of ammonia at 420° on ferrous chloride or bromide, reduced iron, or iron amalgam, as a dull grey powder (Fowler, Chem. Soc. Trans. 1901, 285).

It may be prepared in the compact state by heating iron wire or rod to a bright red heat in a large excess of ammonia. The product is so brittle that it can be powdered, and has sp.gr. 6·0–6·5. When heated in air it is oxidised, and it ignites when warmed in chlorine. Dilute acids dissolve it with the formation of ferrous and ammonium salts (Beilby and Henderson, Chem. Soc. Trans. 1901, 1249; Guntz, Compt. rend. 1902, 135, 738).

Phosphides of iron. A phosphide Fe_2P is produced by heating a mixture of ferrous or ferric phosphate under common salt or by heating iron filings with cuprous phosphide in the electric furnace. It forms lustrous grey crystals, probably hexagonal in form; sp.gr. 6·56; m.p. 1290° (Maronneau, Compt. rend. 1900, 130, 656; Le Chatelier and Wologdine, *ibid.* 1909, 149, 709). Heated in air it forms the basic phosphate $2Fe_2O_3,P_2O_5$.

When iron is heated in phosphorus vapour, or the monosulphide is heated in hydrogen phosphide gas, the phosphide FeP is formed. It is a dark grey powder of sp.gr. 5·76.

Another phosphide Fe_2P_3 is formed by strongly heating phosphorus and ferric chloride vapours in a current of carbon dioxide (Granger, Compt. rend. 1896, 122, 936); or by the action of the vapour of phosphorus iodide on finely divided iron. It forms hard, non-magnetic, steel-grey crystals; sp.gr. 4·5.

A phosphide Fe_3P of sp.gr. 6·74 and m.p. 1110° has also been described (Le Chatelier and Wologdine, *l.c.*).

Iron borides. Two borides of iron have been described:

Fe_2B forms steel-grey prisms; sp.gr. 7·37 at 18°. It is oxidised by dry air at a red-heat and by moist air at the ordinary temperature.

FeB_2 has not been obtained pure, but has sp.gr. *circa* 5, and is extremely hard (Binet du Jassonneix, Compt. rend. 1907, 145, 121).

Iron silicide $SiFe_2$ (ferro-silicon) is produced by heating iron with silicon, or with silica and carbon, in the electric furnace (Moissan, Compt. rend. 1895, 121, 621; Bertolus, Fr. Pat. 393, 818, 1908). It forms grey magnetic prisms of sp.gr. 7, and is readily attacked by acids.

Under certain circumstances commercial ferro-silicon may evolve the gaseous hydrides of arsenic and phosphorus (present as impurities) with very bad effect on human beings (*e.g. see* J. Soc. Chem. Ind. 1909, 25).

Iron carbide (*see* CEMENTITE and STEEL).

FERROUS SALTS.

Anhydrous ferrous salts are usually colourless; the hydrated salts are greenish or blue. The solutions are sweet and astringent and ink-like in taste, and form powerful reducing agents.

Ferrous chloride $FeCl_2$ may be prepared by passing dry hydrogen chloride over red-hot iron or by reducing ferric chloride in a current of hydrogen, when the anhydrous salt is deposited in colourless shining scales, sp.gr. 2·528, which are very deliquescent and easily soluble in water and alcohol. It fuses at a red-heat, and volatilises at a yellow-heat, the V.D. being 6·4–6·6 (V. Meyer, Ber. 1884, 17, 1335). At 1300°–1500° the V.D. is normal=4·3 (Nilson and Pettersson, Chem. Soc. Trans. 1888, 827).

In solution it is obtained by dissolving iron in hydrochloric acid. It crystallises in deliquescent, bluish-green, monoclinic crystals, sp.gr. 1·93, containing 4 molecules of water.

The anhydrous salt absorbs ammonia to form the compound $FeCl_2{\cdot}6NH_3$, which gives off ammonia at 100°, and at higher temperatures yields ammonium chloride, nitrogen, and iron nitride (Fowler, Chem. Soc. Trans. 1901, 288). It combines with bromine to form the unstable compound $FeCl_2Br$ (Lenormand, Compt. rend. 1893, 116, 820).

Ferrous bromide $FeBr_2$ is obtained as a yellowish crystalline solid by the union of its elements. The hydrated bromide crystallises in bluish-green rhombic tablets with 6 molecules of water.

Ferrous iodide FeI_2 is obtained by heating iron with iodine as a grey lamino-crystalline mass; m.p. 177° (Carius and Wanklyn, Annalen, 1861, 120, 69).

Ferrous sulphite $FeSO_3$. Iron dissolves in aqueous sulphurous acid in absence of air, with formation of ferrous sulphite and thiosulphate. The latter salt is very soluble, but the sulphite is deposited in greenish crystals.

Ferrous sulphate, green vitriol, or **copperas,** $FeSO_4,7H_2O$, occurs as *melanterite*, being derived from the decomposition of the native sulphide, especially of marcasite, and is manufactured in large quantities in South Lancashire by the oxidation of pyrites by air and rain.

The pure salt is prepared by heating an excess of iron wire or 1½ parts of precipitated ferrous sulphide in 1½ parts of sulphuric acid diluted with four times its weight of water. The solution is acidified if necessary, and is filtered quickly. Bluish-green monoclinic crystals containing $FeSO_4,7H_2O$, and having a sp.gr. of 1·889 at 4° (Joule and Playfair), are thus produced.

Large quantities of this sulphate are obtained in the manufacture of copper sulphate (*v.* COPPER), and small quantities in the preparation of sulphuretted hydrogen for precipitating arsenic from sulphuric acid. It is prepared on the large scale by dissolving scrap iron in warm sulphuric acid of 1·150 sp.gr., and concentrating the nearly neutral solution. The liquid is settled, quickly drawn off, allowed to clear for 24 hours, and run into crystallising tanks, in which strings, straws, or wooden laths are suspended to induce crystallisation. The crystals are washed with a minimum quantity of water and dried.

When sulphur is distilled from iron pyrites, the residue, known as *sulphur waste*, is laid upon inclined shelves in contact with air to oxidise. The weathered mass is levigated, and the ferrous sulphate is crystallised out.

Ferrous sulphate is obtained at Fahlun during the extraction of copper sulphate from mine water, and also from the runnings of other mines.

The *Salzburg vitriol* prepared at Buxweiler contains ferrous and copper sulphates (*v.* COPPER). The copper may be separated as metal and any excess of acid converted into sulphate by the addition of scrap iron to the liquid.

Crude ferrous sulphate always contains ferric sulphate, which gives the crystals a more decided green colour; they are frequently coated with a yellow deposit due to oxidation. By washing with absolute alcohol, this deposit, being soluble, is removed, and the crystals are rendered more permanent.

The pure salt may be obtained in the most permanent condition by precipitating a concentrated aqueous solution by addition of excess of alcohol and washing the precipitated crystals with nearly absolute alcohol. The presence of even a trace of ferric salt increases the liability of the crystals to oxidation. The crystals usually contain 7 molecules of water and are monoclinic, of sp.gr. 1·889 at 4°. Another hydrate contains $5H_2O$ and crystallises in the triclinic system, being isomorphous with $CuSO_4,5H_2O$. The monohydrate is obtained when the heptahydrate is allowed to effloresce over conc. sulphuric acid, or when it is melted in its water of crystallisation and allowed to solidify (Etard, Compt. rend. 1878, 87, 502;

Scott, Chem. Soc. Trans. 1897, 564). Ferrous sulphate may be obtained in rhombic prisms containing 4 molecules of water, isomorphous with zinc sulphate. Crystals may also be produced containing 3 and 2 molecules of water.

Ferrous sulphate is insoluble in absolute alcohol. Its solubility in 100 parts of water is:

10°	15°	25°	32·5°	46°	60°	90°	100°
61	70	115	151	227	263	370	333

The reduced solubility at 100° may be attributed to partial dehydration or dissociation.

The aqueous solution slowly oxidises on exposure to air, and deposits a yellowish, highly basic ferric sulphate, leaving the normal ferric sulphate in solution. The acid finally becomes divided between the precipitated salt and that in solution, rendering the former less basic but still insoluble, and converting the normal salt into a soluble basic sulphate. Ferrous sulphate, like the chloride, absorbs nitric oxide in solution. The gas is given off in a vacuum, or when the solution is heated, but it probably forms the compound $FeSO_4 \cdot NO$. When such a solution is mixed with sulphuric acid and cooled a purple-red colour is produced, which is used in the well-known ring test for nitrates (*see* also Machot and Zechentmacher, Annalen, 1906, 350, 368).

On account of its reducing power, it precipitates gold and palladium from solution, and reduces indigo to the leuco compound.

When gradually heated to 140° *in vacuô* it loses 6 molecules of water and becomes colourless, but the remaining molecule is not removed at 260°, and, except when heated in small quantities, it is impossible to render the salt anhydrous without loss of acid. At a red heat a basic sulphate is produced, with evolution of sulphur trioxide, and, at higher temperatures, ferric oxide is left. A complete investigation of the dissociation of ferrous sulphate has been made by L. Wöhler, Plüddemann, and P. Wöhler (Ber. 1908, 41, 703).

Ferrous sulphate is largely used in dyeing and tanning, and in the manufacture of inks (*v.* INK), Prussian blue, and other pigments, Nordhausen sulphuric acid, red oxide of iron, &c. In weak solution it is said to promote the growth of certain plants, especially of roots. When added to excremental matters it absorbs ammonia and other volatile substances, and renders the matter almost odourless. It is largely used for the treatment of sewage (*see e.g.* Pochin and Richardson, Eng. Pats. 15239 and 17976, 1908).

In dyeing textiles, leather, wood, &c., it is largely used for the production of various shades of black, grey, lilac, and brown. It is used as a mordant for the production of Prussian blue in calico-printing, and is the raw material from which acetates, nitrosulphates, and other iron mordants are prepared.

Ferrous disulphate FeS_2O_7 is separated as a white powder on addition of excess of concentrated sulphuric acid to a concentrated aqueous solution of the normal sulphate. On addition of water, it is decomposed into the normal salt and free acid (Bolas, Chem. Soc. Trans. 1874, 212).

With ammonium and potassium sulphates, ferrous sulphate produces double salts containing 6 molecules of water and of great stability and fine crystalline form.

Ferrous ammonium sulphate

$FeSO_4,(NH_4)_2SO_4,6H_2O$

is prepared by dissolving molecular proportions of the two sulphates in the minimum quantity of hot water, filtering hot, and crystallising. It forms fine bluish-green monoclinic crystals of sp.gr. 1·813, of which 100 parts of water dissolves 21·6 parts at 20° and 56·7 parts at 75°.

The double salt is permanent in air, particularly when precipitated by addition of alcohol to the concentrated aqueous solution and washed with absolute alcohol, and is used by chemists in place of ferrous sulphate, especially for standardising solutions.

Ferrous phosphate $Fe_3(PO_4)_2,8H_2O$ occurs as *Vivianite* or *blue iron earth*, sometimes mixed with clay and peat or associated with bog iron ore. It may be produced by addition of sodium phosphate to ferrous sulphate. The fresh precipitate is used medicinally. When quite pure it is colourless, but it rapidly becomes bluish or green from oxidation. When iron is dissolved in phosphoric acid the solution deposits colourless needles of $Fe(H_2PO_4)_2,2H_2O$, which rapidly alter in air (Erlenmeyer, Annalen, 1878, 194, 182).

Ferrous arsenate prepared from ferrous sulphate and sodium arsenate has been proposed for use as an insecticide, for which purpose it has many advantages over Scheele's green (Vermorel and Dantony, Compt. rend. 1909, 148, 302).

Ferrous carbonate $FeCO_3$ occurs as *spathic iron ore*, together with the carbonates of lime, magnesia, and manganese. *Clay iron stone* is an argillaceous ferrous carbonate.

Ferrous carbonate dissolves in water containing free carbonic acid, the acid salt so produced being the essential constituent of chalybeate waters. The solution is decomposed rapidly on boiling and slowly on exposure to air, with precipitation of an ochreous deposit of the hydrated oxide, which, in the case of mineral waters, frequently contains organic matter and ferric arsenate, and is occasionally found to contain antimony.

Spathic iron ore can be obtained artificially in microscopic rhombohedra by precipitating ferrous sulphate with sodium hydrogen carbonate and heating the solution for 12–36 hours at 150°. When sodium carbonate solution is added to ferrous sulphate solution a flocculent white precipitate is obtained which rapidly becomes green, and is ultimately completely converted into ferric hydroxide.

Ferrous nitrate $Fe(NO_3)_2,6H_2O$ is prepared by dissolving ferrous sulphide in dilute nitric acid, or, preferably, by addition of barium nitrate to ferrous sulphate solution.

The solid salt is very soluble in water and very unstable, changing to ferric nitrate. The action between iron and dilute nitric acid does not result in the formation of ferrous nitrate, and is extremely complicated (Montemartini, Chem. Soc. Abstr. 1892, 1278).

Cyanogen compounds of iron (*see* CYANIDES).

FERRIC SALTS.

Are usually of yellowish or reddish brown colour. In solution they are reduced to the ferrous condition by zinc, or, with precipitation of sulphur, by sulphuretted hydrogen. Potassium or other soluble thiocyanate imparts an intense blood-red colour to a neutral or acid solution of a ferric salt.

Ferric chloride $FeCl_3$ or Fe_2Cl_6 may be obtained in the anhydrous condition by passing excess of chlorine gas over red-hot iron or by passing hydrogen chloride over the heated sesquioxide, and thus occurs not infrequently in the craters of volcanos. Thus prepared, it forms iridescent iron-black scales which are dichroic, appearing red by transmitted and green by reflected light.

In solution it may be prepared by dissolving the precipitated sesquioxide in hydrochloric acid, and driving off the excess of acid by heat; or, preferably, by dissolving iron in hydrochloric acid and passing chlorine through the liquid until saturated with that gas, finally entirely removing the chlorine by passage of a current of carbon dioxide through the warm liquid. A commercial method for the preparation of ferric chloride from native phosphate of iron and aluminium has been described by Schröder (D. R. P. 192591).

Ferric chloride readily volatilises at 448°, and the V.D. is then less than that required for Fe_2Cl_6. It is, therefore, probable that the molecular formula is $FeCl_3$ (Grünewald and V. Meyer, Ber. 1888, 21, 687). In boiling alcohol or ether it also appears to have the molecular formula $FeCl_3$ (Müller, Compt. rend. 1894, 118, 641). At the ordinary temperature it forms unstable compounds with nitric oxide, but at higher temperatures it is reduced by that gas to ferrous chloride (Besson, Compt. rend. 1889, 108, 1012; Thomas, *ibid.* 1895, 120, 447; 121, 128).

Ferric chloride is very deliquescent, and dissolves in alcohol and ether. The concentrated aqueous solution is dark brown and oily; if diluted it becomes of a pale yellow colour. In dilute solution the salt may exist as $Fe_2Cl_4{\cdot}Cl_2$ (Tufereff, Zeitsch. anorg. Chem. 1908, 59, 82).

There are four hydrates of ferric chloride, $FeCl_3,6H_2O$, m.p. 37°; $2FeCl_3,7H_2O$, m.p. 32·5°; $2FeCl_3,5H_2O$, m.p. 56°; and $FeCl_3,2H_2O$, m.p. 73·5°. Solutions which contain more of the chloride than corresponds with the composition $FeCl_3,2H_2O$ deposit the anhydrous salt when heated above 66° (Roozeboom, Zeitsch. physikal. Chem. 1892, 10, 477).

Compounds of the formulæ $FeCl_3,HCl,2H_2O$, $FeCl_3,HCl,4H_2O$, and $FeCl_3,HCl,6H_2O$ are known (Sabatier, Bull. Soc. chim. 1881, [ii.] 36, 197; Roozeboom and Schreinemacker, Zeitsch. physikal. Chem. 1894, 15, 588).

Ferric chloride is partly hydrolysed by water with the formation of many complex colloid bodies (Malfitano and Michel, Compt. rend. 1907, 145, 185, and 1275; Michel, *ibid.* 1908, 147, 1052, and 1288).

Ferric chloride forms compounds with alkaloids, most of which have definite melting-points. The use of these substances has been suggested for the identification of the alkaloids (Scholtz, Chem. Soc. Abstr. 1908, i. 202, from Ber. Deut. pharm. Ges. 1908, 18, 44).

Solutions of ferric chloride in methyl alcohol are reduced by light, which acts, not as a catalyst, but as the source of the energy required to bring about the reaction (Benrath, J. pr. Chem. 1909, [ii.] 80, 283).

Ferric chloride is sometimes used as a disinfectant. It deodorises sewage with partial reduction to ferrous chloride.

With potassium chloride it produces a finely crystallised garnet-coloured double chloride $Fe_2Cl_6,4KCl,2H_2O$ decomposed by water. A similar garnet-coloured salt crystallising in cubes is formed with ammonium chloride and is used medicinally as *ammonio-chloride of iron*. The salt used, however, does not correspond to the potassium salt, but usually contains less than 2 p.c. of iron. It is very deliquescent and may be considered as formed by the combination of the normal salt $FeCl_6,4NH_4Cl,2H_2O$ with variable proportions of ammonium chloride.

Soluble and insoluble *oxychlorides* of iron are known, but are unimportant.

Ferric sulphate $Fe_2(SO_4)_3$ occurs in Chile as *coquimbite* in white silky pyramids containing $Fe_2(SO_4)_3,9H_2O$. It is usually prepared by mixing one equivalent of concentrated sulphuric acid with a solution of two equivalents of ferrous sulphate, concentrated nitric acid being added in portions to the hot solution until red fumes cease to be evolved. On concentrating the solution to a syrup colourless crystals are obtained.

Several hydrated basic sulphates are prepared artificially, or occur in nature.

Ferric sulphate is used to a slight extent in dyeing cotton, but not in printing. The basic sulphates are used for dyeing cotton, for the production of buffs, or, in combination with logwood and sumach, for blacks. The iron mordant prepared by treating ferrous sulphate with nitric acid is sold as *nitrosulphate* or *nitrate of iron*, and is used in dyeing, but not in printing cotton.

With alkaline sulphates ferric sulphate forms double salts, resembling and corresponding in composition to alum.

The potassium salt, *potassium iron alum* $Fe_2(SO_4)_3,K_2SO_4,24H_2O$, is prepared by mixing molecular proportions of ferric and potassium sulphates and concentrating the solution spontaneously. It forms fine violet octahedra very liable to decompose into a brown, gummy, deliquescent mass. This alum is used to a limited extent in dyeing and calico printing. If caustic potash is added to a solution of iron alum, and the brown liquid allowed to evaporate, yellowish-brown crystals separate of the composition $5K_2SO_4,2Fe(SO_4)_2(OH)_2,16H_2O$. These crystals have the peculiar optical properties of tourmaline (*see* Lachaud and Lepierre, Compt. rend. 1892, 114, 915).

The corresponding ammonium alum is more permanent, and has been proposed as a standard in titrations (de Coninck, Bull. Soc. chim. 1909, 23, 222).

Ferric nitrate $Fe_2(NO_3)_6$ may be obtained in several states of hydration by crystallising the solution obtained by the action of concentrated nitric acid on scrap iron or iron oxide. The hydrate $Fe(NO_3)_3,6H_2O$ crystallises in cubes and the hydrate $Fe(NO_3)_3,9H_2O$ in colourless monoclinic crystals. It is usually prepared by the first method for use as a mordant for producing buffs and blacks in dyeing. An alkaline mordant is prepared for dyeing and calico printing by treating a ferric salt with caustic soda, with addition preferably of glycerol, or sometimes of glucose, to prevent precipitation of the oxide.

Nitroso-compounds of Iron. Anhydrous ferric chloride absorbs nitric oxide, forming the compounds $2FeCl_3{\cdot}NO$ and $4FeCl_3{\cdot}NO$ as reddish-brown, hygroscopic powders. The action of nitric oxide on an ethereal solution of ferric chloride gives nitrosyl chloride and a solution which, when evaporated over sulphuric acid, deposits black needles of the composition $FeCl_2{\cdot}NO,2H_2O$; or at 60° gives the anhydrous salt $FeCl_3{\cdot}NO$, crystallising in yellow needles (Thomas, Compt. rend. 1895, 120, 447).

The stable nitroso compounds were discovered by Roussin (Compt. rend. 1858, 46, 224), and are formed by the action of ferrous sulphate on alkali nitrites and sulphides. They are salts of complex acids, containing iron and the monovalent group NO′ in the acid radicle (Cambi, Atti. R. Accad. Lincei. 1908, [v.] 17, i. 202), and fall into two classes:

(1) *Ferrodinitroso* derivatives.
(2) *Ferroheptanitroso* derivatives.

Potassium ferrodinitroso sulphide

$$K[Fe(NO)_2S],2H_2O$$

is formed by the action of caustic potash on the heptanitrososulphide (*v. infra*). It forms dark red crystals, insoluble in water, and decomposes violently when heated, yielding potassium and ammonium sulphates and other products.

The free acid $H[Fe(NO)_2S]$ is obtained by the action of sulphuric acid on the potassium salt and slowly decomposes into hydrogen sulphide, nitrogen, nitrous oxide, and the heptanitroso acid. The ethyl and phenyl derivatives have been prepared: $C_2H_5[Fe(NO)_2S]$, and

$$C_6H_5[Fe(NO)_2S].$$

Potassium ferrodinitroso thiosulphate

$$K[Fe(NO)_2S_2O_3],H_2O$$

is prepared by passing nitric oxide into a solution of ferrous sulphate and potassium thiosulphate for 10 hours. It forms reddish-brown crystals with a bronze lustre which are but slightly soluble in water. The ammonium and sodium salts are similar, but the latter is the more soluble.

Potassium ferroheptanitroso sulphide

$$K[Fe_4(NO)_7S_3],H_2O$$

is the most stable of these salts and is formed by the action of ferrous sulphate on potassium nitrite and sulphide in solution, or by boiling a solution of the ferrodinitroso thiosulphate. It forms dark-coloured monoclinic crystals having an adamantine lustre and is only sparingly soluble in water.

The free acid is obtained as an amorphous brown mass by the action of sulphuric acid on the potassium salt.

The ammonium salt may be prepared by the action of nitric oxide on freshly precipitated ferrous sulphide suspended in water.

(For details as to these compounds *see:* Proczinsky, Annalen, 1863, 125, 302; Rosenberg, Ber. 1879, 3, 312; Pavel, *ibid.* 1882, 15, 2600; Marchlewski and Sachs, Zeitsch. anorg. Chem. 1892, 2, 175; Marié and Marquis, Compt. rend. 1896, 122, 137; Hofmann and Wiede, Zeitsch. anorg. Chem. 1895, 8, 318; 1895, 9 295; 1895, 11, 281; *see* also Atti. R. Accad. Lincei, 1906, [v.] 15, ii. 467; 1907, [v.] 16, i. 654.)

Ferric phosphates occur native as *beraunite* $Fe_2(PO_4)_2{\cdot}4Fe_2PO_4(HO)_3,8H_2O$, formed by the oxidation of *vivianite*, and as *dufrenite* $Fe_2(HO)_3PO_4$.

The normal phosphate, $FePO_4$, is produced as a yellowish-white precipitate by adding sodium hydrogen phosphate to ferric chloride solution; it is soluble in dilute acids (except acetic acid) and is slowly decomposed by water.

When ferric hydroxide is dissolved in orthophosphoric acid and the solution rapidly evaporated, the di-acid salt $Fe(H_2PO_4)_3$ is obtained as a pink crystalline powder, decomposed by moist air, with formation of the monacid salt $2FeH_3(PO_4)_2,5H_2O$.

Ferric metaphosphate is deposited in pink plates when the hydroxide is digested with glacial phosphoric acid at 100° (Hautefeuille and Margotte, Compt. rend. 1888, 106, 138; Johnson, Ber. 1889, 22, 976).

Pascal has described (Compt. rend. 1908, 146, 231, 279) certain complex salts of iron with phosphoric acid in which the iron exists in the acid radicle.

Sodium ferripyrophosphate $Na_6Fe_2(P_2O_7)_3$ is precipitated as a pale violet, micro-crystalline powder from a saturated solution of ferric pyrophosphate in 15 p.c. sodium pyrophosphate solution maintained at 30°. The silver and copper salts and the free acid have been prepared.

Ferric arsenite $Fe_2(AsO_3)_2$ is of interest as being the salt produced when freshly precipitated hydrated oxide of iron is taken as an antidote in cases of arsenical poisoning. It may be obtained as a brown precipitate by addition of arsenious acid or an arsenite to a solution of ferric acetate.

Ferric acetate *v.* ACETATES.

Ferric ferrocyanide *v.* CYANIDES.

Ferric tannate or *gallo-tannate* forms the basis of black inks (*v.* INK). The sponges, sand, pumice-stone, &c., of Gerson's filters are impregnated with the tannate, which is said to completely remove all organic matter from water (*v.* Steiger, J. Soc. Chem. Ind. 1886, 416).

Ferric citrate $Fe(C_6H_5O_7)$ is prepared by dissolving the hydrated oxide in citric acid, and evaporating the solution in thin layers. It forms permanent, transparent, garnet-coloured scales, which dissolve slowly in water, but are insoluble in alcohol.

Ferric ammonium citrate is prepared as above, with addition of ammonia. It forms thin, transparent, deep-red scales, which dissolve readily in water, but not in absolute alcohol.

It is used in medicine as is also the double citrate of iron and quinine.

IRON CARBONYLS. Three carbonyls of iron are known; viz.: Iron pentacarbonyl $Fe(CO)_5$, iron tetracarbonyl $Fe(CO)_4$, and diferrononacarbonyl $Fe_2(CO)_9$.

Iron pentacarbonyl. This compound was discovered by Mond, Langer, and Quincke, who prepared it by treating finely divided iron, obtained by reducing ferrous oxalate by hydrogen, with carbon monoxide. On heating to 120°, the carbonyl distilled over and was collected in a cooled tube. The yield is about 1 gram per 100 grams of iron (Chem. Soc. Trans. 1891, 604 and 1090).

Iron pentacarbonyl is a viscid yellow liquid of sp.gr. 1·466 at 18°; b.p. 102·8° at 749 mm.

At −21° yellow crystals are formed, which become white at the temperature of liquid air.

It is not acted upon by dilute acids, but concentrated acids form the corresponding salt with evolution of carbon monoxide and hydrogen. Upon exposure to air, it is converted into ferrous hydroxide and eventually into the red ferric hydroxide. The pentacarbonyl is soluble in most organic solvents and in nickel tetracarbonyl, forming $FeNi(CO)_9$ (?), insoluble in water.

Light decomposes the pentacarbonyl, giving the diferrononacarbonyl and carbon monoxide: $2Fe(CO)_5=Fe_2(CO)_9+CO$ (Dewar and Jones, Proc. Roy. Soc. 1905, A. 76, 588; 1907, A. 79, 66).

The decomposition of the pentacarbonyl is most rapid in blue light and least of all in red, green and yellow being intermediate in their effects; in fact, a solution exposed to blue light will deposit about ten times as much solid as a similar solution exposed for the same period to red light.

The action of light on the pentacarbonyl is reversible, as the substance in sealed tubes, after exposure to light, when left in the dark, gradually become colourless.

Diferrononacarbonyl crystallises in lustrous hexagonal golden or orange coloured crystals of sp.gr. 2·085 at 18°, which are perfectly stable in dry air. They are decomposed at 100° yielding the pentacarbonyl, carbon monoxide, and iron: $Fe_2(CO)_9=Fe(CO)_5+4CO+Fe$. It is insoluble in water and nearly so in benzene, but is slightly soluble in alcohol or acetone and very soluble in pyridine. The nonacarbonyl in solution heated to 95° becomes green and then contains the *tetracarbonyl* $Fe(CO)_4$. At a higher temperature it forms the pentacarbonyl together with iron and carbon monoxide, the reaction taking place in two stages:

$$2Fe_2(CO)_9=2Fe(CO)_5+2Fe(CO)_4$$
$$2Fe(CO)_4=Fe(CO)_5+Fe+3CO.$$

When strongly heated the action is:

$$2Fe_2(CO)_9=3Fe(CO)_5+Fe+3CO.$$

Iron tetracarbonyl. The method of preparation of the tetracarbonyl is as follows: a solution of the diferrononacarbonyl in toluene (1 gram to 20 c.c.) is gradually heated to 95° in an atmosphere of carbon dioxide until the reddish yellow solid has disappeared. On cooling, green crystals of the tetracarbonyl are formed:

$$Fe_2(CO)_9=Fe(CO)_4+Fe(CO)_5.$$

The yield is 20 p.c.

The tetracarbonyl forms dark green lustrous crystals of sp.gr. 1·996 at 18°, stable at ordinary temperatures: on heating at 140°–150°, iron and carbon monoxide are formed. The empirical formula is $Fe(CO)_4$, but the molecular formula in benzene appears to be $[Fe(CO)_4]_{20}$.

The substance is insoluble in water but soluble in most organic solvents giving green solutions. In pyridine, the solutions are first green, but soon become red, especially on warming. The change in colour is probably due to molecular dissociation. The green solutions lose their colour upon exposure to light, iron being deposited, but the red ones are unaffected by light.

IRON CEMENT *v.* Lutes.

IRONE *v.* Ketones.

IRON LIQUOR. *Ferrous acetate* (*v.* Acetic acid).

IRON PYRITES. *Ferric sulphide* (*v.* Pyrites; Iron).

IRVINGIA BUTTER *v.* Waxes.

ISATIN *v.* Bone-oil; Indigo, Natural; Indigo, Artificial.

ISATIN BLUE *v.* Bone-oil.

ISINGLASS (Fr. *Colle de poisson*; Ger. *Hausenblase*) consists of the dried swimming-bladders of various fishes. These bladders differ in shape and size, according to their origin, and are prepared either by simply drying them whilst slightly distended, which process forms ‘pipe isinglass,’ or by splitting them open, pressing, and drying them in the form of ‘leaf isinglass.’ That form, again, which is known as ‘purse isinglass,’ consists of such bladders as contain a natural opening.

The chief supply of isinglass is derived from Russia and Hudson’s Bay; some portion also being obtained from Brazil, West Indies, Penang, Bombay. and Manilla; the finest kind, the ‘Beluga leaf,’ coming from the first-named of these countries, and being the produce of a species of sturgeon. Other Russian or Siberian varieties are ‘Astrakhan leaf,’ ‘Saliansky leaf,’ and ‘Samovy leaf.’

The following are the principal species of fish from which Russian isinglass is obtained: *Acipenser huso*, or the Hausen; *A. Güldenstædtii*, or the Osseter; *A. ruthenus*, or the Sterlet; *A. stellatus*, or the Sewruga; *Silurus glanis* and *Cyprinus carpio*. The isinglass of New York is derived from *Labrus squeteague*; that of New England—the ‘ribbon isinglass’—from the common Cod, *Gadus Morrhua*. In Brazil, it is taken from a species of *Silurus*; and in Iceland, from *Gadus* and *Molva vulgaris*, or the Ling.

The chief emporium for Russian isinglass is the great fair of Nijni-Novgorod, whence the largest part of the merchandise finds its way to London, through the agency of St. Petersburg traders. It arrives here about the end of June. Those supplies which reach us from Brazil and other countries are received at all seasons.

The fish being taken, the bladders are immediately removed, sufficient care in the cleansing of them from mucus and blood-stains being often purposely neglected, since a loss of weight results in the process when properly performed. In consequence of this neglect, the value of the material is diminished in proportion to the impurities which it contains.

On its arrival here isinglass is a hard, tough substance, and for many purposes it is necessary to ‘cut’ it. The operations of ‘cutting’ consist, first, in soaking the flakes until somewhat pliable, trimming the edges, and scraping off the dark spots; next, in putting them through two sets of rollers, under great pressure, by which they are flattened to the thickness of writing-paper; and, finally, in cutting them into fibres of extreme fineness, a process now almost always effected by a machine constructed for that purpose.

The uses for which isinglass is employed are the ‘fining’ or clarifying of fermented beverages, as ale and wine, and various culinary preparations. For the former purpose, the properties of isinglass are remarkable; for, whilst possessing the exact chemical composition of gelatin, it has the power, which is wanting in gelatin, of entangling in the film or web which it forms as it dissolves, all the suspended impurities contained in the liquids which it is sought to clarify. The lower grades of isinglass are used either in the natural or the manufactured condition by brewers and the manufacturers of cider, and the better classes of the Russian material by wine merchants. For the purpose of the brewer it is usual to dissolve the isinglass in sulphurous acid which has a tendency to preserve the ale.

The choicest descriptions are used by the cook and the confectioner for the thickening of soups, jellies, &c., but as for these purposes the fining properties of isinglass are not of any account, gelatin serves equally well, and has, under the name of patent isinglass, been so employed (*v.* GLUE).

ISOCETIC ACID $C_{14}H_{29}COOH$, m.p. 55°, is obtained from the oil extracted from the seeds of *Jatropha Curcas* (Linn.) (Bouis, J. 1854, 462).

ISOFORM *v.* SYNTHETIC DRUGS.

ISOPRAL *v.* SYNTHETIC DRUGS.

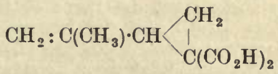
ISOPRENE. *β-Methyldivinyl*

$$CH_2:C(CH_3)CH:CH_2.$$

Discovered by Greville Williams among the products obtained by the destructive distillation of rubber (Phil. Trans. 1860, 241). Tilden obtained it among the more volatile compounds obtained by the action of heat on oil of turpentine and other terpenes (Chem. Soc. Trans. 1879, 417; 1884, 415), and Gladstone rom refraction and dispersion measurements came to the same conclusion as Tilden, viz. that the so-called *pentine* obtained from turpentine was identical with isoprene from rubber (Chem. Soc. Trans. 1896, 619). Mokiewski (J. Russ. Phys. Chem. Soc. 1898, 30, 885) found that isoprene obtained from turpentine contains some trimethylethylene, for on treatment with one molecule of bromine in a cooled ethereal solution, isoprene dibromide and an amylene derivative were obtained. Ipatiew and Wittorf (J. pr. Chem. 1897, [ii.] 55, 1) proved the presence of trimethylethylene in isoprene obtained from rubber. By treating isoprene dibromide with zinc-dust, pure isoprene is obtained. Staudinger and Klevor (Ber. 1911, 44, 2212), using Tilden's method, have shown that a better yield of isoprene can be obtained by working under reduced pressure. A 60 p.c. yield of isoprene can be obtained by passing the vapours of dipentene or limonene under very greatly reduced pressure over an electrically heated platinum spiral; the isoprene so obtained is almost pure, containing very little trimethylethylene. Terpineol, terpinene and camphene do not yield isoprene under these conditions.

Constitution.—Ipatiew (J. pr. Chem. 1897, [ii.] 55, 1, 4) found that isoprene unites with hydrogen bromide in acetic acid to form a dihydrobromide identical with β-methyl-βδ-dibromobutane $(CH_3)_2CBr{\cdot}CH_2{\cdot}CH_2Br$, b.p. 74°–75° (16 mm.). Alcoholic potash converts the latter into a hydrocarbon, which is not a monosubstituted acetylene, since it has no action on ammoniacal cuprous chloride or silver nitrate, is not a disubstituted acetylene, since the boiling-point is too low, and finally is not dimethylallene, since its boiling-point is not 40°–41° but 34°–35°. Hence it must be β-methyldivinyl. Euler (J. pr. Chem. [iii. iv.] 57, 131; Ber. 1897, 1989) synthesised β-methyldivinyl by treating β-methylpyrollidine twice with methyliodide followed by caustic potash, and found it to be identical with isoprene, and both substances yielded the same addition product with hypochlorous acid. Mokiewski (J. Russ. Phys. Chem. Soc. 1900, 32, 207) obtained a compound C_5H_9Br, b.p. 66°–67°, by the action of hydrogen bromide on isoprene, and treatment with alcoholic potash converted this into an alcohol $C_5H_{10}O$. The esterification constant was determined and it was found that both the alcohol and bromide were tertiary, and since dimethylallene gives the same bromide, this confirms isoprene as being β-methyldivinyl.

Isoprene is a colourless liquid, b.p. 33·5° (Mokiewski; Ipatiew, *l.c.*); sp.gr. 0°/0° 0·6989 (M. *l.c.*); magnetic rotation, 7·529; sp.gr., 15°/15°, (from turpentine) 0·6768, (from rubber) 0·6748 (Perkin, Chem. Soc. Trans. 1895, 258); thermal expansion (Thorpe and Jones, *ibid.* 1893, 277). By heating isoprene to 300°, only a little dipentene is formed, but a quantity of another hydrocarbon (b.p. 64°–66° (12 mm.)), possibly diisoprene, and also di- and polymyrcene (*v.* RUBBER) (Harries, Ber. 1902, 3265; Tilden, Chem. News, 46, 120; Bouchardt, Compt. rend. 87, 654; 89, 361). According to Bouchardt (*l.c.*) and Tilden (Chem. News, 1892, 65, 265), strong acids, such as hydrochloric acid, convert isoprene into a tough elastic substance resembling rubber. Bourchardt (Gummi-Zeit, 1901, 16, [viii.] 133) finds that when isoprene (1 part) and hydrochloric acid (12–15 parts) saturated at 0° are sealed in a tube and placed in a freezing mixture, much heat is evolved on shaking. After leaving for 2 or 3 weeks, the contents were diluted and distilled until oily drops ceased coming over. The residue was purified by boiling with water, had all the properties of rubber and gave similar distillation products. Analysis gave the following figures: C=87·1; H=11·7; Cl=1·7. Tilden found that on standing for some months, isoprene is slowly polymerised into a rubber-like substance. Harries (Chem. Zeit. 1910, 34, 315) converted isoprene into rubber by means of acetic acid, but could not effect the change with hydrochloric acid. Chromic acid oxidises isoprene into carbon dioxide, formic and acetic acids; nitric acid yields oxalic acid. Isoprene dibromide $CH_2:C(CH_3)CHBr{\cdot}CH_2Br$ is formed when isoprene is treated with bromine in carbon disulphide solution at 0° (Blaise and Courtot, Bull. Soc. chim. [iii.] 35, 989); b.p. 101° (19 mm.). On treatment with sodium ethoxide and ethyl malonate, it yields an ethyl ester $C_{12}H_{18}O_4$, which on hydrolysis yields isoprenic acid (*iso*propyltrimethylenedicarboxylic acid)



$$CH_2:C(CH_3){\cdot}CH\left\langle\begin{array}{l}CH_2\\ |\\ C(CO_2H)_2\end{array}\right.$$

m.p. 115° (Ipatiew, J. Russ. Phys. Chem. Soc. 1901, 33, 540).

ITROL *v.* SYNTHETIC DRUGS.

IVORY is essentially *dentine*, the main constituent of all teeth, but usage restricts the term to the dentine of those teeth which are available for industrial purposes; chiefly those of the elephant, hippopotamus, walrus, narwhal, and sperm-whale.

Ivory contains 57–60 p.c. of calcium salts, chiefly the phosphate, with 40–43 p.c. of an organic matrix and 0·24–0·34 p.c. of fat. It differs from other dentines chiefly in the large amount of organic matter it contains (*cp.* human dentine containing 25 p.c. of organic matter), and in its structure (*v. infra*) and from bone in its greater elasticity and the absence of the larger canals conveying blood vessels.

The substance of ivory is permeated by an immense number of fine canals, about $\frac{1}{1500}$ inch in diameter and strongly curved, to which are due its fineness of grain and probably much of its elasticity. That obtained from the tusks of *Proboscidea* exhibits, on a transverse section, a characteristic pattern of curved decussating lines. The cross-section shows a central spot, the residue of the pulp-centre (*v. infra*), surrounded by concentric circular 'contour lines,' due to a number of minute, irregular 'interglobular spaces.' These spaces and the canals are probably filled with protoplasmic matter in the living tooth. The exterior of the tooth is covered with cementum, usually of a brown colour.

Most of the ivory now used is obtained from the upper incisor teeth of the elephant. The tusks of the African elephant are 9–10 feet long and weigh up to 160 lbs., and are possessed by both males and females. Of Indian elephants, none of the females and not all the males have tusks, and those of the latter are usually less than 8 feet in length and 90 lbs. weight. Captive elephants have their tusks shortened and the ends bound with metal. The tusks grow continuously, and if cut at intervals of ten years yield a useful amount of ivory, although that from wild elephants, especially African elephants, is more highly valued.

The tusks are implanted to the extent of about half their length in curved bony sockets which run nearly vertically upwards to the level of the eyes. The part within the socket has a conical centre of pulp by the conversion of which into dentine growth takes place, fresh pulp being continually formed at the base of the tooth. The pulp is not easily injured and sometimes foreign bodies, such as bullets and spear-heads, have been found embedded in solid ivory, their presence in the pulp having failed to inhibit its conversion into dentine.

In Russia the tusks of mammoths from North Siberia are much used: they have been preserved unchanged from prehistoric times by the low temperatures of that region.

The canine teeth of the hippopotamus yield an ivory harder and whiter than that of the elephant, and less prone to turn yellow.

Among Northern nations, the upper canine teeth of the walrus are used as a source of ivory. They consist of dentine covered with cementum and have an axis of secondary dentine which is nodular in appearance but usually dense and uniform. The spiral tusk of the narwhal is similarly employed.

Ivory is largely used for making billiard balls, graduated scales, knife-handles, piano-keys, combs, fans, &c., and a considerable quantity is imported into China for the manufacture of ornamented articles. Dieppe is the principal centre for ivory-working in Europe.

As ivory shrinks when dried it is usually cut roughly to shape first, then dried spontaneously or by heat, and finally finished. Because of its high price, great care is taken to cut it up economically and all chips, cuttings, &c., are used for making *ivory-black* or for the preparation of a very pure gelatin.

Ivory can be made flexible by treatment with phosphoric acid and re-hardened by washing and drying, but not without injury to its quality. It takes dyes well and it may be bleached by exposure to sunlight and moisture, by the action of hydrogen peroxide, or by washing alternately with solutions of potassium permanganate and of oxalic acid (Textile Colourist, 1901. 23, 285; *v.* also Livache, J. Soc. Chem. Ind. 1903, 307).

J

JABORANDI. *Pilocarpus.* The natives of the eastern parts of South America employ the word 'jaborandi' to designate a group of plants having similar diaphoretic and sialagogue properties. The most important of these, the official jaborandi, was introduced into European medicine by Coutinho and Gubler in 1874 (Rép. de Pharm. 2, 171). The leaves of the plants are used. The jaborandi leaves at present in the market are those of *Pilocarpus pennatifolius* (Lem.) and the Maranham jaborandi, *Pilocarpus microphyllus* (Stapf.).

Three alkaloids have been separated from jaborandi. Rabuteau (Pharm. J. [iii.] 4, 911) and Byasson (*ibid.* [iii.] 5, 826) investigated the leaves chemically, but the first definite compound, *pilocarpine* $C_{11}H_{16}N_2O_2$, was discovered by Hardy (Compt. rend. Soc. Biol. 1875, 109; Bull. Soc. chim. 24, 497; J. Pharm. Chim. [iv.] 23, 95; Pharm. J. [iii.] 6, 887; 7, 496) and independently just afterwards by Gerrard (*ibid.* [iii.] 5, 865, 965; 6, 227; 7. 255; 10, 214; 11, 608). To obtain it, Hardy prepares an aqueous extract which is treated with alcohol, the alcoholic solution evaporated to a thick syrup, and this dissolved in a little water and precipitated with ammoniacal lead acetate. The mixture is filtered and the lead removed from the filtrate by sulphuretted hydrogen which then contains the alkaloid as acetate. Mercuric chloride is added, which forms an insoluble double chloride. This is separated, washed with water and decomposed by sulphuretted hydrogen. The solution contains pilocarpine hydrochloride, and treated with ammonia and chloroform it yields to the latter the free alkaloid. Gerrard suggests the following process. The leaves are exhausted with 84 p.c. alcohol, containing 1 p.c. of strong solution of ammonia. The solution is neutralised with tartaric acid, the alcohol removed by distillation, and the residue treated with excess of ammonia and alcohol and the alcohol again distilled off. From the residue chloroform extracts crude pilocarpine which is best purified by conversion into the nitrate; this admits of easy recrystallisation from alcohol, and from it the free alkaloid may be readily obtained. Poehl (Bull. Soc. chim. [ii.] 24, 340) uses phosphomolybdic acid as a precipitant for pilocarpine, both in valuing the drug and in the preparation of the alkaloid; and Christensen (Pharm. J. [iii.] 12, 400) for the former purpose weighs the alkaloid in the form of a gold salt. Another process is proposed by Petit (*ibid.* [iii.] 8, 46).

Pilocarpine forms long colourless crystals, melting at 34°, but is usually obtained as a thick syrup. It is freely soluble in alcohol, water, or chloroform, but is almost insoluble in ether or light petroleum. It is poisonous, and like nicotine, which it resembles in physiological action, it contracts the pupil of the eye. Pilocarpine yields well defined salts and when dissolved in sodium hydroxide forms the sodium salt of *pilocarpic acid*, of which pilocarpine is the anhydride (Petit and Polonowsky, J. Pharm. Chim. [vi.] 5, 370, 430, 475; Jowett, Chem. Soc. Trans. 77, 473; Pinner and Schwartz, Ber. 1902, 35, 192).

Pilocarpidine $C_{10}H_{14}N_2O_2$ was isolated from jaborandi leaves by Merck (Pharm. J. [iii.] 16, 106) and by Harnack (Annalen, 238, 230). It is a syrupy liquid, moderately soluble in water, easily in alcohol and chloroform, but insoluble in light petroleum. The researches of Jowett show that this base is found only in the leaves of the true jaborandi, *P. jaborandi* (Baill.), and is not contained in the leaves at present available.

isoPilocarpine is isomeric with pilocarpine and is formed by the action of heat or alkalis on this base. It was discovered by Petit and Polonowsky, but was considered by them to be the same as the pilocarpidine described above. *iso*Pilocarpine occurs in small quantity in the leaves of the drug but the greater portion is formed during the process of manufacture. It forms colourless deliquescent prisms (Petit and Polonowsky) or a viscid oil (Jowett). It can be distilled in a vacuum without decomposition. A solution of *isopilocarpic acid*, the analogue of pilocarpic acid, may be obtained by passing carbon dioxide into a solution of its salts in absolute alcohol and removing the alkali carbonate by filtration. *iso*Pilocarpine nitrate is present as an impurity in the commercial pilocarpine nitrate.

(For the constitution and reactions of the above compounds, *v.* ALKALOIDS.)

The alkaloid described as jaborine by Harnack and Meyer (Annalen, 204, 67), appears to be a mixture of *iso*pilocarpine, pilocarpidine, and possibly pilocarpine.

The physiological action of the jaborandi alkaloids has been studied by Marshall (J. Physiol. 31, 123). Pilocarpine is the most active physiologically, *iso*pilocarpine produces a similar but much weaker effect than pilocarpine, while pilocarpidine is so very slightly active, it may be said to be almost inactive.

The microchemical detection of the alkaloids in the leaves of *Pilocarpus pennatifolius* (Lem.) has been investigated by Tunmann (Chem. Zentr. 1909, i. 1510).

Of the constituents of jaborandi which have been examined, there only remains to be mentioned the volatile oil, which exists to the extent of about ½ p.c. in the leaves. This consists of a dextrorotatory terpene which boils at 178°, *pilocarpene* $C_{10}H_{16}$, and some higher boiling liquid and solid compounds. Pilocarpene has the sp.gr. 0·852, and forms a crystalline hydrochloride $C_{10}H_{16},2HCl$ which melts at 49·5°.

An examination of a species of jaborandi, *Pilocarpus spicatus* (St. Hilaire) [*Aracati jaborandi* (Holmes)], by Petit and Polonowsky (J. Pharm. Chim. [vi.] 5, 369), has led to the isolation of two alkaloids. The leaves were extracted in the usual way and the mixture of the bases converted into nitrates. The mixed nitrates were then treated with sodium hydroxide and extracted with chloroform. From the chloroform solution, *pseudo-jaborine* was obtained as a colourless oil with strongly alkaline properties. The second alkaloid *pseudo-pilocarpine* has very much the same properties as pilocarpine except that it is optically inactive. A. S.

JADE. Under this term are included two distinct minerals differing widely in chemical composition, but strikingly similar to one another in external characters. These are nephrite and jadeite. They rank as precious stones, being especially valued in the East as the material for elaborately carved ornaments. Stone implements worked in these materials have been found in the ancient Swiss lake-dwellings and amongst prehistoric remains in many other countries. These minerals have, in common, a white to green (rarely a pale violet) colour, with a certain degree of translucency and a greasy appearance on highly polished surfaces. They are remarkable for their extreme toughness (as distinct from hardness), it being very difficult to fracture pebbles by blows from a hammer. This toughness is a result of the peculiar texture of the material: thin sections examined under the microscope show a close, felted aggregate of short, minute fibres.

The name nephrite from the older name *lapis nephriticus*, meaning kidney-stone, refers to the ancient belief that when worn as a charm this stone was a remedy for kidney disease. The name jade has the same meaning, through the Spanish 'piedra de yjada.' A well-known Chinese name is 'yu,' and the ancient Mexican is 'chalchihuitl.' Jadeite was first distinguished chemically and so named by A. Damour in 1863.

Nephrite is a metasilicate of magnesium and calcium $CaMg_3(SiO_3)_4$, with usually a small and variable amount of ferrous oxide (to which is due the range in colour). It is a member of the amphibole group, differing from tremolite, actinolite, and amphibole-asbestos only by reason of the peculiar texture of the material. Under the microscope, the fibres show prismatic cleavages inclined at 124° and the optical characters of amphibole; sp.gr. 2·91–3·1.

Jadeite is a metasilicate of sodium and aluminium $NaAl(SiO_3)_2$; small amounts of ferrous and ferric oxides are often present, and in the dark green variety known as chloromelanite there is 6–10 p.c. Fe_2O_3 isomorphously replacing alumina. Jadeite is a member of the pyroxene group, having an angle of 93° between the prismatic cleavages and the optical properties characteristic of this group; sp.gr. 3·30–3·35 (3·4 in chloromelanite). The hardness (H. 6½–7) is rather greater in jadeite than in nephrite (H. 6–6½).

These two minerals are of course readily distinguished by chemical tests; and also by the easier fusibility of jadeite, which at the same time imparts a yellow colour to the flame. In thin sections under the microscope, the optical characters and cleavage angles afford distinguishing features. In many cases, however, it is the material of a carved ornament that requires determination, and then the only available test is that given by the difference in sp.gr. Some other minerals, *e.g.* the hard compact variety of serpentine known as bowenite (sp.gr. 2·6), which are often confused with jade, may also be readily distinguished by their sp.gr.

Nephrite and jadeite each occur as constituents of metamorphic silicate rocks, and they are frequently so intimately intermixed with other minerals that the material itself is at times of the nature of a rock. Much of the material used for carving is collected as pebbles and boulders from the beds of streams. Quarries in the solid rock are, however, worked in Eastern Turkestan (nephrite) and at Tawmaw in Upper Burma (jadeite). The well-known New Zealand 'greenstone' is a dark green nephrite. (On New Zealand nephrite, *see* A. M. Finlayson, Quart. J. Geol. Soc. 1909, 65, 366.)

Jade presents many points of interest to the ethnologist and collector as well as to the mineralogist, and it is the subject of a considerable literature. A monumental work in two huge, beautifully illustrated volumes is the 'Investigations and Studies in Jade,' based on the Heber R. Bishop collection (New York, 1906; a privately printed edition limited to 100 copies was prepared at enormous expense for free distribution to the principal royal and public libraries of the world). The subject is here dealt with by numerous contributors from all possible points of view; in the chemical portion 58 new analyses are given. A briefer and more accessible general account of jade is given in M. Bauer's Edelsteinkunde, 2nd edit. 1909; English translation, Precious Stones, by L. J. Spencer, 1904. L. J. S.

JAK-WOOD, or Jack-wood, is derived from the *Artocarpus integrifolia* (Linn.) which belongs to the *Urticaceæ*, and is cultivated throughout India, Burmah, and Ceylon, except in the north. It is largely used for carpentery, furniture, &c., and is stated to be imported to Europe for this purpose. The rasped wood is used by the natives of India and Java as a yellow dye in conjunction with alum, for the robes of the Burmese priests, also for dyeing silk and for general purposes.

An aqueous solution of the wood possesses the characteristic property that when it is treated with alkali and gently warmed, the yellow solution at first obtained assumes a beautiful blue tint.

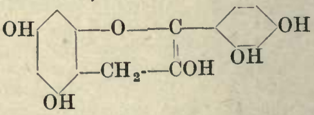
Jackwood (Perkin and Cope, Chem. Soc. Trans. 1895, 67, 937) is very similar to old fustic, and its dyeing properties are due to *morin* (*see* OLD FUSTIC). Unlike old fustic, however, it contains no maclurin, but there is present a second substance, cyanomaclurin, which is devoid of tinctorial property. These compounds can be isolated from jackwood by methods which are almost identical with those which have been applied to fustic itself, and their separation may be effected by means of lead acetate as this precipitates only the morin.

Cyanomaclurin $C_{15}H_{12}O_6$ crystallises in colourless prisms, somewhat readily soluble in water, and gives with basic lead acetate a colourless precipitate, and with ferric chloride a violet coloured liquid. Its solution in dilute alkalis is colourless, but if this be gently warmed a beautiful deep indigo colouration is produced, which on longer digestion passes into green and finally becomes brown-yellow. When fused with alkali, it gives *β-resorcylic acid* and *phloroglucinol.*

Acetylcyanomaclurin $C_{15}H_7O_6(C_2H_3O)_5$, colourless needles, melts at 136°–138°, and *benzoylcyanomaclurin* $C_{15}H_7O_6(C_7H_5O)_5$, colourless prisms, melts at 171°–172°. *Disazobenzenecyanomaclurin* $C_{15}H_{10}O_6(C_6H_5N_2)_2$, scarlet needles, m.p. 245°–247° (decomp.), gives an *acetyl* derivative probably

$$C_{15}H_7O_6(C_6H_5N_2)_2(C_2H_3O)_3$$

orange red needles, m.p. 209°–210° (decomp.) (Perkin, Chem. Soc. Trans. 1905, 87, 715). In certain respects, cyanomaclurin resembles the catechins of gambier and acacia catechus, and more especially so in that by boiling with dilute acids it gives reddish-brown amorphous substances, which are very similar to the so-called catechin anhydrides. The product obtained by the action of hydrochloric acid on a boiling acetic acid solution of cyanomaclurin is insoluble in alkalis and all solvents, and has a percentage composition almost identical with the catechin anhydride similarly produced. According to Perkin, cyanomaclurin is possibly a reduction product of morin, thus:



Jackwood dyes shades very similar to those given by old fustic; that is, olive yellow with chromium, dull yellow with aluminium, and a brighter yellow with tin mordant. On the other hand, the sample examined by Perkin and Cope possessed only about one-third of the dyeing power of old fustic. A. G. P.

JALAP *v.* RESINS.

JALAPIN *v.* GLUCOSIDES.

JAMBA OIL is obtained from a plant belonging to a variety of the genus *Brassica.* The oil behaves, in most respects, very similarly to ordinary rape oil, but differs from it most distinctly in that it does not lend itself so readily to the manufacture of 'blown' oil, as the other oils belonging to the rape oil group. Hence jamba oil is distinctly inferior to rape oil prepared from genuine rape seed oil, a difference which finds its ready expression in the lower commercial value of jamba oil, as compared with that of colza oil.

Jamba oil is most readily recognised by its peculiar taste and smell. It is chiefly used as a burning oil, although it does not burn so well as colza oil. It is also used for lubricating purposes, and takes its place, as regards quality, between Indian rape oil and ravison oil.

J. L.

JAMESONITE. A sulphantimonite of lead, invariably containing 2–3 p.c. of iron, the formula being $4PbS\cdot FeS\cdot 3Sb_2S_3$ (W. T. Schaller, Zeitsch. Kryst. Min. 1911, 48, 562; L. J. Spencer, Min. Mag. 1907, 14, 207, 310). It is orthorhombic with a distinct basal cleavage, but only acicular crystals (*v.* Feather-ore), columnar masses, or more usually finely fibrous masses have been found. Coarse columnar masses associated with stibnite have been mined at Endellion in Cornwall. The mineral is of frequent occurrence in Bolivia, and, as it sometimes contains small amounts of silver, it has been worked as a silver-lead ore as well as for antimony. L. J. S.

JANTHONE. A synthetic perfume obtained by condensing citral or lippial and mesityl oxide. *Lippial* $C_{10}H_{16}O$ is present in the oil of *Lippia citriodora* (H. B. & K.). Janthone is a tetrahydrobenzene derivative containing two ethylene bonds in the ketone side chain: b.p. 162° under 10 mm.; sp.gr. 0·9452. When diluted it has a characteristic odour of violets and orris root. (D. R. P. 118288, 1898; Farbw. Durand, Hugenin & Co., Zeitsch. angew. Chem. 1901, 14, 346.)

JAPACONITINE *v.* Vegeto-alkaloids.

JAPAN BLACK *v.* Brunswick black.

JAPAN EARTH. *Terra japonica v.* Catechu.

JAPANESE SARDINE OIL is obtained from *Clupanodon melanosticta* (T. and S.), a fish belonging to the *Clupeidæ*. Japanese sardine oil differs distinctly from the ordinary sardine oil (*see* Sardine oil) by its higher iodine value, which in pure specimens reaches as high a figure as 187. The commercial oil has, until recently, been prepared in a very crude manner, the fish refuse having been boiled with water to separate the oil. Japanese sardine oil is characterised by a considerable proportion of *clupanodonic acid*, of which as much as 14·2 p.c. is yielded by genuine specimens.

The commercial Japanese sardine oil has hitherto been more or less mixed with other fish oils, so that the commercial specimens of oil exhibit much lower iodine values than the genuine oils. Japanese fish oil (which must not be confounded with Japanese cod liver oil) is largely exported to Europe and to Australia, where it is used in soap making and in the leather industries. J. L.

JAPANNING. A term synonymous with 'lacquering' (*v.* Lacquer).

In Europe, japanning is also taken to mean the art of coating surfaces with varnishes which are then hardened by subjecting them to a high temperature, an art which holds an intermediate position between painting and enamelling. The varnishes are transparent and durable bodies, in black or other colours, black being the hue which is most extensively used. Black varnish is composed of pure natural asphaltum mixed into a preparation of gum anime dissolved in linseed oil and turpentine. This in thin coatings appears brown, and requires several courses to acquire the requisite blackness; the article treated being placed in a stove at about 150° after each coating. For colours, the necessary mineral pigments or metallic powders are mixed with a transparent copal varnish of less body than ordinary painters' varnish.

European japanning, although very far behind the work produced by the process described as in use among the Japanese, produces a very brilliant and durable coating to small articles of metal work and papier mâché. It is also applied as a facing for stone to imitate marble.

JAPAN SAGO. Starch obtained from the stem of *Cycas revoluta* (Thunb.).

JAPAN WAX (Japan tallow) is obtained from the berries of several species of the sumach tree, viz.: *Rhus succedanea* (L.), known in Japan as 'hazé'; *R. acuminata* (DC.); *R. vernicifera* (DC.), known in Japan as 'urushinoki'; *R. sylvestris* (Sieb. et Zucc). The first-named species is grown chiefly in China, whereas the last-named one flourishes especially in the western provinces of Japan; the species *R. succedanea* grows also in Indo-China and in India. In China, Japan, and Tonkin, the trees are cultivated chiefly for the sake of the lacquer which they exude. Japan wax must therefore be considered as a by-product of the lacquer industry.

The seeds of the several species of *Rhus* consist of a small kernel surrounded by a greenish, striated, shrivelled mass. In China the wax is prepared by crushing the seeds, together with their coating, and steaming them in perforated cylinders so that the fat melts and runs off. In Japan the manufacture is still carried out in a somewhat crude fashion, by storing the berries in straw until they are fully matured, then crushing them by hand in a wooden funnel-shaped trough, and winnowing the mass so as to separate the kernels. The powdered mass thus obtained is put into hempen sacks and subjected to pressure in wooden wedge presses. The yield from the berries ranges from 15 to 20 p.c. The fat is a coarse greenish tallow-like mass. It is refined by remelting, pressing through cotton sacks, and allowing the fat to drop into cold water. The thin flakes of the wax are then bleached by exposure to the sun in shallow baskets (in a similar manner as is done in the process of bleaching bees' wax), the material being continually turned over and sprinkled with water. The bleached wax is finally melted and cast into slabs, in which form it is exported to Europe.

The production of Japan wax cannot be largely extended, as it takes 7 to 8 years for a wax tree to reach maturity, and if the tree promises to become a fruitful source of lacquer, this leads to its sacrifice as a source of wax.

Japan wax is a pale yellow, somewhat hard substance of conchoidal, somewhat lustrous fracture. On keeping, Japan wax turns deep yellow and becomes coated with a white powder consisting of microscopical prismatic needles. The term 'wax' is a misnomer, as Japan wax is a glyceride, consisting chiefly of palmitin and free palmitic acid. Hence, it is more appropriately termed Japan tallow.

Japan wax is insoluble in cold alcohol, but dissolves readily in boiling alcohol, separating almost completely on cooling as a granular, crystalline mass. In addition to palmitic acid, it also contains small quantities of dibasic acids, as also of a soluble acid, the proportion of which has been found to amount to almost 6 p.c. The proportion of dibasic acids amounts to nearly 1 p.c.; amongst these, the largest in amount is *japanic acid* $C_{19}H_{38}(COOH)_2$ (nonadecamethylenedicarboxylic acid), which is accompanied by its lower homologues, heptadecamethylenedicarboxylic acid $C_{17}H_{34}(COOH)_2$, and octodecamethylenedicarboxylic acid

$$C_{18}H_{36}(COOH)_2.$$

These dibasic acids probably occur as mixed glycerides of palmitic and dibasic acids. The constitution of Japan wax being that of a glyceride, it is most readily differentiated from the true waxes by yielding glycerol on saponification. The iodine value of genuine Japan wax is about 4. The commercial wax has a higher iodine value—from 10 to 15—as in consequence of the increased demand for Japan wax it has become the practice in Japan to extract the press residues with the (hazé) kernel oil. In the Chinese mode of manufacture, the kernel oil passes automatically into the 'wax.' At a temperature of 16°–18°, Japan wax has the density of water of the same temperature.

Japan wax is largely used for waxing floors, and as a constituent of polishes. As it forms an emulsion with water, it can be used for currying leather. Notwithstanding its high proportion of palmitic acid, it does not constitute a suitable candle material. The proposal to use it as an admixture with edible fats, or with margarine, is to be strongly deprecated. J. L.

JARGON or **JARGOON** *v.* ZIRCON.

JASMAL. The active odoriferous principle of the jasmine flower. Is the methylene acetal of phenyl glycol,  $\begin{matrix} CH_2{\cdot}O \\ | \\ CH_2{\cdot}O \end{matrix}\!\!>CH{\cdot}C_6H_5$, and may be synthetically formed by condensation of phenyl glycol and formaldehyde in presence of sulphuric acid: b.p. 218°; sp.gr. 1·1334 (Verley, Compt. rend. 1899, 128, 314).

JASPER. A compact and opaque variety of quartz, intimately intermixed with iron oxide and hydroxide, clay, &c.; these impurities being present sometimes to the extent of 20 p.c. The material has a dull, even fracture, but it takes a good polish; the colours are various—red, yellow, brown, green, &c. It is cut and polished as an ornamental stone, and was much prized by the ancients, but their *jaspis* included other minerals than those now designated as jasper. The well-known *Egyptian jasper* is found as nodules and pebbles in the Nile Valley, and resembles a brown flint, with dark zones and cloudings. *Banded jasper* is a striped variety, well illustrated by the beautiful red and green 'riband jaspers' of the Ural Mountains. Some banded jaspers appear to be metamorphic sedimentary rocks, whilst others are striated felsitic tuffs. The so-called *porcelain-jasper* is merely a shale highly indurated by exposure to a high temperature. F. W. R.

JAUNE ACIDE. *Acid yellow* (*v.* AZO-COLOURING MATTERS).

JAUNE ANGLAIS. *Victoria yellow* (*v.* CRESOL).

JAUNE BRILLIANT. *Cadmium sulphide* (*v.* CADMIUM).

JAUNE DE FER, JAUNE DE MARS. *Mars yellow* (*v.* PIGMENTS).

JAUNE D'OR. *Martius's yellow* (*v.* NAPHTHALENE).

JAUNE N. *Curcumeïn; Orange N.* (*v.* AZO-COLOURING MATTERS).

JAUNE SOLIDE. *Fast yellow* (*v.* AZO-COLOURING MATTERS).

JAVA WAX, FIG WAX *v.* WAXES.

JESTERIN *v.* GLUCOSIDES.

JET. (Fr. *Jais, Jaïet*; Ger. *Gagat, Agstein.*) A variety of fossil coal or lignite, similar in appearance to cannel-coal. Being hard and capable of taking a lustrous surface by polishing, it is used for making small ornamental articles; sp.gr. 1·35. It is found on the Yorkshire coast near Whitby, in Spain, France, and Würtemberg, occurring in the shale and limestone formations. The name is supposed to be a corruption of the *Gagates* of Pliny and Dioscorides, who described the mineral as found near the mouth of the river Gagas in Lycia, Asia Minor.

The jet of Whitby is evidently a fossilised coniferous wood, as shown by its structure in thin sections under the microscope. On its surface impressions of fossils, especially ammonites, frequently appear.

Whitby jet is divided into 'hard' and 'soft,' of which the former is the more esteemed; it is found near the base of the Upper Lias and, sparingly, in other parts of that formation. Soft jet occurs in the sandstones and oolitic shales. The hard variety is obtained in compressed layers varying from an inch or two in length and $\frac{1}{8}$th in thickness, to 6 feet long, 30 inches wide, and 4 inches thick. The largest piece ever found was 6 feet 4 inches long, $4\frac{1}{2}$ to $5\frac{1}{2}$ inches wide, and 1 and $1\frac{1}{2}$ inches thick; it weighed 11 lbs. 8 oz.

The collection of jet was formerly effected by cutting down the cliffs until the jet-veins showed themselves; to-day the cliffs are almost abandoned and the works are carried on inland to a distance of 20 miles. The operation is described by J. A. Bower (Jour. Soc. of Arts, 22) in these words: 'The process of obtaining jet here is simple; the faces of the hills are turned down bodily, and by then tunnelling for some distance, and after carrying several passages parallel from the face of the hill, transverse shafts are cut. When the rock becomes too hard the miners retire, pulling down the roofs on their return; in these falls the bulk of the jet is found.' The rough jet obtained from the inland mines is encased in a brown skin; that from the cliffs is covered with a blue skin. This is chipped off, the pieces of jet are sawn into suitable sizes and handed over to the carver or turner. (*See* Whitby Jet and its Manufacture, Jour. Soc. of Arts, 22, 80; Illustrations of the Geology of Yorkshire, Part I. The Yorkshire Coast, by John Phillips; A. C. Seward, The Structure and Origin of Jet, Rep. Brit. Assoc. 1901, 856; P. E. Spielmann, The Origin of Jet, Chem. News, 1906, 94, 281; 1908, 97, 181). L. J. S.

JUAR-ROOT. A powerful narcotic used in India to enhance the intoxicating power of bhang.

JUDSON POWDER *v.* EXPLOSIVES.

JUGLONE *v.* NAPHTHALENE.

JUNIPER. (*Genièvre*, Fr.; *Wachholder*, Ger.) The fruit, or so-called berries, of juniper have been employed in medicine from very early times. It is a reputed diuretic. Sometimes it has been used as an article of food, and the large proportion of sugar which it contains has rendered it available for fermentation and the distillation of spirit. Such a product was in France called *Genièvre* and hence the contracted form *gin* employed in this country for a spirit which now is merely flavoured with juniper. The juniper of modern medicine is the *Juniperus communis* (Linn.) (Bentl. a. Trim. 255) a well-known evergreen shrub which inhabits the northern regions of both hemispheres. The fruits are gathered chiefly in Hungary, Austria, and the south of France (Flück. a. Hanb. 624; Morel, Pharm. J. [iii.] 8, 886).

The most important constituent of juniper is the *volatile oil*, which although it occurs in all parts of the plant, is found chiefly in, and is always distilled from, the fruit. Both the quantity and quality of the oil varies with the age of the fruit. That obtained from the green fruit is larger in proportion, and is a lighter oil, than that distilled from the ripe fruit. The former is the more highly esteemed. The yield varies from 0·4 to 1·2 or perhaps 2·0 p.c. It is a colourless liquid, having a strong odour of juniper and a hot aromatic taste. It boils at 155° to 200° or 205° and its sp.gr. varies from 0·86 to 0·88 (Morel). It consists of a *terpene* boiling at 155°, sp.gr. 0·839 at 25° (Blanchet, Annalen, 7, 165), together with *polymeric terpenes*, chiefly $(C_{10}H_{16})_2$(?), which boil above 180°, mostly about 200°. Wallach (Annalen, 227, 228) has examined the terpene (*pinene*). The oil is lævorotatory. According to Blanchet, it forms a crystalline *hydrate*, and Soubeiran and Capitaine (J. Pharm. Chim. 26, 78) describe a liquid *hydrochloride*. Tilden (Pharm. J. [iii.] 8, 189) prepared from it a *nitrosyl chloride compound* $C_{10}H_{16}NOCl$. On long standing it deposits a *camphor* (Gm. 14, 295). Generally, its reactions are similar to those of turpentine oil (Gm. 14, 292; Dragendorff, Pharm. J. [iii.] 6, 581; Barth, Zeitsch. Chem. 1867, 509; Morel). The analytical constants of oil of juniper are given in Haensel's Half-yearly Report, Oct. 1908.

The other constituents of juniper fruits may be seen from the analyses of Donath (Dingl. poly. J. 208, 300) and Ritthausen (Landw. Versuchs-Stat. 20, 423). The chief of these is *glucose*, of which Donath finds 29·65 and Ritthausen 14·36 p.c. The bitter substance *juniperin*, which occurs only to the extent of 0·37 p.c., was first studied by Steer (Sitz. Ber. 21, 383). *Resins*, *cf.* Trommsdorff (Gm. 17, 449). A. S.

JUNIPER, OIL OF, *v.* OILS, ESSENTIAL.

JUTE is the bast fibre almost exclusively of two plants of the natural order *Tiliaceæ*, viz. *Corchorus capsularis* (Linn.) and *Corchorus olitorius* (Linn.), cultivated for the most part in Bengal, where they are indigenous. Although differing in size and in the form of their seed-pods, the plants are not greatly dissimilar in appearance and are not commercially distinguished from each other. The seed is sown annually, in April or May, and the plants after flowering, which takes place from August to September, and having now attained a height of 5 or 6 feet in the case of *C. olitorius*, and of 5 to 10 feet in that of *C. capsularis*, are cut down and thrown into pits of water to soak, after the manner of steeping flax. From a few days to a month is required to bring the stalks into a condition for stripping the bast from the wood and freeing it from cortex, these operations being purely manual. After being washed and dried the jute is made up into bales for sale.

Jute is very largely used for the manufacture of sacking and wrapping cloths (Hessians), as a paper-making fibre, and as a substitute for hair in making theatrical wigs. It is also employed for carpet-making and inferior cordage and, in India, for making small domestic articles such as nets and muzzles for oxen. In these islands the principal seat of the jute industry is Dundee.

The fibre occurs in strands of considerable length, 6–12 feet; the spinning unit or filament is of various lengths, according to the degree of subdivision practised. The filament is a complex of the ultimate fibres, of which from 5 to 12 are usually seen in the section at any point. They are polygonal in section and much thickened (lignified); their length does not exceed 2–3 mm., whereas those of flax and hemp—also bast fibres—are from 25–40 mm. long. This structural inferiority, together with the fact that the fibre substance yields somewhat readily to the action of oxidants (air and light) in presence of water, characterises jute as a 'weak fibre.'

Treated by the 'line spinning' process it may be spun into yarns of considerable fineness, but, owing to the large proportion of waste ('tow'), at relatively large cost. These yarns when bleached—preferably by 'soda bleach' (sodium hypochlorite)—have considerable lustre; they are soft and of a cream shade, and take up the majority of colouring matters—wood and aniline dyes—directly from the dye-bath. Jute fabrics are also successfully printed in steam styles, the presence of sodium sulphite being necessary to preserve the fibre substance from the action of the steaming process (Développement de l'Industrie de Jute, Cross and Witt, Bull. Mulhouse, 1881).

According to the investigations of Cross and Bevan, jute does not contain cellulose as such, but in the form of bastose or lignocellulose, which is a link between the carbohydrates and the aromatic compounds. Treated with chlorine it gives a yellow chlorinated derivative which when hydrolysed yields substances belonging to the tannic acid group. Hence it may be said that jute possesses a mordant which makes it receptive of aniline colours in a degree possessed by none of those fibrous materials which require the intervention of a mordant. When quantities of the fibre are kept in a damp situation, more especially when exposed to sea-water, it is decomposed into substances analogous to tannin and to acids of the pectic acid group. Under treatment by acids, jute is disintegrated, yielding xylose and furfural (*v.* also Tollens, Annalen, 254, 325). It is easily bleached by potassium permanganate after cleansing with soap or alkali, with a loss in weight of 3 to 4 p.c. In practice this is generally too expensive a process, and the substances usually employed are hypochlorites, in which great care is necessary, as chlorinated compounds may be formed and the fibre destroyed (*supra*) (*v.* CELLULOSE).

K

KAINITE. A hydrated double salt

$$MgSO_4 \cdot KCl, 3H_2O,$$

occasionally found in the potash-salt deposits as sharply developed, water-clear, monoclinic crystals; sp.gr. 2·1. As granular masses of a white, grey, or reddish colour it forms large beds near Stassfurt in Prussia, and at Kalusz in Galicia (*v.* POTASSIUM). On the artificial production of kainite, *see* van 't Hoff, Sitz.-Ber. Akad. Wiss. Berlin, 1901, 420; 1903, 678.

L. J. S.

KAIRINE, KAIROCOLL, KAIROLINE, *v.* QUINOLINE.

KAISERGELB *v.* AURANTIA.

KAISERROTH. The sodium salt of dinitrodibromfluoresceïn. Called also Eosin Scarlet, Safrosine, and Lutétienne.

KALIBORITE. A mineral resembling *pinnoite*, found by Feit in the salt deposits at Schmidtsmannshall, near Ascherleben, Prussia. Is a hydrated borate of potassium and magnesium

$$2K_2B_6O_{10} \cdot 9MgB_4O_7, 39H_2O.$$

Water disintegrates the mineral, but is otherwise without action on it. Easily soluble in warm mineral acids. Sp.gr. 2·05 (Chem. Zeit. 13, 1188).

KAMALA. Kamala is the orange red powder which exists as a glandular pubescence on the exterior of the fruits of the *Mallotus phillipinensis* (Muell.) (*Rottlera tinctoria* [Roxb.]), a small evergreen tree, met with throughout tropical India, Burma, and Ceylon, also in Java, China, the Malay Islands, and Australia. The ripe capsules are gathered in February or March, and shaken in bags until the powder separates.

Kamala is extensively employed by the Hindoos as an antithelmic drug and for dyeing silk and wool a bright orange colour. The fabric is dyed in a boiling bath containing 4 parts kamala, 1 part alum and 2 parts sodium carbonate (native barilla), previously well rubbed together in the powdered state with a small quantity of oil of sesamum. The alum is sometimes omitted, but the addition of alkali is absolutely necessary in order to dissolve the colouring matter, which is of a resinous character and quite insoluble in water. Kamala is also apparently used for the adulteration of Annatto. According to Perkin (private communication), samples of calico obtained from India and presumably dyed with kamala have proved on examination to owe their colour partially if not entirely to annatto. Kamala was formerly employed in this country as a remedy for taenia, but appears now to be very little used for this purpose.

Anderson was the first chemist to investigate kamala (Edin. New. Phil. J. 1, 300), and he isolated from it by means of ether a crystalline compound *rottlerin* $C_{11}H_{10}O_3$, a wax $C_{20}H_{34}O_4$, and a resin melting below 100°, to which he gave the formula $C_{30}H_{30}O_7$. Leube (J. 1860, 562) was unable to obtain any crystalline product from this drug, but he describes two resins, $C_{15}H_{18}O_4$, m.p. 80°, and $C_8H_{12}O_5$, m.p. 191°. Oettingen (Dissert. St. Petersburg, 1862) also could not obtain any crystalline substance from kamala. A. and W. Perkin (Ber. 1886, 19, 3109), however, isolated the crystalline rottlerin ('mallotoxin') of Anderson, and its existence was subsequently confirmed by Jawein (Ber. 20, 182).

As the result of a more extended examination of kamala and employing carbon disulphide for the extraction, A. G. Perkin (Chem. Soc. Trans. 1893, 63, 975) isolated not only Anderson's compounds, but small quantities of two crystalline substances, homorottlerin, which is yellow, and *iso*rottlerin, a salmon coloured powder, together with a high melting resin.

Rottlerin $C_{33}H_{30}O_9$ (Perkin, *ibid.* 1895, 67. 230), salmon coloured plates, melts at 191°–191·5° (P.), 200° (Jawein), 202°–204° (Telle, Arch. Pharm. 1906, 244, 441), readily soluble in ether. Solutions of the alkali carbonates and hydroxides dissolve rottlerin, the former only on gently warming. On boiling these orange-coloured liquids, decomposition gradually takes place, an odour of benzaldehyde is evolved and a resinous product separates. An alcoholic solution of rottlerin is coloured brown on the addition of ferric chloride.

Acetylrottlerin $(C_{11}H_8O_3(C_2H_3O)_2)_3$, yellow crystalline powder, m.p. 130°–135° (P.), and *benzoylrottlerin* $C_{33}H_{24}O_9(C_7H_5O)_6$, yellow powder (Bartolotti, Gazz. chim. ital. 24, [ii.] 480), have been prepared.

Rottlerin forms the following salts:

$$C_{33}H_{29}O_9Na, H_2O$$

orange brown glistening leaflets; $C_{33}H_{29}O_9K, H_2O$ leaflets; $(C_{33}H_{29}O_9)_2Ba$ minute reddish brown prisms; $(C_{33}H_{29}O_9)_2Sr$, $(C_{33}H_{29}O_9)_2Ca$, and $C_{33}H_{29}O_9Ag$, fine yellow needles.

Fused with alkali, rottlerin gives *benzoic acid, acetic acid*, and *phloroglucinol* (P.), and when oxidised with hydrogen peroxide in alkaline solution, *benzaldehyde* and *benzoic acid* are produced. With potassium permanaganate (Bartolotti), benzoic acid is also formed. Nitric acid (sp.gr. 1·5) gives *p-nitrocinnamic acid, o-nitrocinnamic acid, p-nitrobenzaldehyde,* and *p-nitrobenzoic acid* (P.). When heated with 2 p.c. sodium carbonate solution, a compound termed *rottlerone* separates (P.), which crystallises in garnet-red prisms, and to which the formula $C_{29}H_{26}O_6$ has been provisionally assigned.

According to Telle, if rottlerin is heated for 10 minutes with barium hydroxide solution, *phloroglucinolmethylether,* a resinous substance and *ψ-rottlerin,* m.p. 235°, are produced. When heated for 10 minutes with zinc powder and sodium hydroxide, rottlerin gives 60 p.c. of resin and about 30 p.c. of phenols, also *β-phenylpropionic acid,* acetic acid, and a small quantity of a crystalline acid, m.p. 185°–185·5. From the mixture of phenols, *phloroglucinolmonomethylether* and *phloroglucinoldimethylether,* were isolated. *Phloroglucinoltrimethylether* and a camphor-like substance, m.p. 170°–172°, were produced, when, with the zinc powder, only 2 p.c. sodium hydroxide solution was employed.

The molecular weight of rottlerin, determined cryoscopically in naphthalene, was 486, and agrees with that assigned to this substance by Perkin (*l.c.*).

Homorottlerin $C_{33}H_{36}O_9$(?), pale yellow needles, m.p. 192°–193°, is present in exceedingly small amount in kamala. It differs from rottlerin in being much less soluble in toluene, chloroform, or acetic acid, but otherwise the properties of these two compounds are similar (P.).

iso-Rottlerin $C_{12}H_{12}O_5$ (?), has been obtained in the form of plates, m.p. 198°–199°, insoluble in hot benzene, carbon disulphide, or chloroform. Cold solutions of the alkali carbonates dissolve it readily, and these solutions when boiled do not deposit resinous matter or emit an odour of benzaldehyde, as is the case with the alkali salts of rottlerin itself. It is probable that this compound, very little of which has been yet obtained, may prove to consist of hydroxyrottlerin (P.).

The low melting resin of Anderson, $C_{30}H_{30}O_7$(?), $C_{12}H_{12}O_3$(?) (Perkin), consists of a brittle transparent dark red mass, melting below 100°, and is readily soluble in carbon disulphide, ether, or chloroform. With hot alkaline solutions, it behaves similarly to rottlerin and evolves an odour of benzaldehyde, and with nitric acid (sp.gr. 1·5) gives *p*-nitrobenzoic acid. Perkin's *high melting resin* is a pale straw coloured mass, m.p. about 150°, and in general properties resembles the low melting variety.

According to Hummel and Perkin (J. Soc. Chem. Ind. 1895, 14), for silk dyeing it is best to add 1 part of kamala, and 0·5–1 part sodium carbonate to boiling water, then to enter the silk and to dye at the boiling temperature for 2–5 minutes only. Other experiments indicated that the amount of sodium carbonate to employ should be regulated by the quantity of water used rather than by that of the kamala, namely at the rate of 13–14 grams (Na_2CO_3,10aq) per litre. After dyeing for a short time with the addition of alkali only, to the extent of one-fifth of the weight of the kamala used, the addition of alum or stannous chloride to the dyebath makes the colour fuller and more orange. A similar but by no means identical effect is obtained by making a slight addition of sulphuric acid.

As pointed out by Perkin (*l.c.*), rottlerin is decomposed by boiling sodium carbonate solution, and the colour ultimately fixed on the fibre most probably consists of rottlerone. Although rottlerin itself does not dye mordanted fabrics, the potassium and sodium salts of this colouring matter give on calico mordanted with aluminium and iron, pale orange red and brownish-black shades.

Pure Java kamala contains, according to Flückiger (Arch. Pharm. 1892), 1·363 to 1·488 p.c. of ash, whereas in the kamala examined by Anderson (*l.c.*), 3·49 p.c. was present. The best commercial varieties usually contain about 5 p.c. of mineral matter (Seidler and Waage, Ber. Deut. pharm. Ges. 1891, 80); but the inferior qualities are highly adulterated (50 to 87 p.c.) with sand, earthy impurities, red brick dust, &c. (Perkin (*l.c.*) and J. Soc. Chem. Ind. 1900). A. G. P.

KAMALA RESINS *v.* RESINS.

KAMPHERITRIN *v.* GLUCOSIDES.

KAOLIN *v.* KAOLINITE.

KAOLINITE. A mineral species consisting of hydrated aluminium silicate $H_4Al_2Si_2O_9$, crystallising in the monoclinic system. Analyses of the pure crystallised material agree closely with the theoretical quantities: SiO_2, 46·5; Al_2O_3, 39·5; H_2O, 14·0 p.c. The water is expelled only at a high temperature (above 330°). As a white, glistening, crystalline powder, the mineral is occasionally met with in small amount in cavities and fissures in sedimentary rocks and in mineral-veins. The best crystals have been found near Amlwch in the island of Anglesey, and in the National Bell mine near Silverton in Colorado. These crystals have the form of six-sided plates or pyramids with a perfect micaceous cleavage parallel to the base; and do not exceed 0·1 to 0·2 mm. across. Their mean index of refraction is 1·563, and their birefringence (0·004) is much lower than that of mica (with small scales of which the mineral might be confused); sp.gr. 2·62; H. 2½. On the optical characters of crystals of kaolinite, *see* A. B. Dick, Min. Mag. 1888, 8, 15; 1908, 15, 124. The 'nacrite' of the Einigkeit mine, Freiberg, Saxony, and 'pholerite,' also from Saxony, form fan-shaped aggregates of rather larger pearly scales of kaolinite.

The mineralogical name *kaolinite* was proposed by S. W. Johnson and J. M. Blake in 1867 for this crystallised mineral, which is usually assumed to form a large part of kaolin or china-clay. The name *kaolin* is a French corruption of the Chinese name *kau-ling* for the white, earthy material long used in the manufacture of porcelain at King-te-chin (prov. Kiangsi), and first brought to Europe in the year 1712. This material is obtained in the neighbouring Kau-ling Hills (= 'high ridge') from a compact, green stone, occurring in clay-slates and somewhat resembling jade in appearance, from which when crushed the finer particles are separated by washing (F. von Richthofen, Amer. J. Sci. 1871, 1, 180). This material, although a hydrated aluminium silicate, differs essentially from our kaolin, containing as much as 73 p.c. of silica and only a few p.c. of water. It is perhaps the same as the Japanese 'rōseki,' which has been referred to the agalmatolite (*q.v.*) variety of pyrophyllite.

It is thus seen that the name kaolin has been loosely applied to any white clays suitable for the manufacture of porcelain (*v.* CLAY), such as those found near Limoges in France, St. Austell in Cornwall, &c. These white clays have been formed by the decomposition of granite under somewhat special conditions; and when separated from grains of quartz, scales of mica, &c., by a process of washing, they yield the china-clay of commerce. In composition this varies between wide limits; but in many instances it approximates to the kaolinite formula given above. Microscopical examination very rarely reveals the presence of any six-sided scales that can be definitely referred to the species kaolinite. L. J. S.

KAURI-COPAL (-Bush Copal, -Gum or -Resin) is the solidified turpentine of the Kauri tree (*Dammara australis* [Steud.]) and occurs in great abundance in a fossil condition in various parts of New Zealand. It is dug up on the driest fern-hills as well as in the deepest swamps, but that from the latter is of inferior quality as is also the gum obtained from the forks of living trees (J. Soc. Chem. Ind. 1893, 71; *ibid.* 1895, 528; *ibid.* 1898, 621; Bull. Imp. Inst. 1904, 2, 91). To obtain kauri-copal, it is first searched out a little below the surface by feeling for it with a steel-pointed piece of iron, after which it is dug out with an ordinary spade. It is then prepared for the market by scraping off the outer crust by hand, or better, by machinery (Eng. Pat. 17009, 1890).

Four types of kauri-copal are known in commerce: (1) Pale kauri or fossil copal found in large masses varying from yellowish white to clear yellow in colour, has an aromatic smell, brilliant fracture and can be pulverised to a white powder. It has sp.gr. 1·036, m.p. 165°, acid value 70·9, saponification value 73. (2) Brown kauri fossil copal is of a yellow brown or deep yellow colour. It is difficult to powder, has a conchoidal fracture and an aromatic camphor-like odour. It has sp.gr. 1·053; m.p. 185°, acid value 78·8, saponification value 89·7. (3) Bush kauri is obtained at the foot of trees in irregular amber-like masses. It can readily be reduced to a yellow powder with an aromatic odour and has sp.gr. 1·03, m.p. 150°, acid value 83·1, saponification value 78·5. (4) Bush kauri gathered from the tree itself has a vitreous fracture; sp.gr. 1·038, m.p. 125°, acid value 81·8, saponification value 87 (Coffignier, Bull. Soc. chim. 1909, 5, 289; *see* also Tschirsch and Niederstadt, Arch. Pharm. 1901, 239, 145; Worstall, J. Amer. Chem. Soc. 1903, 25, 860). The various kinds of kauri differ in their solubilities in organic solvents but all of them are only very slightly soluble in turpentine and more readily so in alcohol (Coffignier, *l.c.*). They are all almost completely soluble in amyl alcohol, amyl acetate, benzaldehyde, or aniline.

Kauri-copal is readily attacked by chlorine, bromine, or concentrated nitric acid (Muir, J. 1874, 923). On dry distillation it yields pinene and dipentene (Wallach, Annalen, 271, 309; Rennie, Chem. Soc. Trans. 1881, 240).

A recent fossil specimen of kauri copal was found by Tschirsch and Niederstadt (*l.c.*) to consist of the following substances: 50 p.c. α and β-*kaurolic acids* $C_{12}H_{20}O_2$, m.p. 81°–83° and 85°–87° respectively (the α-acid yields a lead salt insoluble in alcohol, whereas the β-acid gives a soluble lead salt); 20 p.c. *kaurinolic* $C_{17}H_{34}O_2$, m.p. 128°–130°, and *kauronolic acids* $C_{12}H_{24}O_2$, m.p. 86°–89° (all these acids are monobasic and give a monoiodide); 12·0 p.c. *kauroresene* a light yellow indifferent substance, m.p. 63°–65° and not volatile in steam; 12·5 p.c. of an ethereal essential oil, b.p. 150°–160°, sp.gr. 0·835 at 15°; 1·5 p.c. *kauric acid* $C_{10}H_{16}O_2$, m.p. 192°, forming microscopic crystals $[\alpha]_D$ $+51{\cdot}66°$. It is a monobasic acid, yielding an iodine number corresponding to a monoiodide and a potassium and lead salt. Only about 2 p.c. of carbon was left on distillation of the kauri-copal (*see* also Thomson, Annalen, 1843, 47, 351). Kauri gum is used in the manufacture of oil varnishes, as an ingredient of the cement for linoleum manufacture, and also for dressing glazed calico. The transparent and semitransparent varieties are employed as substitutes for amber in the manufacture of mouthpieces for cigar-holders, pipes, &c.

The commercial product often contains as an admixture dammar resin, which is a much cheaper substance. Whether the kauri contains the latter can be determined rapidly in the following way: 0·5 gram of the finely ground sample is stirred up with chloroform in a porcelain crucible. It is then filtered through a small filter into a test tube, washed once and absolute alcohol added to the filtrate, when if the sample is pure kauri, the solution will remain clear, whereas if dammar is present a cloudiness or a precipitate will appear, according to the amount (Stewart, J. Soc. Chem. Ind. 1909, 349).

KEENE'S CEMENT *v.* CALCIUM.

KELP *v.* IODINE.

KEPHIR *v.* MILK.

KERAMYL. An aqueous solution of commercial hydrofluosilicic acid used as a disinfectant.

KERATIN is the principal constituent of the epidermis, hair, nails, hoofs, horns, wool, feathers, the skin of egg shells, &c. (Hedin, Zeitsch. physiol. Chem. 1894, 20, 186; Mohr, *ibid.* 1895, 20, 403; Abderhalden, *ibid.* 1905, 46, 31, 40; *ibid.* 48, 530, 535; *ibid.* 1907, 52, 348; *ibid.* 1908, 57, 339; Breinl and Baudisch, *ibid.* 1907, 52, 159; Friedmann, Chem. Zentr. 1903, i. 15).

It can be prepared from any of these substances by treating them successively with ether, alcohol, water, and dilute acids, or successively with artificial gastric juice, artificial pancreatic juice, boiling alcohol and boiling ether, pure keratin then remaining as a residue. Keratin is an albuminoid or sclero-protein, rich in sulphur (Bibra, Annalen, 96, 292; Raikow, Chem. Zeit. 1905, 29, 900; Baudisch, *ibid.* 1908, 32, 620), and like the other members of this class of substances, it is insoluble in all neutral solvents. When treated with concentrated alkalis it swells and dissolves on warming, but it is more sparingly soluble in dilute acids.

When boiled with acids and generally on hydrolysis, it yields a variety of decomposition products amongst which may be mentioned leucine, cystine, glycine, tyrosine, aspartic, and glutamic acids, alanine, arginine, &c., the relative quantities of the products as well as their nature depending on the source of the keratin (*see* above references; also Bleunard, Ann. Chim. Phys. 1882, [v.] 26, 40). Keratin resists the action of pepsin and trypsin. When treated with hydrogen peroxide it gives sulphur, ammonia, sulphuretted hydrogen, carbon dioxide, acetaldehyde, and nitric, sulphuric, acetic, oxalic, succinic, and a small quantity of aromatic amino acids (Breinl and Baudisch, *l.c.*). According to Lissizin (Zeitsch. physiol. Chem. 1909, 62, 226), azelaic acid is also an oxidation product of keratin. Keratin gives Millon's protein reaction and a yellow colour with nitric acid, this being the origin of the yellow colour when nitric acid comes in contact with the skin. Keratin has been converted into useful products which can be used instead of casein for many purposes, by treating horn scraps, hair, &c., with 15 p.c. hydrochloric acid at ordinary temperature. After 10 days the liquid is decanted, the residue washed with water, digested with 6 p.c. sodium hydroxide solution for 24 hours; potassium permanganate is then added and after standing for 12 hours the residue is washed and subjected to a pressure of 400 atmospheres

(Eng. Pat. 360895; J. Soc. Chem. Ind. 1906, 548).

Keratin or keratin substances can be converted into digestible albumoses and peptones containing sulphur by treatment with dilute mineral acids at moderate temperatures. The reaction is complete and the albumoses and peptones are isolated when a diluted sample, after treatment with phosphotungstic acid or other reagent for albumoses, gives a filtrate containing but little amino acid (U. S. Pat. 926999, 1909).

Thermoplastic keratin compounds have been obtained by mixing intimately keratin with β-naphthol and subjecting the mixture to heat and pressure (U. S. Pat. 922692; J. Soc. Chem. Ind. 1909, 721).

Atmidkeratin and *atmidkeratose* are the products obtained when keratin is acted on by superheated steam; the gaseous products of this reaction being sulphuretted hydrogen and methyl mercaptan (Bauer, Zeitsch. physiol. Chem. 1902, 35, 343; *see* also Krukenberg, Jahrb. Thierchem. 1886, 27).

KERMES. Kermes is the most ancient dyestuff on record, for it was known in the time of Moses, and is mentioned in Scripture by its Hebrew name, 'tola' or 'tolaschani.' According to Tychsen (Bancroft's Philosophy of Permanent Colours, 1, 394) 'the scarlet or kermes dye was known in the East in the earliest ages before Moses, and was a discovery of Phœnicians in Palestine, but certainly not of the small wandering Hebrew tribes.' Under the name 'coccus' it is frequently referred to by the Greek and Latin writers.

Kermes is an insect found on the oak kermes (*Quercus coccifera* [Linn.]), and when living the female insects, which are fixed to the twigs of the tree, resemble bluish berries, and are covered with a whitish powder. As soon as their eggs are on the point of hatching these insects should be collected, killed by exposure to the steam of vinegar, and dried, and the product has then the appearance of pale reddish-brown grains. According to Bancroft it would require 10 or 12 lbs. of kermes to produce the effect of a single lb. of cochineal.

Kermesic acid $C_{18}H_{12}O_9$. The colouring matter of kermes was first isolated, in the crystalline condition, by Heise (Arbeit. ausd. Kaiserl. Gesundheitsamt, 1895, 513), and has been examined subsequently by Dimroth (Ber. 1910, 43, 1387). To isolate the kermesic acid, the kermes is first extracted with ether to remove wax, and the residue is then allowed to stand overnight with an ethereal solution of hydrochloric acid. By this means the kermesic acid which exists in the kermes in the form of a salt is liberated, and can now be removed by repeated extraction with ether. For purification the substance is converted into its sparingly soluble sodium salt; this is collected and dissolved in sodium hydroxide solution. The boiling liquid, when treated with excess of hydrochloric acid, yields a crystalline precipitate of kermesic acid.

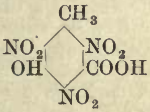
Thus obtained it consists of brick-red needles, which decompose without melting at about 250°. It is distinguished from carminic acid by the fact that it is soluble in ether, and is much more sparingly soluble in cold water. On the other hand, the colour of the alkaline solutions of both colouring matters is practically identical.

Disodium kermesate $C_{18}H_{10}O_9Na_2$, prepared by means of sodium acetate, consists of a red-brown crystalline powder, soluble in water, with a violet-red colour.

Barium kermesate $(C_{18}H_{11}O_9)_2Ba$ is brown, and contains water of crystallisation.

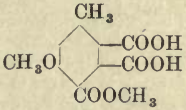
Tetra-acetylkermesic acid $C_{18}H_8O_9(C_2H_3O)_4$, yellow needles, melts at 245°, and *kermesic acid trimethyl ether* $C_{21}H_{18}O_9$ orange-red needles, m.p. 310°, dissolves in sulphuric acid with a violet colour, and is prepared from the potassium salt by means of methyl sulphate in the presence of boiling toluene.

Kermesic acid is decomposed by warm concentrated nitric acid, and thus yields *nitrococcusic acid* (trinitro-cresotic acid)



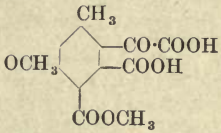
identical with the acid obtained in a similar way from carminic acid.

When oxidised with potassium permanganate kermesic acid methyl ether gives *methyl cochenillate monomethyl ether*, which melts at 178°–180°



with formation of the anhydride, m.p. 149°. Digestion with boiling potassium hydroxide solution gives cochenillic acid methyl ether $C_{11}H_{10}O_7$, m.p. 200°.

A second product of the oxidation consists of the *dimethyl ether* of *cresotinglyoxyldicarboxylic acid*



m.p. 108°–110°, and this by oxidation with permanganate is converted into the above-described *methyl cochenillate methyl ether.* There can be little doubt, therefore, that a very close relationship exists between kermesic and carminic acids.

Dyeing properties.—According to Hellot (Bancroft, Philosophy of Permanent Colours, 1, 404) 'the red draperies of the figures exhibited in the ancient Brussels and other Flemish tapestries were all dyed from kermes.' 'The fine red or crimson colour of these tapestries, which was originally called simply scarlet, took the name of *Venetian scarlet*, after the cochineal scarlet upon a tin base was discovered, . . .' For the production of this scarlet, the wool, previous to dyeing, was mordanted with alum and tartar; and, according to Bancroft, there is no evidence even in more recent years of the employment of a tin mordant in respect of this colouring matter, although the experiments he carried out indicated that by this latter method a scarlet colour could be produced 'in every respect as beautiful and estimable as any which can be dyed with cochineal.' A. G. P.

KERMESITE. *Red antimony. Antimony blende. Pyrantimonite. Pyrostibite.* An oxysulphide of antimony formed by the oxidation of antimony sulphide, and occurring associated with grey and white antimony in Hungary, Saxony, Dauphiné, &c. Found in monoclinic crystals or in capillary tufts of six-sided prisms, of a cherry-red colour and adamantine lustre. Composition $Sb_2O_3 \cdot 2Sb_2S_3$ (*v.* ANTIMONY).

KEROSENE or **KEROSINE** *v.* PETROLEUM.

KETENES. A series of compounds containing the group $>C:CO$. They were discovered in 1905 by Staudinger, the first member to be isolated being diphenylketene $(C_6H_5)_2C:CO$. Ketenes may be prepared: (i) by the action of zinc on the chloride or bromide of an α-halogen substituted fatty acid; or (ii) by the action of heat on the anhydride of a dibasic acid. The ketenes are very reactive substances, and may be divided into two groups:—

I. *Aldo-ketenes.* These consist of ketene itself, monoalkyl derivatives and carbon suboxide. They are colourless and do not undergo auto-oxidation. They are polymerised by pyridine and quinoline, and do not form additive compounds with substances containing the $>C:O$ and $>C:N—$ groups.

II. *Keto-ketenes.* The dialkyl derivatives of ketene belong to this group. They are coloured substances, and readily undergo auto-oxidation. They yield ketene bases with pyridine and quinoline, and form additive compounds with substances containing the $>C:O$ and $>C:N—$ groups, such as quinone and benzylidineaniline.

Both groups combine readily with water, alcohols, and amines, and also with chlorine and bromine (Staudinger and Klever, Ber. 1908, 41, 906).

Ketene $H_2C:CO$. Discovered by Wilsmore and Stewart, who obtained it by the action of a heated platinum wire on the vapour of acetic anhydride. The gaseous products were liquefied, and then submitted to fractional distillation (Nature, 1907, 75, 510; Chem. Soc. Trans. 1907, 1938). Schmidlin and Bergman (Ber. 1910, 43, 2821) obtained a 14 p.c. yield of ketene by passing the vapour of acetone through a hard glass tube filled with porous earthenware, heated at 500°–600°. It may also be prepared by the action of zinc on bromacetyl bromide in ethyl acetate. The products of the reaction are rapidly distilled, the ketene being removed from the warm solvent in a current of hydrogen, condensed in liquid air, and freed from traces of ethyl acetate by repeated fractionation at −60° (Staudinger and Klever, Ber. 1908, 41, 594). By the last method the yield of ketene from bromacetyl bromide is 7–13 p.c.; from bromacetyl chloride 3–4 p.c.; from chloracetyl chloride or chloracetyl bromide *nil* (Staudinger and Kubinsky, Ber. 1909, 42, 4213).

Ketene is a colourless liquid, b.p. −56°, and can be solidified to a mass of colourless crystals, m.p. −151°. It has a very penetrating odour, and its vapour attacks the mucous membrane. It combines with water, alcohol, aniline, &c., to form acetic acid, ethyl acetate, and acetanilide respectively, and with bromine in ethereal solution to form bromacetyl bromide. Liquid hydrogen chloride and sulphuretted hydrogen at the ordinary temperature yield acetyl chloride and thioacetic anhydride. When it reacts with water no trace of glycollic aldehyde is produced, and for this and other reasons, ketene is represented as $H_2C:CO$ and not as $CH:C \cdot OH$ (Staudinger and Klever, *l.c.*; Chick and Wilsmore, Chem. Soc. Proc. 1908, 77). It does not give an additive compound with quinone, nor ketene bases with pyridine and quinoline. Metallic chlorides and tertiary bases induce polymerisation to a dark-coloured liquid, this change also taking place when ketene is kept for some time. The chief constituent of this polymeride is a colourless liquid of pungent odour, b.p. 126°–127°, and when frozen, m.p. −6° to −7°. It has the formula $C_4H_4O_2$, and hence is formed by the condensation of two molecules of ketene. It combines with water and aniline to form acetoacetic acid and acetoacetanilide respectively, but only combines with alcohol to produce ethyl acetoacetate on addition of a trace of acid. On standing in sealed tubes, or by the addition of pyridine, dehydracetic acid is formed. Hence this substance may be acetylketene $CH_3COCH:CO$ or Δ′-*cyclo*butene-1-ol-3-one  $CO{<}\begin{smallmatrix}CH_2\\CH\end{smallmatrix}{>}C \cdot OH$, the semi-enol of *cyclo*butane-1:3-dione. The action of bromine was found to result in the formation of a γ- derivative  $CH_2{<}\begin{smallmatrix}COBr\\COCH_2Br\end{smallmatrix}$ and not an α- derivative, $CH_3CO \cdot CHBr \cdot COBr$, thus proving it to have the latter configuration (Chick and Wilsmore, Chem. Soc. Trans. 1908, 946; 1909, 1978; *cf.* Staudinger and Bereza, Ber. 1909, 42, 4908).

Methyl ketene $CH_3 \cdot CH:CO$. Obtained in dilute ethereal solution by the action of zinc on an ethereal solution of α-bromopropionyl bromide.

Ethyl ketene $C_2H_5 \cdot CH:CO$. Similarly from α-bromobutyl bromide.

Carbon suboxide $O:C:C:C:O$. Obtained by action of zinc on dibromomalonyl bromide *v.* CARBON SUBOXIDE.

Dimethyl ketene $(CH_3)_2C:CO$. Prepared by the action of zinc on a solution of α-bromo*iso*butylbromide in ethyl acetate, and distilling the resulting product under 15–16 mm. at −20° (Staudinger and Klever, Ber. 1906, 39, 968). Also by heating dimethylmalonic anhydride under 12 mm. pressure at 160°–180° (Staudinger and Ott, Ber. 1908, 41, 2208). It is a mobile yellow liquid, b.p. 48·5° (12 mm.); m.p. −97·5°; stable at −20° under atmospheric pressure, but at ordinary temperature polymerises to a colourless substance, m.p. 112°, apparently the diketone $(C \cdot (CH_3)_2CO)_2$. Water converts dimethylketene into *iso*butyric acid, and it undergoes the other reactions common to the keto-ketenes. Dimethylketene bases *v.* Staudinger, Klever, and Kober, Annalen, 1910, 374, 1. In the preparation of this ketene a liquid polymeride $(C_4H_6O)_2$, b.p. 170°–171°, having an odour of peppermint, is also formed (Staudinger and Klever, Ber. 1907, 40, 1149).

Diethylketene $(C_2H_5)_2C:CO$. Prepared by heating diethylmalonic anhydride under 12 mm. pressure at 160°–180°. It forms a yellow liquid, b.p. 91°–92° (749 mm.), solidifying to a mass of yellow crystals in liquid air (Staudinger and Ott, *l.c.*)

Diphenylketene $(C_6H_5)_2C:CO$. Prepared by the action of zinc on diphenylchloracetyl chloride in ethereal solution (Staudinger, Ber. 1905, 38, 1735); by the action of tertiary bases on diphenylacetyl chloride (Ber. 1907, 40, 1145); or by the interaction of benzil and hydrazine, oxidation of the hydrazibenzil, and warming the azibenzil to 60° (Curtius, Ber. 1889, 2161; J. pr. Chem. [ii.] 4, 182; Schroeter, Ber. 1909, 2346). It is a liquid having the colour of a concentrated solution of potassium dichromate, and solidifies in a freezing mixture to a mass of yellow crystals; b.p. 146° (12 mm.). Water converts it into diphenylacetic acid, and it undergoes similar reactions to the other keto-ketenes. On exposure to air it becomes viscid, addition of light petroleum throwing out a white oxidation product. Dry hydrogen chloride passed into a benzene solution of the ketene yields diphenylacetylchloride, whilst a dilute solution of hydrochloric acid yields diphenyl acetic anhydride. It shows no tendency to polymerise and treated with magnesium phenylbromide, yields triphenylvinyl alcohol. With quinone the β-lactone $O:C_6H_4<\begin{matrix}C(C_6H_5)_2\\ O\end{matrix}>CO$ is formed, and with benzylidine aniline the β-lactam $C(C_6H_5)_2<\begin{matrix}CO\\ CH(C_6H_5)\end{matrix}>N{\cdot}C_6H_5$. The former, on heating yield compounds of the type of diphenylquinomethane and tetraphenylquinodimethane, and the latter acylic fulvenes (Staudinger, Ber. 1908, 41, 1355, 1493).

Diphenylene ketene $\begin{matrix}C_6H_4\\ |\\ C_6H_4\end{matrix}>C:CO$. Prepared by the action of zinc on chlorodiphenylene acetyl chloride (from phosphorus pentachloride and diphenyleneglycollic acid) in ether in absence of air and moisture. It forms red crystals, m.p. 90° to a red liquid, decomposing at 150°; gives an indigo blue colour with sulphuric acid. With excess of water diphenylene acetic acid is formed, and with the requisite quantity diphenylene acetic anhydride. It undergoes the usual reactions (Staudinger, Ber. 1906, 39, 3062).

Ethylketene carboxylate

$$CO:C(C_2H_5){\cdot}CO_2{\cdot}C_2H_5.$$

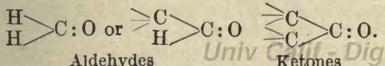
An ethereal solution of ethylbromomethylmalonate chloride $C_2H_5{\cdot}CBr<\begin{matrix}CO_2C_2H_5\\ COCl\end{matrix}$ reacts with zinc, producing ethylketenecarboxylate, which rapidly polymerises into 1 : 3-diethyl-*cyclo*-butane-2 : 4-dione-1 : 3-dicarboxylate

$$C_2H_5O_2C{\cdot}C(C_3H_5)<\begin{matrix}CO\\ CO\end{matrix}>C(C_2H_5)CO_2C_2H_5.$$

This, on heating at 180°–200°, yields the ketene as a colourless liquid, b.p. 48° (15 mm.), m.p. 57·8° (Staudinger and Bereza, Ber. 1909, 42, 4908).

KETOHYDRINDENE *v.* Indene.

KETONES. The ketones are a class of organic compounds characterised by the presence of the carbonyl group $>C:O$, united by each of its valencies to carbon. They are differentiated in this way from the aldehydes which contain the carbonyl group united on the one hand to hydrogen, and on the other to hydrogen or carbon. The characteristic groupings of aldehydes and ketones are shown as follows:—



Aldehydes Ketones

Ketones proper have hydrocarbon radicles or simple derivatives thereof (substituted by halogens, &c.) united with the carbonyl group, but a large number of other compounds of ketonic character are known, such as the keto-alcohols (*e.g.* $CH_3{\cdot}CO{\cdot}CH_2OH$), and the ketonic acids (*e.g.* $CH_3{\cdot}CO{\cdot}CO_2H$). Such compounds, besides showing specific properties due to the presence of the carbinol or carboxyl groups, also exhibit ketonic reactions due to the presence of the carbonyl group.

Ketones may be classified according to the number of carbonyl groups into *simple ketones, diketones*, &c., whilst, according to the radicles united with the carbonyl, they may be separated into *aliphatic*, *aromatic*, and *mixed ketones.*

Another type of ketone is furnished by those compounds in which the carbon atom of the carbonyl group is a member of a closed ring; such *cyclic ketones*, in which the carbon chain is saturated, closely resemble the aliphatic ketones in their properties. Unsaturated cyclic ketones also exist; one class, the quinones, will be treated separately, as they possess many distinctive properties not shared by the other ketones.

Respecting the nomenclature of the ketones, a few are known by trivial names, *e.g.* acetone, benzophenone, acetophenone, &c., but usually a more systematic nomenclature is adopted. This may refer either to the radicles attached to the carbonyl group, or to the position of the carbonyl groups in the chain. Acetone $CH_3{\cdot}CO{\cdot}CH_3$ may be more systematically termed dimethylketone or propanone; benzophenone $C_6H_5{\cdot}CO{\cdot}C_6H_5$ diphenylketone or diphenylmethanone; and acetophenone $C_6H_5{\cdot}CO{\cdot}CH_3$ phenyl methyl ketone or ethylonephene.

Whilst for simple ketones the second systematic nomenclature, that recommended by the Geneva Congress, has no striking advantages; in the case of polyketones it is very useful, as it enables the trivial names given to various substances to be replaced and rational names to be given to new compounds as they are discovered. Thus diacetyl becomes butane-dione, acetylacetone is pentane-2 : 4-dione, and is thus completely differentiated from acetylpropional which is pentane-2 : 3-dione.

Open Chain Monoketones.

Preparation.—(1) By addition of water to hydrocarbons of the type $R{\cdot}C{\vdots}C{\cdot}H$; thus allylene, if led into an aqueous solution of mercuric chloride at 90°–95°, yields acetone (Kutscherow, Ber. 1884, 17, 15)

$$CH_3{\cdot}C{\vdots}CH+H_2O=CH_3{\cdot}CO{\cdot}CH_3.$$

Béhal and Desgrez find that hydrocarbons of the formula C_nH_{2n-2} add the elements of acetic acid at 280°, the addition products being decomposed by water with formation of ketones.

(2) Secondary alcohols are directly oxidised to ketones. The use of manganic salts for this purpose has been patented by W. Lang (D. R. P. 166357). Ketones may also be obtained from secondary alcohols by passing their vapours over heated, finely divided copper (P. Sabatier and J. B. Senderens, Ann. Chim. Phys. 1905 [viii.] 4, 433).

(3) Primary alcohols of the type

$$CHRR'{\cdot}CH_2OH$$

give formic acid and a ketone on oxidation

(Kannonikow and Saytzew, Annalen, 1875, 175, 377)

$$CH(CH_3)(C_2H_5)CH_2OH+3O = CH_3\cdot CO\cdot C_2H_5+H\cdot CO_2H+H_2O.$$

(4) Hydrolysis of some halogen compounds which might be expected to yield unsaturated tertiary alcohols furnishes ketones in their place

$$CH_3\cdot CCl:CH_2 \rightarrow (CH_3\cdot C(OH):CH_2) \rightarrow CH_3\cdot CO\cdot CH_3$$

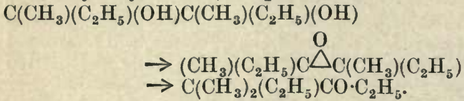
(Oppenheim, Annalen, 1868, Spl. 6, 365).

It has also been found that certain chlorhydrins when heated with water under pressure, yield ketones instead of glycols:

$$C(CH_3)_2(OH)CH(CH_3)Cl = CH(CH_3)_2CO\cdot CH_3+HCl$$

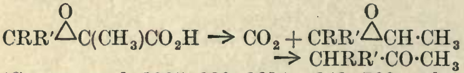
(K. Krassusky, J. Russ. Phys. Chem. Soc. 1901, 33, 791; 1902, 34, 287).

(5) On warming pinacones (ditertiary glycols) with dilute acids pinacolines (ketones containing a tertiary alkyl radicle) are produced:



$$C(CH_3)(C_2H_5)(OH)C(CH_3)(C_2H_5)(OH) \rightarrow (CH_3)(C_2H_5)C\overset{O}{\triangle}C(CH_3)(C_2H_5) \rightarrow C(CH_3)_2(C_2H_5)CO\cdot C_2H_5.$$

The mechanism of the reaction discovered by G. Darzens is probably similar. Ethyl α-chloropropionate condenses with ketones $R\cdot CO\cdot R'$ to form αβ-trisubstituted glycidic esters of the general type $CRR'\overset{O}{\triangle}C(CH_3)CO_2C_2H_5$. When these are hydrolysed the unstable acid loses carbon dioxide, and the oxide isomerises to a ketone



$$CRR'\overset{O}{\triangle}C(CH_3)CO_2H \rightarrow CO_2+CRR'\overset{O}{\triangle}CH\cdot CH_3 \rightarrow CHRR'\cdot CO\cdot CH_3$$

(Compt. rend. 1905, 139, 1214; 141, 766; also R. Stoermer, Ber. 1906, 39, 2288; 1907, 40, 488; M. Tiffeneau and Dorlencourt, Compt. rend. 1906, 143, 126; Ann. Chim. Phys. 1907, [viii.] 10, 322).

(6) By the dry distillation of the calcium or barium salts of acids

$$(R\cdot CO\cdot O)_2Ca = CaCO_3+R\cdot CO\cdot R.$$

The products obtained in this way are never pure; calcium acetate, for example, yields not only acetone, but also homologous ketones (R. Fittig, Annalen, 1859, 110, 17). When a mixture of the calcium salts of two acids is distilled together the separate ketones corresponding to each salt and their usual impurities are obtained, together with a greater or less yield of the mixed ketone.

The aliphatic acids are directly converted into ketones by heating with iron-filings or passing their vapours over heated aluminium or thorium oxides:

$$2R\cdot COOH = R\cdot CO\cdot R+CO_2+H_2O$$

(W. Ipatiew, J. Russ. Phys. Chem. Soc. 1908, 40, 514; Ber. 1910, 43, 3383; J. B. Senderens, Compt. rend. 1909, 148, 297; 149, 995; 1910, 150, 111; 1911, 152, 384; Easterfield and Taylor, Chem. Soc. Trans., 1911, 2298).

(7) Ketones are obtained from tertiary α-hydroxy acids either by oxidation (chromic acid) or by heating with mineral acids:

$$CRR'(OH)CO_2H+O = R\cdot CO\cdot R'+CO_2+H_2O.$$

$$CRR'(OH)CO_2H = R\cdot CO\cdot R'+H\cdot CO_2H \text{ (or } H_2O+CO).$$

Since acids of the type $CRR'H\cdot CO_2H$ may be oxidised by alkaline permanganate to acids with the structure $CRR'(OH)CO_2H$, they might serve as a source of ketones; in fact, electrolytic oxidation of *iso*butyric acid leads directly to acetone (M. Moest, D. R. P. 138442).

An analogous reaction is that by which the amides of α-bromo acids lose hydrogen bromide and cyanide on heating with aqueous or alcoholic sodium hydroxide, an aldehyde or a ketone being produced (G. Mossler, Monatsh. 1908, 29, 69):

$$CRR'Br\cdot CO\cdot NH_2+2NaOH = R\cdot CO\cdot R'+NaCN+NaBr+2H_2O.$$

Aldehydes and ketones are respectively obtained from amino acids $R\cdot CH(NH_2)CO_2H$ and $RR'C(NH_2)CO_2H$ by the action of hypochlorites:

$$RR'C(NH_2)CO_2H+HOCl = RR'C{:}O+CO_2+NH_4Cl$$

(K. Langheld, D. R. PP. 226226 and 226227).

(8) The β-ketocarboxylic acids, or their esters, undergo 'ketonic fission' on heating with dilute acids or alkalis (heating with concentrated alkaline solutions effects acid fission):

$$R\cdot CO\cdot CHR'\cdot CO_2C_2H_5+H_2O = R\cdot CO\cdot CH_2R'+CO_2+C_2H_5OH.$$

A simple method of effecting the ketonic fission of higher members of this series of esters by heating for a few minutes with sulphuric acid, pouring into water and distilling in a current of steam has been described by L. Bouveault and R. Locquin (Bull. Soc. chim. 1904, [iii.] 31, 1153; *cp.* Michael and Wolgast, Ber. 1909, 42, 3176).

(9) Ketones are produced by the interaction of acid chlorides and organo-metallic compounds (Freund, Annalen, 1861, 118, 1):

$$2C_nH_{2n+1}\cdot COCl+Zn(C_mH_{2m+1})_2 = ZnCl_2+2C_nH_{2n+1}\cdot CO\cdot C_mH_{2m+1}.$$

(10) Latterly magnesium alkyl halides (Grignard's reagents) have been largely applied to the synthesis of ketones. Nitriles yield imino derivatives, which are hydrolysed by dilute acids to ammonia and ketones (E. E. Blaise, Compt. rend. 1901, 132, 38; 133, 1217):

$$R\cdot C{⋮}N+MgBrR' = RR'C:N\cdot MgBr.$$

$$2RR'C:N\cdot MgBr+2H_2SO_4+2H_2O = MgBr_2+MgSO_4+(NH_4)_2SO_4+2RR'C:O.$$

A similar reaction using the esters of α-bromo acids and zinc leads to the synthesis of β-ketonic esters

$$R\cdot C{⋮}N+Zn+CR'HBr\cdot CO_2C_2H_5 = BrZn\cdot N:CR\cdot CHR'\cdot CO_2C_2H_5.$$

Ketones may also be obtained from cyanogen by the action of magnesium alkyl halides:

$$CN\cdot CN+Mg(C_2H_5)I = CN\cdot C(C_2H_5):N\cdot MgI$$

$$CN\cdot C(C_2H_5):NMgI+Mg(C_2H_5)I = MgI(CN)+C(C_2H_5)_2:N\cdot MgI$$

(11) Acid amides may be employed in place of nitriles (C. Béis, Compt. rend. 1903, 137, 575):

$$R\cdot CO\cdot NH_2+2MgR'X = CRR'(NHMgX)OMgX+R'H.$$

$$CRR'(NHMgX)OMgX+2H_2O = NH_2\cdot CRR'\cdot OH+MgX_2+Mg(OH)_2.$$

$$NH_2\cdot CRR'\cdot OH = R\cdot CO\cdot R'+NH_3.$$

The yields obtained by this method vary from 20 to 50 p.c., increasing as the complexity of the radicle R increases.

Imino esters (*e.g.* $C_6H_5\cdot C(:N\cdot C_6H_5)\cdot OCH_3$)

and imino chlorides may also be employed (R. Marquis, Compt. rend. 1906, 142, 711), whilst H. Fournier finds ketones amongst the products of the reactions between Grignard's reagents and acid anhydrides (Bull. Soc. chim., 1910, [iv.] 7, 836).

In certain cases ketones may be obtained by the action of organo-magnesium compounds on dried sodium salts, *e.g.* methyl *iso*butyl ketone from magnesium *iso*butyl bromide and sodium acetate (Salkind and Beburischwili, Ber. 1909, 42, 4500). For other syntheses involving organo-metallic compounds *v.* Blaise and Maire (Ann. Chim. Phys. 1908, [viii.] 15, 556; Barbier and Locquin, Bull. Soc. Chim., 1911, 9, 717, 722; Reynolds, Amer. Chem. J., 1911, 46, 198; Darzens a. Rost, Compt. rend. 1911, 153, 772).

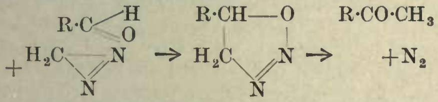
(12) The nitrile oxside yield ketones on reaction with magnesium alkyl halides. Thus benzonitrile-oxide and magnesium methyl iodide yield benzonitrile (by reduction), acetophenone, and its oxime:

$C_6H_5{\cdot}C{=}N + Mg(CH_3)I$

$\rightarrow C_6H_5{\cdot}C(:NO{\cdot}MgI)CH_3 \rightarrow C_6H_5{\cdot}C(:NOH){\cdot}CH_3$

(H. Wieland, Ber. 1907, 40, 1667).

(13) Ketones containing one methyl group can be obtained by the reaction of diazomethane with aldehydes. In this case it is probable that an unstable furodiazole is first produced, which breaks down into nitrogen and a ketone:



The method is of general applicability; ketones may be obtained from *iso*valeraldehyde, benzaldehyde, &c., whilst trichloroacetone has been obtained in a pure condition by using chloral (Schlotterbeck, Ber. 1907, 40, 479, 1826, 3000; 1909, 42, 2559, 2565).

(14) In certain cases ketones may be converted into higher homologues by the action of sodamide and an alkyl halide. In this way diethyl ketone yields ethyl *iso*propyl ketone, di*iso*propyl ketone, and a compound $C_{15}H_{26}O$:

$$CH_3{\cdot}CH_2{\cdot}CO{\cdot}CH_2{\cdot}CH_3 \rightarrow (CH_3)_2CH{\cdot}CO{\cdot}CH_2{\cdot}CH_3$$
$$\rightarrow (CH_3)_2CH{\cdot}CO{\cdot}CH(CH_3)_2$$

(A. Haller and Bauer, Compt. rend. 1910, 150, 661; 1911, 153, 21, 1415; 1912, 154, 555).

(15) Formaldehyde acts on ketones in presence of alkaline condensing agents, giving keto alcohols, which may be dehydrated to unsaturated ketones (Farbenfab. vorm. Fr. Bayer & Co. D. R. PP. 222551 and 223207):

$$CH_3{\cdot}CO{\cdot}CH_3 + CH_2O = CH_3{\cdot}CO{\cdot}CH_2{\cdot}CH_2OH$$
$$= CH_3{\cdot}CO{\cdot}CH : CH_2 + H_2O.$$

(16) Aromatic ketones (also mixed ketones) can be obtained by the action of acid chlorides on aromatic hydrocarbons in presence of aluminium chloride, &c. (Friedel and Crafts, Ann. Chim. Phys. 1884, [vi.] 1, 507):

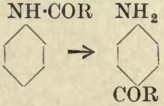
$$C_6H_6 + CH_3{\cdot}CO{\cdot}Cl = CH_3{\cdot}CO{\cdot}C_6H_5 + HCl.$$

Ketones in which both radicles attached to the carbonyl group are the same may be obtained by the action of carbonyl chloride on aromatic hydrocarbons in presence of aluminium chloride:

$$2C_6H_6 + COCl_2 = C_6H_5{\cdot}CO{\cdot}C_6H_5 + 2HCl.$$

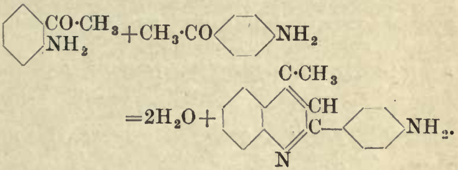
When acetyl chloride acts on a solution of *cyclo*hexene in carbon disulphide solution under the influence of aluminium chloride, an addition product  $\begin{array}{l} CH_2{\cdot}CH_2{\cdot}CHCl \\ | \qquad\qquad\quad | \\ CH_2{\cdot}CH_2{\cdot}CH{\cdot}CO{\cdot}CH_3 \end{array}$ is formed, from which tertiary bases remove the elements of hydrogen chloride with production of tetrahydroacetophenone (Darzens, Compt. rend. 1910, 150, 707).

(17) The introduction of amino or hydroxyl groups renders aromatic nucleï still more liable to attack. Dimethylaminobenzoyl chloride and tetramethyldiaminobenzophenone (Michler's ketone) are successively produced by the reaction of phosgene with dimethylaniline, no condensing agent being necessary (Ber. 1876, 9, 715, 1900). *p*-Aminoacetophenone is formed by boiling 2 parts of aniline with 5 parts of acetic anhydride and 3 parts of zinc chloride for 4–5 hours (Klingel, Ber. 1885, 18, 2688); whilst 2:4-dihydroxyacetophenone (resacetophenone) is obtained when 2 parts of resorcinol and 3 parts each of acetic acid and zinc chloride are heated to 150° (Nencki and Sieber, J. pr. Chem. 1881, [ii.] 23, 147). Probably acyl derivatives are first formed which subsequently undergo isomerisation, *e.g.*:



For the mechanism of isomerisation of acyl anilides, *see* F. D. Chattaway (Chem. Soc. Trans. 1904, 85, 340, 386, 589, 1663).

The conversion of acetanilide into aminoacetophenone is of interest in connection with the formation of flavaniline, which may be obtained by several hours' heating at 250°–270° of 2 parts of acetanilide with 1 part of zinc chloride (O. Fischer and Rudolph, Ber. 1882, 15, 1500); or a mixture of *o*- and *p*-aminoacetophenones with zinc chloride at 90° (O. Fischer Ber. 1886, 19, 1038):



(18) Aromatic ketones may be obtained by the oxidation of diaryl methanes with chromic acid (Zincke, Annalen, 1871, 159, 377):

$$C_6H_5{\cdot}CH_2{\cdot}C_6H_5 + 2O = C_6H_5{\cdot}CO{\cdot}C_6H_5 + H_2O.$$

General properties and reactions.—(1) The aliphatic ketones are generally liquid, the aromatic ketones solid at ordinary temperatures; usually they possess an ethereal or aromatic odour; most of them are insoluble in water, but dissolve easily in alcohol, ether, &c. They usually boil without decomposition; on passing the vapour of acetone over baked clay at 500°–600°, methane and ketene $CH_2:CO$ are produced (J. Schmidlin and M. Bergman, Ber. 1910, 43, 2821).

(2) Reduction of ketones by sodium amalgam gives secondary alcohols, ditertiary glycols (pinacones) are formed at the same time:

$$CH_3{\cdot}CO{\cdot}CH_3 + 2H = CH_3{\cdot}CH(OH)CH_3.$$
$$2CH_3{\cdot}CO{\cdot}CH_3 + 2H = (CH_3)_2C(OH)C(OH)(CH_3)_2$$

(3) Ketones resist the action of oxidising agents to a far greater extent than aldehydes. They do not readily reduce ammoniacal silver solutions; the resistency to alkaline oxidation is instanced by the fact that substances may be dissolved in acetone for treatment with permanganate. Ketones are, however, attacked by chromic acid, the carboxyl group usually remaining attached to the smaller hydrocarbon radicle; thus methyl propyl ketone yields a mixture of acetic and propionic acids, but a good deal depends on the nature of the radicle (Popow, Annalen, 1872, 161, 285). Wagner has found that propyl *iso*butyl ketone gives propionic and *iso*valeric acids, whilst, when ethyl *iso*propyl ketone is oxidised, for every molecule of acetic and *iso*butyric acids produced, 4 molecules of acetone and propionic acid are formed (Ber. 1882, 15, 1194; 1885, 18, 2266; J. Russ. Phys. Chem. Soc. 1884, 16, 645).

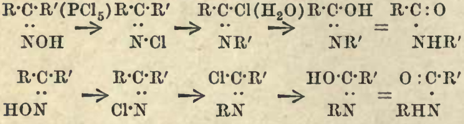
Oxygen may also be added to ketones without rupturing the molecule; thus by the use of Caro's acid, acetone gives a peroxide $C_3H_6O_2$ (A. V. Baeyer and V. Villiger, Ber. 1899, 32, 3627; 1900, 33, 124, 859; *see* also J. Pastureau, Bull. Soc. chim. 1909, [iv.] 5, 227).

(4) Ketones react less readily than aldehydes with ammonia, but resemble aldehydes in giving oximes, although not always as easily as aldehydes

$$(CH_3)_2C:O+H_2NOH=H_2O+(CH_3)_2C:NOH$$

(V. Meyer and Janny, Ber. 1882, 15, 1324; Janny, *ibid.* 1778; *cf.* Lapworth and Steele, Chem. Soc. Trans. 1911, 1884; Clarke, Lapworth and Wechsler, *ibid.* 1908, 30).

When the radicles connected with the carbonyl group are different, two oximes may be produced from a monoketone. The isomerisim in such cases is generally referred to different spatial arrangement (Hantzsch and Werner, Ber. 1890, 23, 11). In determining the configuration of stereoisomeric oximes considerable use has been made of the Beckmann rearrangement (Ber. 1886, 19, 992), whereby they map be converted into one of two structurally isomeric substituted acid amides:

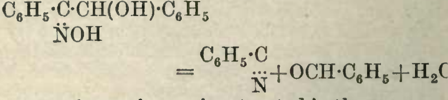


$$\underset{\ddot{N}OH}{R\cdot C\cdot R'}(PCl_5)\rightarrow\underset{\ddot{N}\cdot Cl}{R\cdot C\cdot R'}\rightarrow\underset{\ddot{N}R'}{R\cdot C\cdot Cl}(H_2O)\rightarrow\underset{\ddot{N}R'}{R\cdot C\cdot OH}=\underset{\dot{N}HR'}{R\cdot C:O}$$

$$\underset{HO\ddot{N}}{R\cdot C\cdot R'}\rightarrow\underset{Cl\cdot\ddot{N}}{R\cdot C\cdot R'}\rightarrow\underset{R\ddot{N}}{Cl\cdot C\cdot R'}\rightarrow\underset{R\ddot{N}}{HO\cdot C\cdot R'}=\underset{RH\dot{N}}{O:C\cdot R'}$$

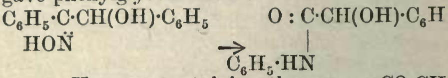
In effecting the transformation, a very dilute and strongly cooled ethereal solution of the oxime is treated with a considerable excess of phosphorus pentachloride, which is added in small portions at a time. The ethereal solution is decanted from the excess of the pentachloride and shaken with ice-cold water, separated and dried by potassium carbonate. The substituted amide is left on evaporation.

The rearrangement may sometimes be effected by warming for 1 hour with 10 parts of sulphuric acid on the water bath, whilst benzene-sulphonyl chloride has been used by Tiemann and Pinnow (Ber. 1891, 24, 4162) and A. Werner and A. Pignet (Ber. 1904, 37, 4295). The latter chemists determined the configuration of the oximes of benzoïn in the following manner: 5 grams of α-benzoïn oxime were dissolved in 20 c.c. of pyridine, 4 grams of benzene-sulphonyl chloride added drop by drop, and the mixture allowed to stand 3 hours at th ordinary temperature. After adding dilut sulphuric acid, the benzaldehyde and benzo nitrile were extracted with ether:



$$\underset{\ddot{N}OH}{C_6H_5\cdot C}\cdot CH(OH)\cdot C_6H_5=\underset{\dddot{N}}{C_6H_5\cdot C}+OCH\cdot C_6H_5+H_2$$

The isomeric β-oxime treated in the same wa gave phenylglycollanilide:



$$\underset{HO\ddot{N}}{C_6H_5\cdot C}\cdot CH(OH)\cdot C_6H_5\rightarrow\underset{C_6H_5\cdot HN}{\overset{|}{O:C}}\cdot CH(OH)\cdot C_6H$$

(5) Ketones containing the group ·CO·CH react with nitrous acid, giving the monoxim of diketones:

$$CH_3\cdot CO\cdot CH_2\cdot CH_3+HNO_2$$
$$=CH_3\cdot CO\cdot C(:NOH)\cdot CH_3+H_2$$

(L. Claissen and Manasse, Ber. 1889, 22, 526 O. Diels, Ber. 1902, 35, 3290; 1907, 40, 4336).

(6) Ketones react with hydrazine to giv ketazines (Curtius and Thun, J. pr. Chem. 189 [ii.] 44, 161):

$$2R\cdot CO\cdot R'+N_2H_4=2H_2O+RR'C:N\cdot N:CRR$$

or hydrazones (E. Fischer, Annalen, 1878, 19 136; Ber. 1883, 16, 661, 2241; 1884, 17, 572 1889, 22, 90; 1897, 30, 1240):

$$R\cdot CO\cdot R'+H_2N\cdot NHR''=H_2O+RR'C:N\cdot NH\cdot$$

In using phenylhydrazine, a dilute acet acid solution is generally employed; whe hydrazone formation only takes place wit difficulty the ketone may be dissolved in glaci acetic acid, treated with a slight excess phenylhydrazine and allowed to stand in t cold. In certain cases (*e.g.* carvole, v. Baeye Ber. 1894, 27, 813) the ketone and phenylhydr zine may be mixed in equimolecular proportio without solvent and allowed to stand.

In many cases the use of phenylhydrazine f the isolation and identification of aldehydes a ketones may be advantageously replaced by o of the following hydrazino compounds:

p-Bromophenylhydrazine (E. Fischer, Be 1891, 24, 4221; L. Michaelis, *ibid.* 1893, 2 2190).

p-Nitrophenylhydrazine (A. Purgotti, Atti. Accad. Linc. 1902, 7, ii. 266; E. Bamberger a H. Sterintzki, Ber. 1893, 26, 1306; E. Hyd *ibid.* 1899, 32, 1810; H. D. Dakin, J. Biol. Che 1908, 4, 235).

as-Methylphenylhydrazine $C_6H_5(CH_3)N\cdot N$ (C. Neuberg, Ber. 1902, 35, 959, 2626).

Semicarbazide $NH_2\cdot CO\cdot NH\cdot NH_2$ (Baey Ber. 1894, 27, 1918).

Aminoguanidine $NH_2\cdot C(:NH)NH\cdot NH_2$. T condensation products with ketones may isolated as well crystallised picrates (Baey Ber. 1894, 27, 1919).

Thiosemicarbazide $NH_2\cdot CS\cdot NH\cdot NH_2$. T resulting thiosemicarbazones

$$NH_2\cdot CS\cdot NH\cdot N:CRR'$$

give insoluble or sparingly soluble salts of t heavy metals (C. Neuberg and W. Neiman Ber. 1902, 35, 2049).

Benzhydrazide $C_6H_5\cdot CO\cdot NH\cdot NH_2$ and its *m*-, and *p*-nitro- derivatives

$$C_6H_4(NO_2)CO\cdot NH\cdot NH_2.$$

With aromatic ketones it is advisable to war in alcoholic solution; aldehydes react mo readily (Curtius and co-workers, J. pr. Che 1894, [ii.] 50, 275, 295; 1895, 51, 165, 353).

(7) Ketones react with phosphorus pentachloride as follows:—

$$R{\cdot}CO{\cdot}R'+PCl_5=POCl_3+R{\cdot}CCl_2{\cdot}R'.$$

(8) Some ketones, usually those containing the group $CH_3{\cdot}CO{\cdot}$, unite with acid sodium sulphite; acetone, for example, gives

$$(CH_3)_2C(OH)(SO_3Na),H_2O.$$

The ketone is regenerated by sodium carbonate solution.

(9) Hydrogen cyanide yields nitriles

$$RR'C(OH)CN$$

which react with ammonia to give the nitriles of α-amino acids $RR'C(NH_2)CN$.

(10) Hydrogen sulphide converts the ketones into thioketones, *e.g.* acetone yields thioacetone (W. Spring, Bull. Acad. Roy. Belg. 1883, [iii.] 5, 236).

(11) The ketones do not so readily form addition products as the aldehydes, *e.g.* with water and alcohol, but when a mixture of a ketone and a mercaptan is treated with gaseous hydrogen chloride a mercaptol is formed (Baumann, Ber. 1885, 18, 887):

$$(CH_3)_2CO+2C_2H_5SH=H_2O+(CH_3)_2C(SC_2H_5)_2$$

(12) Polyhalogenated ketones and polyketones are exceptional, thus trichloracetone gives a hydrate $CCl_3{\cdot}C(OH)_2{\cdot}CH_3$.

(13) The acetals of the ketones (as well as of the aldehydes) may be obtained by the action of orthoformic esters (Claisen, Ber. 1907, 40, 3903):

$$RR'C:O+HC(OC_2H_5)_3 \\ =RR'C(OC_2H_5)_2+H{\cdot}CO{\cdot}OC_2H_5$$

The ketone and calculated amount of ethyl formate are dissolved in alcohol (3 or more molecular proportions) and a small amount of mineral acid, ferric chloride, &c., as catalysing agent added. The mixture is either warmed for a short time or allowed to stand for a longer period at the ordinary temperature.

Nascent ethyl orthoformate from alcohol and ethyl iminoformate hydrochloride may also be used (*cp.* E. Hess, D. R. P. 197804):

$$H{\cdot}C(:NH,HCl)(OC_2H_5)+2C_2H_5OH \\ =NH_4Cl+H{\cdot}C(OC_2H_5)_3$$

(*see* Pinner, Ber. 1883, 16, 356).

(14) Many ketones, notably cyclic ketones, behave towards acylating agents as if they possessed the tautomeric enolic structure, thus *cyclo*hexanone gives esters of *cyclo*hexenol (C. Mannich, Ber. 1906, 39, 1594; 1908, 41, 564; *cp.* F. W. Semmler, *ibid.* 1909, 42, 584, 1161, 2014). A striking example is the conversion of diethyl and dipropyl ketones into acetyl derivatives of their enolic forms by heating with 1½ parts of acetic anhydride, and ⅛ part of fused sodium acetate for 70 hours at 205°–215° (V. Hâncu, Ber. 1909, 42, 1052).

(15) Magnesium alkyl halides react with ketones, giving tertiary alcohols:

$$C_6H_5{\cdot}CO{\cdot}CH_3+CH_3{\cdot}MgI=C_6H_5{\cdot}C(OMgI)(CH_3)_2$$

$$C_6H_5{\cdot}C(OMgI)(CH_3)_2+H_2O \\ =Mg(OH)I+C_6H_5{\cdot}C(CH_3)_2(OH).$$

(V. Grignard, Compt. rend. 1900, 130, 1322; Bull. Soc. chim. 1901, [iii.] 25, 497; Ann. Univ. Lyon. 1901, No. 6, 1–116).

(16) A mixture of alkyl halide and sodium frequently behaves like the Grignard reagents. P. Schorigin has obtained diphenyl ethyl carbinol $C(C_6H_5)_2(C_2H_5)OH$ by the action of 21·5 grams of sodium wire on 30 grams each of ethyl iodide and benzophenone dissolved in 150 c.c. of dry benzene (Ber. 1908, 41, 2711).

(17) Ketones containing at least one aliphatic radicle react with esters and sodium ethoxide to give β-diketones. In this way benzoylacetone may be obtained from ethyl benzoate and acetone (Claisen, Ber. 1887, 20, 655), or from ethyl acetate and acetophenone (Beyer and Claisen, *ibid.* 2180; *see* also R. W. L. Clarke, A. Lapworth, and E. Wechsler, Chem. Soc. Trans. 1908, 93, 30).

(18) Ketones of suitable structure react with 1 or 2 molecules of an aldehyde giving unsaturated ketones. Methyl cinnamyl ketone (monobenzalacetone) may be prepared by adding 10 parts of 10 p.c. caustic soda solution to a mixture of 10 parts of benzaldehyde, 900 parts of water, and 20 parts of acetone, allowing to stand 2 or 3 days in the cold, extracting with ether and distilling under reduced pressure:

$$C_6H_5{\cdot}CHO+CH_3{\cdot}CO{\cdot}CH_3 \\ =H_2O+C_6H_5{\cdot}CH:CH{\cdot}CO{\cdot}CH_3.$$

Benzalacetone forms shining tabular crystals, m.p. 41°–42°, b.p. 260°–262°, b.p. (at 25 mm.) 151°–153° (Claisen and Ponder, Annalen, 1884, 223, 139).

If, however, to 20 parts of benzaldehyde, 6 parts of acetone and 40 parts of acetic acid, 30 parts of sulphuric acid are added drop by drop whilst the mixture is cooled very thoroughly, dibenzalacetone is formed. The mixture, after standing 6–8 hours at 0°, is poured into water, the precipitate washed with caustic soda and crystallised from ether. Monoclinic crystals, m.p. 112°–112·5°.

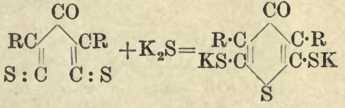
$$2C_6H_5{\cdot}CHO+CH_3{\cdot}CO{\cdot}CH_3 \\ =2H_2O+C_6H_5{\cdot}CH:CH{\cdot}CO{\cdot}CH:CH{\cdot}C_6H_5$$

(Claisen and Claparède, Ber. 1881, 14, 2460).

The colouration produced by strong acids with dibenzalacetone is attributed by Baeyer and Villiger to the formation of quinonoïd carbonium salts (Ber. 1902, 35, 1189, 3013), *e.g.*:

(19) Ketones react with carbon disulphide in presence of caustic alkalis, giving 4-keto-3 : 5-dialphylpenthiophen-2 : 6-dithiols:

$$R{\cdot}CH_2{\cdot}CO{\cdot}CH_2{\cdot}R+2CS_2+4KOH \\ =SC:CR{\cdot}CO{\cdot}CR:C:S+4H_2O+2K_2S.$$



(H. Apitzsch, Ber. 1904, 37, 1599; 1905, 38, 2888; 1908, 41, 4028, 4039, 4047; 1909, 42, 2940; 1910, 43, 1259).

(20) At 180°–200° hydrogen (with nickelised asbestos as catalytic agent) reduces unsaturated to saturated ketones (G. Darzens, Fr. Pat. 350390).

Differentiation of Ketones from Aldehydes.

Aldehydes and ketones possess many reactions in common, but, on oxidation, the ketones do not give acids containing the same number of carbon atoms as the ketone (General Reaction 3).

A. Einhorn finds that aldehydes react with catechol monocarbazinic ester

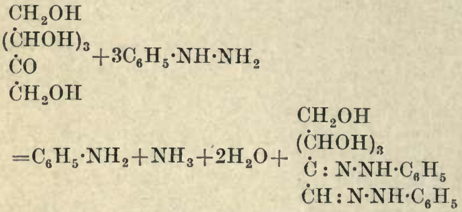
$$C_6H_4(OH)O{\cdot}CO{\cdot}NH{\cdot}NH_2$$

in dilute alcoholic solution, whilst ketones do not, although condensation may be effected in a few cases when glacial acetic acid or zinc chloride is employed as condensing agent (Annalen, 1898, 300, 135; 1901, 317, 190). Resorcinol and quinol monocarbazinates behave similarly.

A. Angeli finds that nitrohydroxylamine and other 'nitroxyl' (NOH) yielding substances convert aldehydes directly into the corresponding hydroxamic acids (Gazz. chim. ital. 1904, 34, i. 50).

Hydroxyl and Amino Substituted Ketones.

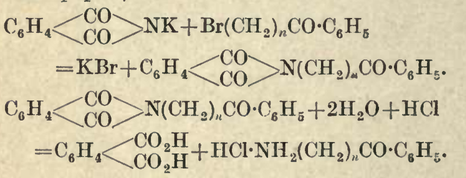
The substituted ketones usually exhibit the specific ketonic characters as well as properties due to the substituent groups. Thus keto alcohols form esters, and amino ketones are basic. The different groupings may, however, affect one another, keto alcohols of the type $R{\cdot}CO{\cdot}CH_2OH$ usually give osazones, as lævulose when warmed with phenylhydrazine solutions gives phenylglucosazone:



$$\begin{array}{l}CH_2OH\\ \dot{C}HOH)_3\\ \dot{C}O\\ \dot{C}H_2OH\end{array} + 3C_6H_5{\cdot}NH{\cdot}NH_2 = C_6H_5{\cdot}NH_2 + NH_3 + 2H_2O + \begin{array}{l}CH_2OH\\ (\dot{C}HOH)_3\\ \dot{C}:N{\cdot}NH{\cdot}C_6H_5\\ \dot{C}H:N{\cdot}NH{\cdot}C_6H_5\end{array}$$

(E. Fischer, Ber. 1884, 17, 579; 1887, 20, 821).

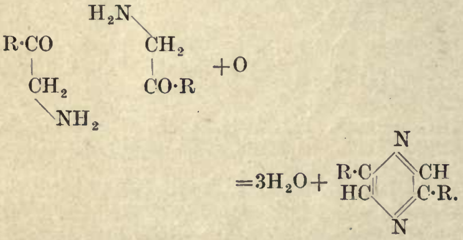
The salts of aminoketones may be prepared from the halogenised ketones by condensation with potassium phthalimide and subsequent hydrolysis (Gabriel, Ber. 1907, 40, 2649, and other papers).



$$C_6H_4{<}^{CO}_{CO}{>}NK + Br(CH_2)_nCO{\cdot}C_6H_5 = KBr + C_6H_4{<}^{CO}_{CO}{>}N(CH_2)_nCO{\cdot}C_6H_5.$$

$$C_6H_4{<}^{CO}_{CO}{>}N(CH_2)_nCO{\cdot}C_6H_5 + 2H_2O + HCl = C_6H_4{<}^{CO_2H}_{CO_2H} + HCl{\cdot}NH_2(CH_2)_nCO{\cdot}C_6H_5.$$

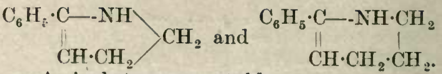
α-Aminoketones, when isolated from their salts, condense in the following manner:



β-Aminoketones are capable of existence as free bases, *e.g.* diacetoneamine

$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}C(CH_3)_2NH_2.$$

γ- and δ-aminoketones condense internally, giving substituted pyrrolines and tetrahydropyridines respectively, *e.g.*:



ε-Aminoketones are stable.

INDIVIDUAL OPEN-CHAIN MONOKETONES.

1. *Aliphatic Ketones.*

Acetone is treated in a separate article (*q.v.*). It forms basic products with ammonia, diacetoneamine $CH_3{\cdot}CO{\cdot}CH_2{\cdot}C(CH_3)_2NH_2$ (Heintz, Annalen, 1877, 189, 214) and triacetoneamine $NH{<}^{C(CH_3)_2CH_2}_{C(CH_3)_2CH_2}{>}CO + H_2O$ (Heintz, *ibid.* 1875, 178, 305), the former of which has found application in the preparation of pharmaceutical products (Schering, D. R. PP. 95620, 95621, 95622, 95623; *cp.* Harries, D. R. PP. 99004, 99005).

The hypnotic, 'sulphonal,'

$$(CH_3)_2C(SO_2C_2H_5)_2$$

is obtained either by the oxidation of the mercaptol $(CH_3)_2C(SC_2H_5)_2$ with potassium permanganate (Baumann, Ber. 1886, 19, 2808), or by the methylation of ethylidene diethylsulphone $CH_3{\cdot}CH(SO_2C_2H_5)_2$, or diethylsulphonemethane $CH_2(SO_2C_2H_5)_2$ with alcoholic potash and methyl iodide (Fromm, Annalen, 1889, 253, 147) (*v.* SULPHONAL).

Methyl ethyl ketone (*Butanone*), b.p. 78·6°, occurs in the distillate from crude calcium acetate, and may be obtained from the water used in washing wool; this is evaporated with lime, and the resultant calcium salts distilled. About 45–50 p.c. of 'acetone oil' is obtained, 80 p.c. is soluble in water, and when fractionated 60 p.c. of methyl ethyl ketone is obtained. This compound is employed for the denaturation of alcohol, the similarity of boiling-points making separation by fractionation nearly impossible (A. and P. Buisine, Compt. rend. 1897, 125, 777; 1898 126, 351; 1899, 128, 561) (*v.* ACETONE OIL).

Methyl ethyl ketone, like acetone, may be employed instead of formaldehyde for preparing sulphoxylates (M. L. B., D. R.-PP. 162875, 207846, 210467).

Methyl hydroxyethyl ketone

$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}OH$$

results from the condensation of acetone and formaldehyde; dehydrated by means of 2 p.c. of zinc chloride *methyl vinyl ketone*

$$CH_3{\cdot}CO{\cdot}CH:CH_2,$$

b.p. 80°, is formed (Farbenfab. vorm. Fr. Bayer & Co., D. R. P. 222551).

Methyl propyl ketone (2-pentanone) is found in the crude acetone obtained by distilling the calcium salts from pyroligneous acid, b.p. 101·7°.

Methyl-*n*-amyl ketone (2-heptanone) occurs in oil of cloves (Schimmel & Co., Ber. April, 1897, 50) and boils at 151°–152°. It possesses a penetrating fruity odour.

Methyl nonyl ketone (2-undecanone) forms the chief constituent of oil of rue (*Ruta graveolens* [Linn.]), being accompanied by a small amount of a ketone $C_{12}H_{24}O$ (Williams, Annalen, 1858, 107, 374). It also forms 75 p.c. of the ketonic portion of the 'essence' of cocoa-nut butter, in which it is accompanied by methyl heptyl and methyl undecyl ketones (A. Haller and A. Lassieur, Compt. rend. 1910, 151, 697).

2-Methyl-Δ²-heptene-6-one

$(CH_3)_2C : CH{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}CH_3$

occurs in oil of linaloes (Barbier and Bouveault, Compt. rend. 1895, 121, 168), and is a constituent of lemon-grass oil (Bertram and Tiemann, Ber. 1899, 32, 834); b.p. 173°–174°, sp.gr. 0·8602, at 20° n^{20}_D 1·4445. This ketone has been artificially prepared by the slow distillation of cineolic anhydride $C_{10}H_{14}O_4 = C_8H_{14}O + CO + CO_2$ (Wallach, Annalen, 1890, 258, 324), and together with other substances by the oxidation of geraniol, gerianial, and methylheptenol by chromic acid (Tiemann and Semmler, Ber. 1893, 26, 2722). The same authors also obtained it by boiling geranonitrile with alcoholic potash and by the oxidation of citral (Ber. 1895, 28, 2126).

Verley (Bull. Soc. chim. 1897 [iii.] 17, 175) obtains it by boiling 500 grams of citral with a solution of 500 grams of potassium carbonate in 5 litres of water for 12 hours, the ketone is then distilled in steam and fractionated under reduced pressure. Verley records the constants, b.p. 168° (84° at 26 mm.), sp.gr. 0·910 at 14°, $n^{31°}_D$ 1·437.

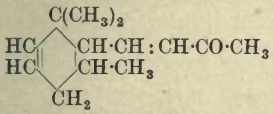
Methylheptenone gives an *oxime* and *phenylhydrazone*; it is converted into dihydro-*m*-xylene by the action of zinc chloride (Wallach) or concentrated sulphuric acid (Verley).

II. *Hydroaromatic Ketones.*

Of the non-cyclic ketones containing hydroaromatic nuclei, irone, and its isomers are of especial importance.

Irone $C_{13}H_{20}O$ was recognised by Tiemann and Kruger (Ber. 1893, 26, 2675; 1895, 28, 1754; Tiemann, *ibid.* 1898, 31, 808; Haarmann and Reimer, D. R. P. 72840) as the odoriferous principle of iris root (*Iris florentina* [Linn.], *I. germanica* [Linn.], *I. pallida* [Linn.]). Violet or iris oil is obtained chiefly from *I. florentina*; at ordinary temperatures it forms a fairly firm yellowish mass, possessing an intense odour of violets. It consists of about 80 p.c. of myristic acid associated with irone, methyl myristate, oleïc aldehyde, acid, and esters. Irone and volatile esters distil in a current of steam, the esters are saponified, the irone again steam distilled, and the product rectified under reduced pressure. Pure irone is dextrorotatory, b.p. (16 mm.) 144°, sp.gr. at 20° 0·939; *oxime* $C_{13}H_{20} : NOH$ m.p. 121·5°; *p*-bromo-phenylhydrazone $C_{13}H_{20} : N{\cdot}NH{\cdot}C_6H_4Br$, m.p. 140°–145°.

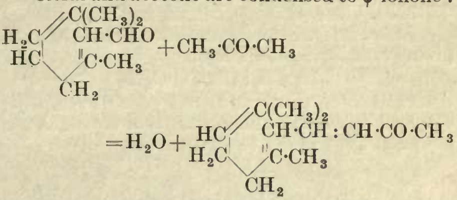
Tiemann and Krüger (*l.c.*) determined the constitution of irone as



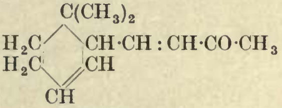
and attempted to synthesise it from citral (lemon-grass oil).

Ionones (α- and β-). These ketones, isomeric with irone, and differing from it and from one another by the position of the double linkage in the ring, were actually obtained from citral; as they also have an odour of violets they have attained very considerable technical importance (Haarmann and Reimer, D. R. PP. 73089, 75128).

Citral and acetone are condensed to ψ-ionone :

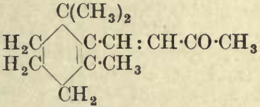


which, on boiling with sulphuric acid, gives a mixture of



α-Ionone

and



β-Ionone

The formation of the former is favoured by a dilute acid, the latter when more concentrated sulphuric acid is employed. The separation of the two isomerides is effected by the more sparing solubility of the bisulphite compound of α-ionone (Tiemann, Ber. 1898, 31, 870), the process may be aided by salting out with sodium chloride (P. Chuit, Rev. gén. Chim. pure appl. 1903, 6, 422).

According to patent D. R. P. 129027 α-ionone is formed preferentially with concentrated phosphoric acid at 30°, β-ionone almost exclusively when 70–100 p.c. sulphuric acid is employed in the cold (Haarmann and Reimer).

Citral may be isomerised to α- and β-*cyclo*-citrals, which condense with acetone, yielding ionones (Haarmann and Reimer, D. R. P. 123747; Tiemann, Ber. 1900, 33, 3721). Other information about the preparation of ionones and higher homologues using methyl ethyl and methyl *iso*propyl ketones in place of acetone is given in Haarmann and Reimer's patents (D. R. PP. 126959, 126960, 127424, 127831, 129027, 132222, 133758, 150827, 183855).

α-Ionone is an oil with strong, sweet smell of fresh violets, b.p. (12 mm.) 127·6°, sp.gr. at 20° 0·9301; *oxime* $C_{13}H_{20} : NOH$, m.p. 89°–90°; *semicarbazone* $C_{13}H_{20} : N{\cdot}NH{\cdot}CO{\cdot}NH_2$, m.p. 107°–108°.

β-Ionone is also an oil smelling pleasantly like violets, b.p. (10 mm.) 127°–128·5°; sp.gr. at 20° 0·9442; *oxime*, oily; *semicarbazone*, m.p. 148°–149°.

III. *Mixed Ketones.*

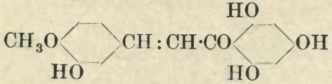
Acetophenone $C_6H_5{\cdot}CO{\cdot}CH_3$, used medicinally as *hypnone*, is formed by distilling a mixture of calcium acetate and benzoate, and is conveniently prepared by the action of acetyl chloride on benzene in the presence of aluminium chloride (Friedel and Crafts, Ann. Chim. Phys. 1884, [vi.] 1, 507), m.p. 20·5°, b.p. 202°, sp.gr. 1·032 at 15°.

Acetophenone does not combine with sodium bisulphite; phosphorus pentachloride gives $C_6H_5{\cdot}CCl_2{\cdot}CH_3$; halogens substitute in the methyl group (Gautier, Bull. Soc. chim. 1886, 45, 875). The *phenylhydrazone* has m.p. 105°.

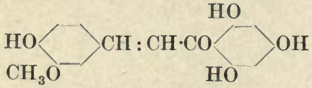
Acetophenone condenses with benzaldehyde, giving *cinnamyl phenyl ketone*

$C_6H_5{\cdot}CH : CH{\cdot}CO{\cdot}C_6H_5$

derivatives of this compound occur naturally; *e.g.* hesperitin and homœriodictyol to which are assigned the respective structures:



and



(Power and Tutin, Trans. Chem. Coc. 1907, 91, 887; *cp.* Tiemann and Will, Ber. 1881, 14, 970; Perkin, Chem. Soc. Trans. 1898, 73, 1037; and Tutin and Caton, *ibid.* 1910, 97, 2062).

ω-Chloroacetophenone (phenacyl chloride) $C_6H_5{\cdot}CO{\cdot}CH_2Cl$ is obtained by leading the theoretical amount of chlorine into boiling acetophenone. The product is distilled, the portion passing over below 200° is chlorinated again, whilst the fraction between 240° and 250° is collected separately, and the monochloro-derivative crystallised by cooling; m.p. 58°–59°; b.p. 244°–245° (Staedel, Ber. 1887, 10, 1830).

ω-Bromoacetophenone $C_6H_5{\cdot}CO{\cdot}CH_2Br$ is prepared by adding gradually one molecular proportion of bromine to acetophenone dissolved in carbon disulphide (Hunnius, Ber. 1877, 10, 2007), a current of dry carbon dioxide being led through (Staedel, Kleinschmidt, *ibid.* 1880, 13, 837; 1883, 16, 22); m.p. 50°.

Both phenacyl chloride and bromide are of use as synthetic agents; thus with ammonia 2 : 5-diphenylpyrazine is produced (Gabriel, Ber. 1908, 41, 1127; Tutin, Chem. Soc. Trans. 1910, 97, 2495) a compound previously described by Staedel and Rügheimer as *iso*indol (Ber. 1876, 9, 563; 1880, 13, 836).

***p*-Aminoacetophenone** $NH_2{\cdot}C_6H_4{\cdot}CO{\cdot}CH_3$; m.p. 106°; b.p. 293°–295°. One method of preparing this compound has been given previously (general methods of preparation, 17). F. Kunckell (Ber. 1900, 33, 2641) obtains *p*-acetylaminoacetophenone by the action of 70 grams of aluminium chloride on a mixture of 20 grams of acetanilide, and 50 grams each of carbon disulphide and acetyl chloride, a yield of 15·5 grams (m.p. 166°–167°) being obtained. The free aminoketone is readily obtained by boiling for half an hour with three times its weight of 15 p.c. hydrochloric acid, and precipitating with sodium carbonate.

***p*-Hydroxyacetophenone** $HO{\cdot}C_6H_4{\cdot}CO{\cdot}CH_3$ may be obtained from the amino compound by diazotisation; m.p. 107° (Klingel, Ber. 1885, 18, 2691).

Resacetophenone

$CH_3{\cdot}CO{\cdot}C_6H_3(OH)_2,(OH : OH = 2 : 4,$

a compound of synthetical importance, is obtained as described in General Method 17; m.p. 142°.

Gallacetophenone 2 : 3 : 4-$(OH)_3C_6H_2{\cdot}CO{\cdot}CH_3$ similarly obtained from acetic acid and pyrogallol is used as a mordant dyestuff. The analogous purely aromatic hydroxy ketones, which are similarly employed, are described later.

IV. *Aromatic Ketones.*

Diphenylketone (Benzophenone)

$C_6H_5{\cdot}CO{\cdot}C_6H_5$.

This ketone is obtained by several of the general methods (2, 4, 6, 7, 10, 11, 16).

Preparation.—(i.) Dry calcium benzoate mixed with one-tenth of its weight of lime is distilled from an iron retort. The distillate is fractionated, the portion distilling at 290°–310° being collected separately. This for the most part solidifies on cooling, liquid impurities are removed by pressure, and the ketone crystallised from alcohol. The yield amounts to about one-fourth of the weight of the calcium benzoate used, the other products of distillation consisting of benzene, diphenyl, and anthraquinone.

(ii.) A mixture of equivalent amounts of benzene and benzoyl chloride dissolved in carbon disulphide is treated with aluminium chloride, equal in weight to the benzoyl chloride used. The reaction is completed under reflux on the water-bath, water is carefully added, and carbon disulphide, unattacked benzene, and benzoic acid removed in a current of steam. The residual oil is washed successively with dilute hydrochloric acid, dilute caustic soda and water, dried and fractionated. Yield 70–75 p.c.

(iii.) Well-cooled benzene is saturated with carbonyl chloride, and aluminium chloride added in small quantities at a time. The operation is conducted under reflux, and the product worked up as in the last case. From 100 grams of benzene, 55 grams of phosgene and 36 grams of aluminium chloride, 33 grams of benzophenone may be obtained.

Properties.—Rhombic prisms; m.p. 48°–49°. An unstable allotropic form (? monoclinic), melts at 26°–27° (Zincke, Annalen, 1871, 159, 377; Oechsner de Coninck, Compt. rend. 1900, 130, 40); b.p. 306° (170° at 15 mm.). For variation of boiling-point with pressure, *see* Crafts (Bull. Soc. chim. 1883, [ii.] 282). *Oxime* $(C_6H_5)_2C : NOH$; m.p. 139·5°–140°; *phenylhydrazone* $(C_6H_5)_2C : N{\cdot}NH{\cdot}C_6H_5$; m.p. 137°.

The ketone gives benzhydrol $(C_6H_5)_2CH(OH)$ when reduced with sodium amalgam, but it is preferable to add zinc dust to an alcoholic solution to which a small amount of aqueous potash has been added (Elbs, J. pr. Chem. 1886, [ii.] 33, 184).

Substitution (halogen, nitro, amino, &c.) derivatives are known; of these the amino and especially the dialkylamino derivatives are of considerable technical importance.

***p*-Aminobenzophenone** $C_6H_5{\cdot}CO{\cdot}C_6H_4{\cdot}NH_2$.

(i.) 75 grams of phthalanil

$C_6H_4\left<\begin{matrix}CO\\CO\end{matrix}\right>N{\cdot}C_6H_5$

and 50 grams of benzoyl chloride are boiled for 10 or 12 hours, zinc chloride (1 gram) being added from time to time. The resulting phthalylbenzoanilide

$C_6H_4\left<\begin{matrix}CO\\CO\end{matrix}\right>N{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_5$

may be purified by crystallisation from glacial acetic acid; when hydrolysed by alcoholic potash it gives *p*-aminobenzophenone (benzoaniline) and phthalic acid (Doebner, Annalen, 1881, 210, 268).

(ii.) Aniline and 2 molecular proportions of benzoyl chloride are heated gradually at 220°–230°, and the temperature maintained for 20 hours. The dibenzanilide first produced is thus isomerised to a mixture of *o*- and *p*-benzoylaminobenzophenones; the change may be aided by the addition of 10 p.c. of zinc chloride. After hydrolysis of the product the two aminobenzophenones may be separated by steam distillation, the ortho- compound being volatile. Calculated on the weight of aniline used, 15 p.c. of the ortho- and 45 p.c. of the para- derivatives are obtained (Chattaway, Chem. Soc. Trans. 1904, 85, 394).

Shining leaflets; m.p. 124°.

Aminobenzophenone and dimethyl- and diethylaminobenzophenones, as well as dimethylaminobenzophenone sulphonic acid condense with pyrogallol in acid solution to form triphenylmethane mordant dyestuffs (Ges. f. Chem. Ind. Basel, D. R. P. 58689).

***p*-Dimethylaminobenzophenone**

$$C_6H_5{\cdot}CO{\cdot}C_6H_4{\cdot}N(CH_3)_2$$

is obtained from malachite green and concentrated hydrochloric acid at 250° (Ber. 1880, 13, 2225), and by methylation of *p*-aminobenzophenone (Doebner, Annalen, 1881, 210, 270). Technically, it is more easily prepared by interaction of benzanilide, dimethylaniline, and phosphoryl chloride, and hydrolysis of the resulting product:

$$C_6H_5{\cdot}CO{\cdot}NH{\cdot}C_6H_5 \rightarrow C_6H_5{\cdot}CCl:N{\cdot}C_6H_5$$
$$\rightarrow C_6H_5{\cdot}C(C_6H_4{\cdot}N[CH_3]_2):N{\cdot}C_6H_5$$
$$\rightarrow C_6H_5{\cdot}CO{\cdot}C_6H_4{\cdot}N(CH_3)_2.$$

20 kilos. benzanilide, 40 kilos. dimethylaniline, and 20 kilos. phosphoryl chloride are stirred and warmed until spontaneous heating takes place, the temperature is then kept below 120°, and the reaction subsequently finished by one or two hours' heating on the water bath.

Hydrolysis may be effected in one of two ways:

(*a*) The mass is poured into 100 litres of water and 5 kilos. of hydrochloric acid warmed to 50°, the liquid allowed to stand, whereby a portion of the ketone separates, the remainder being precipitated by the addition of 500 litres of water and careful neutralisation with caustic soda. The ketone is collected, extracted with hydrochloric acid, washed, and dried.

(*b*) The mass is made alkaline, excess of dimethylaniline removed in a current of steam, and the granular residue hydrolysed at 50°–70° with 100 litres of water and 10 kilos. of hydrochloric acid. A portion of the ketone is precipitated, the remainder is obtained by addition of aqueous caustic soda, care being taken not to throw the aniline out of solution. Other dialkylaminobenzophenones may be similarly obtained (Farb. vorm. Meister, Lucius, and Brüning, D. R. PP. 41751, 42853).

p-Dimethylaminobenzophenone forms colourless leaflets; m.p. 90°–91°. It is a weak base, insoluble in water, sparingly soluble in cold alcohol. Phosphorus trichloride yields a yellow compound, probably

$$C_6H_5{\cdot}CCl_2{\cdot}C_6H_4{\cdot}N(CH_3)_2 \text{ or }$$
$$C_6H_5{\cdot}CCl:C_6H_4:N(CH_3)_2Cl,$$

which can be purified by solution in chloroform and reprecipitation by petroleum spirit. It is easily converted into the original ketone by heating with water, and condenses directly with dimethylaniline, forming malachite green (B. A. S. F., D. R. P. 27789).

The hydrol $C_6H_5{\cdot}CH(OH){\cdot}C_6H_4{\cdot}N(CH_3)_2$ (m.p. 69°–70°), obtained by reduction of dimethylaminobenzophenone, condenses with dimethylaniline to leuco malachite green.

4 : 4′-Diaminobenzophenone

$$NH_2{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_4{\cdot}NH_2$$

(m.p. 172°), and its trimethyl derivative $(CH_3)_2N{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_4{\cdot}NH(CH_3)$ (m.p. 156°) are obtained from pararosaniline (or rosaniline) and pentamethyl violet, respectively by prolonged heating with hydrochloric acid (Wichelhaus, Ber. 1886, 19, 109).

Diaminobenzophenone and its derivatives can be condensed with pyrogallol to green or blue mordant dyestuffs (Ges. f. chem. Ind. Basel, D. R. P. 61326).

Tetramethyldiaminobenzophenone (Michler's ketone) $CO[C_6H_4{\cdot}N(CH_3)_2]_2$ is a valuable intermediate product in the preparation of many dyestuffs, and was first obtained by Michler (Ber. 1876, 9, 716, 1900). Dimethylaniline is saturated at ordinary temperature with the theoretical quantity of phosgene, and the reaction completed by warming in a closed vessel to 100°. Water is added, excess of dimethylaniline removed by steam distillation, and the ketone purified from adherent blue colouring matter by repeated solution in hydrochloric acid and reprecipitation with soda.

Michler's ketone may also be prepared by carefully heating on the water-bath 10 kilos. of dimethylaminobenzanilide

$$(CH_3)_2N{\cdot}C_6H_4{\cdot}CO{\cdot}NH{\cdot}C_6H_5$$

18 kilos. of dimethylaniline, and 8·5 grams of phosphoryl chloride, the product being worked up in a similar manner to that adopted in the case of dimethylaminobenzophenone.

Disubstituted dialkylaminobenzamides (Meister, Lucius, Brüning, D. R. P. 44238) may also be employed. Thus 10 kilos. of dimethylaminobenzodiphenylamine $(CH_3)_2N{\cdot}C_6H_4{\cdot}CO{\cdot}N(C_6H_5)_2$, 12 kilos. of dimethylaniline, and 5 kilos. of phosphoryl chloride are heated on the water-bath for 2 hours; the product being subsequently worked up by hydrolysis with hydrochloric acid, precipitation of the ketone and diphenylamine and separation of the latter by washing with alcohol (D. R. P. 44077).

The ketone forms silvery leaflets, m.p. 174° (corr.), boils with some decomposition above 360°; it is easily soluble in alcohol and ether. The basic properties are weak. *Picrate*

$$C_{17}H_{20}ON_2,C_6H_2(OH)(NO_2)_3;$$

mp. 156°–157°.

Tetraethyldiaminobenzophenone obtained similarly melts at 95°–96° (Michler and Gradman, Ber. 1876, 9, 1914).

Replacement of oxygen in the above ketones by the imino group gives auramines (*q v.*).

In presence of condensing agents (*e.g.* $POCl_3$, $COCl_2$, &c.) the tetralkyldiaminobenzophenones condense with aromatic amines to give dyestuffs of the triphenyl (diphenylnaphthyl, &c.) series, but cleaner products are generally obtained by reducing the ketones to hydrols, and condensing these with amines, &c., to leuco-compounds, which are subsequently oxidised to the corresponding dyestuffs.

Reduction to hydrols may be effected by sodium amalgam in alcoholic solution; technically zinc dust and caustic soda in amyl alcoholic solution are employed (B. A. S. F., D. R.-P. 27032). Tetramethyldiaminobenzhydrol dissolves in acetic acid with an intense blue colour, which is discharged on rendering alkaline.

Amino (and acetamino) derivatives of tetra-alkyldiaminobenzophenones may be obtained from nitro derivatives by reduction. Michler's ketone, when nitrated, gives 3-nitro- and 3 : 3′-dinitro-4 : 4′-tetramethyldiaminobenzophenone (Kliegl, Ber. 1906, 39, 1266); the latter compound has also been obtained by the action of dimethylamine on 3 : 3′-dinitro-4 : 4′-dichlorobenzophenone (Consonno, Gazz. chim. ital. 1904, 34, i. 386). Introduction of the nitro group in position 2 may be effected by nitrating tetramethyldiaminodiphenylmethane, and subsequently oxidising the CH_2 group (Farbenf. vorm. Fr. Bayer & Co., D. R. P. 79250).

Hydroxyl derivatives of Benzophenone.

Numerous hydroxyl derivatives of benzophenone have been prepared, many by reactions involving the condensation of benzoic acid and its derivatives with phenols:

$$C_6H_{5-x}(OH)_xCOOH+C_6H_{6-y}(OH)_y$$
$$=C_6H_{5-x}(OH)_xCO{\cdot}C_6H_{5-y}(OH)_y+H_2O.$$

The trihydroxybenzophenones obtained from pyrogallol contain the grouping $\cdot CO{\cdot}C_6H_2(OH)_3(CO : OH : OH : OH=1 : 2 : 3 : 4)$, they are generally yellow in colour, and are used as mordant dyestuffs.

Alizarin yellow A, $C_6H_5{\cdot}CO{\cdot}C_6H_2(OH)_3$, is obtained by heating 1 part of pyrogallol and 1 part of benzoic acid to 145°, and adding 3 parts of zinc chloride with continuous stirring. The end of the reaction, which takes about 3 hours to complete, is recognised by the solution of the product in hot water giving slender bright yellow needles, and not benzoic acid on cooling. The mass is dissolved in 60 parts of boiling water, boiled 2 hours with animal charcoal, filtered, and allowed to crystallise. It forms yellow needles (with $1H_2O$); m.p. 137°–138°. *Acetyl* derivative, colourless; m.p. 119°. On cotton mordanted with alumina it dyes golden-yellow shades, which incline to orange in presence of calcium salts. A fine yellow is produced with aluminium acetate and tin salt; the chromium lake is brownish-yellow, and the iron lake dark olive. The colours produced are very fast.

Dyestuffs giving similar shades are produced by the condensation of pyrogallol with *m*- and *p*-hydroxybenzoic acid, and *β*-resorcylic acid; those from pyrogallol and salicylic or pyrogallolcarboxylic acids give redder lakes, whilst the lakes are of a greenish-yellow shade if dyestuffs obtained by condensing gallic acid with resorcinol or pyrogallol are employed. The chemistry of these hydroxyketone dyestuffs has been studied by C. Graebe and A. Eichengrün (Annalen, 1892, 269, 295).

New dyestuffs, greener in shade, are obtained by fusing alizarin yellow A or C with the ammonium salts of organic acids (Prud'homme, Rev. gén. Mat. col. 1906, 10, 225).

Two unsaturated aromatic ketones, the benzalacetones, have been described under general methods of preparation (No. 18).

Thioketones.

Thiobenzophenone $C_6H_5{\cdot}CS{\cdot}C_6H_5$ was first obtained by Bergreen (Ber. 1886, 21, 341) in an impure condition by the action of 2 parts of aluminium chloride on 1 part of thiophosgene ($CSCl_2$) dissolved in 5 parts of benzene, the reaction being completed on the water-bath. After treatment with ice, and extraction with ether, the ethereal solution was washed with soda and water, and the ether distilled off, the thioketone remaining as an oil.

L. Gattermann and H. Schulze (Ber. 1896, 29, 2944) found that it is impossible to obtain the thioketone in a pure condition by this method, but were successful in treating benzophenone chloride $C_6H_5{\cdot}CCl_2{\cdot}C_6H_5$ with very slightly over the theoretical quantity of alcoholic potassium sulphide. The mixture becomes hot, potassium chloride separates, and the solution assumes a blue colour. After cooling, water is added, the thioketone extracted with ether, the latter distilled off, and the product fractionated under reduced pressure. The thioketone passes over at 174° (14 mm.) as a deep-blue oil, which solidifies to long blue needles.

Thiobenzophenone is very unstable, and can only be preserved in sealed tubes filled with carbon dioxide. Its colour is discharged on warming with alcoholic potash, benzophenone being regenerated; it reacts with hydroxylamine giving benzophenone-oxime, and on heating with copper powder gives tetraphenylethylene.

Gattermann has also described corresponding alkyloxythioketones obtained by the action of thiophosgene on anisole, phenetole, *o*-cresyl ethyl ether, *o*-cresyl methyl ether, *o*-chloroanisole, *o*-chlorophenetole, and *o*-bromoanisole. The compounds obtained resemble thiobenzophenone in their reactions (Ber. 1895, 28, 2869).

On account of the greater reactivity of the : C : S group as compared with carbonyl, the sulphur analogue of Michler's ketone has been prepared by several methods.

Tetramethyldiaminothiobenzophenone

$$(CH_3)_2N{\cdot}C_6H_4{\cdot}CS{\cdot}C_6H_4{\cdot}N(CH_3)_2.$$

Preparation.—(i.) 5 parts of dimethylaniline are cooled to 0°–10°, and 1 part of thiophosgene in 3 parts of carbon disulphide added in the course of 3 or 4 hours with continual stirring, which is continued for 10–12 hours without further cooling. Alkali is added, carbon disulphide and dimethylaniline removed in a current of steam, and the thioketone crystallised (Kern, D. R. P. 37730).

(ii.) An intimate mixture of Michler's ketone and one-fifth of its weight of phosphorus pentasulphide is heated not above 160°. The mass is exhausted successively with water, very dilute sodium carbonate solution and water, and finally crystallised from amyl alcohol (B. A. S. F., D. R. P. 39074).

(iii.) 100 parts of Michler's ketone, 38 parts of phosphoryl chloride, and 400 parts of toluene are heated on a water bath and hydrogen sulphide led in until a test specimen no longer dissolves in water with a blue colour; or

37 parts of phosgene are passed into a solution of 100 parts of Michler's ketone in 400 parts of chloroform at 15°–20°, after the evolution of carbon dioxide has ceased, 90 parts of sodium sulphide in 800 parts of water are added. The solvent is removed by steam distillation, and the thioketone crystallised from alcohol (B. A. S. F., D. R. P. 40374).

(iv.) An alcoholic solution of auramine base is saturated with hydrogen sulphide, first in the cold, then on the water bath (Fehrmann, Ber. 1887, 20, 2857; Graebe *ibid.* 3267).

Properties.—M.p. 202°. Fairly soluble in chloroform, sparingly so in cold alcohol or ether. Yields Michler's ketone on warming with hydrochloric acid.

OPEN CHAIN DIKETONES.

The diketones are most conveniently classified according to the relative positions of the carbonyl groups in the carbon chain. Thus they may be divided in the following way:—

1 : 2- or α-diketones $R\cdot CO\cdot CO\cdot R'$.
1 : 3- or β-diketones $R\cdot CO\cdot CH_2\cdot CO\cdot R'$.
&c. &c.

1 : 2- *or α-Diketones.*

Preparation.—(1) The α-diketones may be obtained as monoximes by the action of nitrous acid on monoketones or β-ketonic esters:

$$R\cdot CO\cdot CH_2\cdot R' + HNO_2 = H_2O + R\cdot CO:(NOH)\cdot R'.$$

$$R\cdot CO\cdot CHR'\cdot CO_2C_2H_2 + HNO_2 = CO_2 + C_2H_5OH + R\cdot CO\cdot C(:NOH)\cdot R'.$$

The monoximes of the 1 : 2-diketones can often be prepared by the action of diazonium salts on alkaline solutions of *iso*nitrosoacetone (Borsche, Ber. 1907, 40, 707):

$$C_6H_5N_2Cl + NaON:CH\cdot CO\cdot CH_3 = C_6H_5\cdot C(:NOH)\cdot CO\cdot CH_3 + NaCl + N_2.$$

The results with *iso*nitrosoacetophenone are not so favourable.

The replacement of the *iso*nitroso- group by oxygen may be effected:

(i.) By boiling with dilute sulphuric acid (v. Pechmann, Ber. 1887, 20, 3213; 1888, 21, 1411).

$$CH_3\cdot CO\cdot C(:NOH)\cdot CH_3 + H_2O = CH_3\cdot CO\cdot CO\cdot CH_3 + H_2NOH.$$

(ii.) By conversion into salts of iminosulphonic acids by the action of alkaline bisulphites, and subsequently hydrolysing by boiling with 15 p.c. sulphuric acid:

$$CH_3\cdot CO\cdot C(:NOH)\cdot CH_3 + NaHSO_3 = CH_3\cdot CO\cdot C(:N\cdot SO_3Na)\cdot CH_3 + H_2O$$

$$CH_3\cdot CO\cdot C(:N\cdot SO_3H)\cdot CH_3 + 2H_2O = CH_3\cdot CO\cdot CO\cdot CH_3 + (NH_4)HSO_4$$

(v. Pechmann, Ber. 1887, 20, 3162; 1889, 22, 2115).

(iii.) By warming with *iso*amyl nitrite (Manasse, Ber. 1888, 21, 2177):

$$CH_3\cdot CO\cdot C(:NOH)\cdot CH_3 + C_5H_{11}\cdot ONO = CH_3\cdot CO\cdot CO\cdot CH_3 + C_5H_{11}OH + N_2O.$$

Similarly diethyl acetosuccinate gives *iso*nitrosolævulic acid, the latter compound yielding diacetyl on boiling with dilute sulphuric acid (Thal, Ber. 1892, 25, 1723).

The mixed aliphatic-aromatic diketones are obtained in a similar way from mixed *iso*nitrosoketones (v. Pechmann and Müller, Ber. 1888, 21, 2119; 1889, 22, 2128).

(2) Ketones of the structure $CH_3\cdot CO\cdot CH_2R$, when warmed with nitric acid (sp.gr. 1·38) give ketones $CH_3\cdot CO\cdot CO\cdot R$ (Fileti and Ponzio, Gazz. chim. ital. 1895, 25, i. 233).

(3) Aromatic (and some heterocylic) diketones are obtained from aldehydes $R\cdot CHO$ by condensation to the keto alcohols

$$R\cdot CO\cdot CH(OH)\cdot R$$

under the influence of potassium cyanide and subsequent oxidation with chlorine (Laurent. Annalen, 1836, 17, 91), or more frequently nitric acid (Zinin, *ibid.* 1840, 34, 188).

(4) By heating compounds of the type $R\cdot CBr:CBr\cdot R$ with water to 200° (*e.g.* tolane bromide) (Limpricht and Schwanert, Ber. 1871, 4, 380):

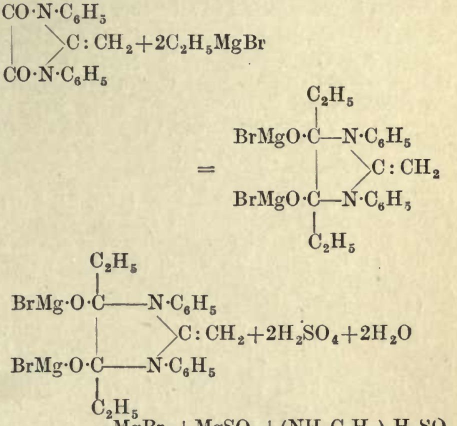
$$2C_6H_5\cdot CBr:CBr\cdot C_6H_5 + 2H_2O = C_6H_5\cdot CO\cdot CO\cdot C_6H_5 + C_6H_5\cdot C:C\cdot C_6H_5 + 4H_2O.$$

(5) By hydrolysis of compounds

$$R\cdot CX_2\cdot CX_2\cdot R$$

(X=halogen). Thus tolane tetrachloride, when heated with sulphuric acid to 165°, or with glacial acetic acid to 230°–250° (Liebermann and Homeyer, Ber. 1879, 12, 1975).

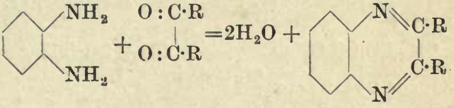
(6) The vinylidene-oxanilide prepared by v. Pechmann by 8 hours boiling of 1 part of oxanilide, 1 part of fused sodium acetate, and 10 parts of acetic anhydride (Ber. 1897, 30, 2791) reacts readily with the Grignard reagents, forming compounds which furnish diketones on decomposition with dilute sulphuric acid:



$$= MgBr_2 + MgSO_4 + (NH_2C_6H_5)_2H_2SO_4 + CH_3\cdot COOH + C_2H_5\cdot CO\cdot CO\cdot C_2H_5$$

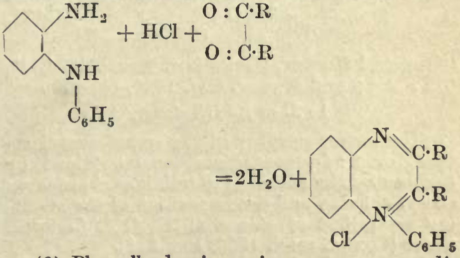
(L. Tschugaeff, Ber. 1907, 40, 186).

General properties and reactions.—(1) The most characteristic reaction of the α-diketones is their condensation with aromatic *o*-diamines to quinoxalines:



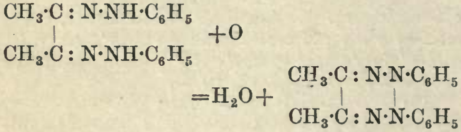
The resulting coloured compounds crystallise well, have definite melting-points, and are readily identified (Hinsberg, Ber. 1884, 17, 322; Annalen, 1887, 237, 327).

When monosubstituted *o*-diamines are employed, salts of ammonium type are produced:



(2) Phenylhydrazine gives *mono-* or *di*-hydrazones; for preparation of the former, *see*

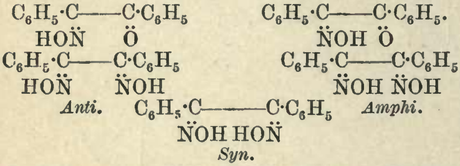
Petrenko-Kritschenko and Eltschaninoff (Ber. 1901, 34, 1699). The dihydrazones (usually called osazones) derived from aliphatic diketones or diketones containing only one aromatic radicle, are readily oxidised by ferric chloride to red or brown osotetrazones (v. Pechmann, Ber. 1888, 21, 2751):



$$\begin{array}{l} CH_3\cdot C:N\cdot NH\cdot C_6H_5 \\ \quad | \qquad\qquad\qquad\qquad +O \\ CH_3\cdot C:N\cdot NH\cdot C_6H_5 \end{array} = H_2O + \begin{array}{l} CH_3\cdot C:N\cdot N\cdot C_6H_5 \\ \qquad | \qquad\quad | \\ CH_3\cdot C:N\cdot N\cdot C_6H_5 \end{array}$$

For action of hydrazine *v.* Curtius and Kastner, J. pr. Chem. 1911, 83, 215.

(3) Hydroxylamine yields *mono-* or *di-*oximes, the former can exist in two, the latter in three modifications, even when the original diketone is symmetrical in structure:



$$\begin{array}{ll} \begin{array}{l} C_6H_5\cdot C\text{——}C\cdot C_6H_5 \\ \quad HO\ddot{N} \qquad \ddot{O} \end{array} & \begin{array}{l} C_6H_5\cdot C\text{——}C\cdot C_6H_5. \\ \quad \ddot{N}OH\ \ \ddot{O} \end{array} \\ \begin{array}{l} C_6H_5\cdot C\text{——}C\cdot C_6H_5 \\ \quad HO\ddot{N} \qquad \ddot{N}OH \end{array} & \begin{array}{l} C_6H_5\cdot C\text{——}C\cdot C_6H_5 \\ \quad \ddot{N}OH\ \ \ddot{N}OH \end{array} \\ \quad \textit{Anti.} & \quad \textit{Amphi.} \end{array}$$

$$\begin{array}{c} C_6H_5\cdot C\text{———}C\cdot C_6H_5 \\ \ddot{N}OH\ HO\ddot{N} \\ \textit{Syn.} \end{array}$$

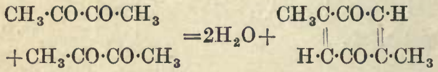
(K. Auwers and V. Meyer, Ber. 1888, 21, 810; 1889, 22, 705; A. Hantzsch and A. Werner, Ber. 1890, 23, 11). The *syn*dioximes are characterised by the ease with which they lose water yielding furazane derivatives.

(4) Semicarbazide gives *mono-* and *di-*semicarbazones and cyclic condensation products (*see* Thiele, Annalen, 1894, 283, 37; Posner, Ber. 1901, 34, 3973; Biltz and Arnd, *ibid.* 1902, 35, 344; Diels, *ibid.* 1902, 35, 347).

(5) With caustic potash the aromatic α-diketones yield diaryl glycollic acids (Liebig, Annalen, 1838, 25, 25; Zinin, *ibid.* 1839, 31, 329):

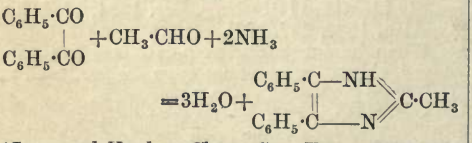
$$C_6H_5\cdot CO\cdot CO\cdot C_6H_5 + KOH = (C_6H_5)_2C(OH)COOK.$$

The aliphatic α-diketones, however, when warmed in alkaline solution undergo condensation with formation of quinones; thus diacetyl gives xyloquinone (v. Pechmann, Ber. 1888, 21, 1417):



$$\begin{array}{l} CH_3\cdot CO\cdot CO\cdot CH_3 \\ +CH_3\cdot CO\cdot CO\cdot CH_3 \end{array} = 2H_2O + \begin{array}{l} CH_3C\cdot CO\cdot C\cdot H \\ \quad\ \| \qquad\quad \| \\ H\cdot C\cdot CO\cdot C\cdot CH_3 \end{array}$$

(6) With aldehydes and ammonia, glyoxalines are formed amongst other products:



(Japp and Hooker, Chem. Soc. Trans. 1884, 45, 672; Japp and Wynne, *ibid.* 1886, 49, 464).

1 : 3- or β- *Diketones.*

The lowest member of the series, acetylacetone, or 2 : 4-pentanedione, was obtained by Combes by the action of aluminium chloride on acetyl chloride and decomposition of the resulting crystalline substance $C_{12}H_{14}O_6Al_2Cl_8$ with water (Compt. rend. 1886, 103, 814).

The usual method of preparation of the 1 : 3-diketones is given under general reaction 17 of monoketones (*vide supra*). As condensing agents for bringing about the reaction

$$R\cdot CO\cdot OC_2H_5 + CH_3\cdot CO\cdot R' \rightarrow R\cdot C(ONa):CH\cdot COR' \rightarrow R\cdot CO\cdot CH_2\cdot CO\cdot R',$$

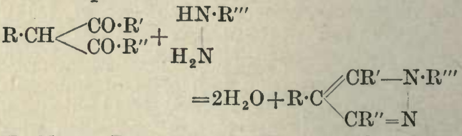
Claisen has found that alcoholic sodium ethoxide works most feebly and in order of increasing activity, are anhydrous sodium ethoxide, metallic sodium (Annalen, 1894, 277, 168), and sodium amide (Ber. 1905, 38, 695).

General properties and reactions.—(1) The 1 : 3-diketones form stable metallic derivatives. Acetylacetone, for example, forms compounds of the types $M^{II}(C_5H_7O_2)_2$, $M^{III}(C_5H_7O_2)_3$, &c., many of which are volatile without decomposition, and may be used for vapour density determinations, thus controlling the valencies of several metals; *e.g.* divalent Gl and Cu, and trivalent Al, Fe, Mn, Co, and Cr (A. Combes, Compt. rend. 1896, 119, 1221; Bull. Soc. chim. 1889, [iii.] 1, 345; Urbain and Debierne, Compt. rend. 1899, 129, 302; Claisen, Ber. 1889, 22, 1010; Annalen, 1893, 277, 170). The metallic radicle may be replaced by acyl groups, branched triketones resulting from the reaction:

$$C_6H_5\cdot C(ONa):CH\cdot CO\cdot C_6H_5 + C_6H_5COCl = NaCl + (C_6H_5CO)_3CH.$$

(v. Baeyer and Perkin, Ber. 1883, 16, 2128; L. Claisen, Ber. 1894, 27, 111; Annalen, 1896, 291, 25; Ber. 1904, 36, 3674).

(2) On warming with arylhydrazines, pyrazoles are produced:

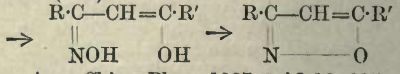


(L. Knorr, Ber. 1885, 18, 311; Annalen, 1887, 238, 37). This reaction can be utilised as the basis of a colour test for β-diketones since pyrazoles are reduced by sodium in boiling alcoholic solution to pyrazolines. If when solution of the metal is complete, water be added and the alcohol boiled off, the pyrazoline may be extracted with ether, and is left when the solvent is evaporated. If the residue be dissolved in fairly concentrated sulphuric acid, addition of a drop of solution of sodium nitrite or potassium dichromate produces a beautiful colouration varying from fuchsine red to blue. This reaction, which can be carried out in test tubes, is general for all pyrazoles derived from phenylhydrazine, not, however, for those obtained from hydrazine itself (L. Knorr, Ber. 1885, 18, 2259; 1893, 26, 101; Annalen, 1887, 238, 200).

(3) Semicarbazide gives similar pyrazole derivatives (T. Posner, Ber. 1901, 34, 3973).

(4) With hydroxylamine the 1 : 3-diketones behave as if one of the ketonic groups were enolised and furnish isoxazoles:

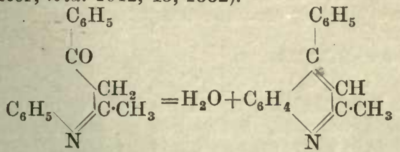
$$R\cdot CO\cdot CH:C(OH)\cdot R'$$



(Combes, Ann. Chim. Phys. 1887, [vi.] 12, 215; Zedel, Ber. 1888, 21, 2178; Claisen, *ibid.* 1891, 24, 3907).

(5) Aniline and benzoylacetone lose 1 molecule of water at 150°, a second molecule of water is removed by heating with concentrated sulphuric

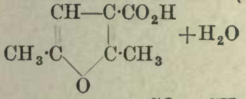
acid, α-methyl-γ-phenylquinoline being formed (C. Beyer, Ber. 1887, 20, 1770; Rügheimer a. Ritter, *ibid.* 1912, 45, 1332).



(6) β-Diketones and β-ketonic esters condense with esters of acetylenic acids, giving unsaturated diketones or ketonic esters. From these, pyrone derivatives have been obtained (Ruhemann, Chem. Soc. Trans. 1899, 75, 245, 411; 1908, 93, 431).

1 : 4- *or γ-Diketones.*

Preparation.—(1) The lowest member of the series, acetonylacetone or 2 : 5-hexanedione was obtained by Paal by heating pyrotritaric acid with water at 150°–160° (Ber. 1885, 18, 58):

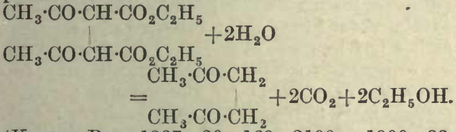


$$=CO_2+CH_3·CO·CH_2·CH_2·CO·CH_3.$$

(2) α-Halogenised ketones react normally with the sodium derivative of ethyl acetoacetate: on hydrolysis 1 : 4-diketones are produced (Paal, Ber. 1883, 16, 2865):

$$CH_3·CO·CH(COOC_2H_5)CH_2·CO·C_6H_5+H_2O$$
$$=CO_2+C_2H_5OH+CH_3·CO·CH_2·CH_2·CO·C_6H_5.$$

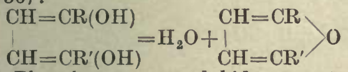
(3) By hydrolysis of compounds of the type of diethyl diacetosuccinate, preferably with potassium carbonate solution:



$$\begin{array}{l}CH_3·CO·CH·CO_2C_2H_5\\ \quad|\\ CH_3·CO·CH·CO_2C_2H_5\end{array}+2H_2O=\begin{array}{l}CH_3·CO·CH_2\\ \quad|\\ CH_3·CO·CH_2\end{array}+2CO_2+2C_2H_5OH.$$

(Knorr, Ber. 1887, 20, 169, 2100; 1900, 33, 1219; Annalen, 1899, 306, 363).

General reactions.—(1) Reacting in the dienolic form, 1 : 4-diketones are dehydrated by fuming hydrochloric acid or acetic anhydride, yielding furfurane derivatives (Paal, Ber. 1884, 17, 2756):



(2) Phosphorus pentasulphide converts them in a similar manner into thiophen compounds.

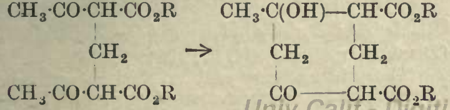
(3) Ammonia similarly yields pyrrole derivatives.

1 : 5-*Diketones, &c.*

Esters of 1 : 5-diketonedicarboxylic acids may be obtained by the condensation of ethyl acetoacetate with aldehydes (P. Rabe, Annalen, 1902, 323, 88; 1904, 332, 11; 1908, 360, 265; Dreckmann a. v. Fischer, Ber. 1911, 44, 966):

$$CH_2O+2CH_3·CO·CH_2·CO_2C_2H_5$$
$$=H_2O+CH_2[CH(COCH_3)·CO_2C_2H_5]_2.$$

Such compounds easily undergo an intramolecular aldol-condensation, yielding 1 : 5-*cyclo*hexanolones:

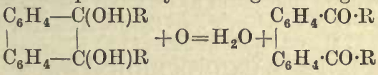


The differentiation of the isomerides is easy, derivatives of dihydropyridine and pyridine being obtained from the 1 : 5-diketonic compounds when treated with ammonia and hydroxylamine respectively.

E. Blaise and A. Koehler (Compt. rend. 1909, 148, 489) have utilised the organo zinc compounds in conjunction with the chlorides of dibasic acids for the synthesis of diketones with far removed carbonyl groups. Whilst succinyl and glutaryl chlorides yield γ- and δ-lactones respectively, the higher acid chlorides react in the sense:

$$COCl(CH_2)_nCOCl+2RZnI$$
$$=ZnCl_2+ZnI_2+R·CO(CH_2)_nCO·R.$$

T. Zincke (Annalen, 1908, 362, 242; 363, 302) has also obtained 1 : 6-diketones by oxidising the ditertiary alcohols obtained from phenanthraquinone by the Grignard reagents:



$$\begin{array}{l}C_6H_4—C(OH)R\\ |\qquad\quad |\\ C_6H_4—C(OH)R\end{array}+O=H_2O+\begin{array}{l}C_6H_4·CO·R\\ |\\ C_6H_4·CO·R\end{array}$$

INDIVIDUAL OPEN-CHAIN DIKETONES.

Diacetyl $CH_3·CO·CO·CH_3$ may be prepared by the method of O. Diels and E. Stephan (Ber. 1907, 40, 4336). Methyl ethyl ketone (850 c.c.) is converted into the *iso*nitroso derivative (diacetyl monoxime) by amyl nitrite (1 litre) and hydrochloric acid (30 c.c., sp.gr. 1·19). The oxime is extracted with dilute sodium hydroxide solution; after acidifying the diacetyl is blown over in a current of steam and the ketone eventually separated from water. 4 kilos. of methyl ethyl ketone give 1300 grams of diacetyl; b.p. 87°–88°.

Diacetyldioxime (dimethylglyoxime)

$$CH_3·C(:NOH)C(:NOH)CH_3$$

has acquired importance as a reagent for nickel. The solution to be tested is treated with an excess of ammonia or sodium acetate and then a little dimethylglyoxime is added and the solution boiled. If nickel is present a scarlet precipitate is produced. Definite results may be obtained with solutions containing 1 part of nickel in 400,000 of water. When cobalt is present, the solution is first shaken with a large excess of ammonia, 0·1mg. of nickel can be detected in the presence of 500 mg. of cobalt (L. Tschugaeff, Ber. 1905, 38, 2520).

Convenient methods for the preparation of dimethylglyoxime have been given by Tschugaeff (*l.c.*), A. Gandarin (J. pr. Chem. 1908, [ii.] 77, 414), and H. Biltz (Zeitsch. anal. Chem. 1909, 48, 164). Biltz's method consists in passing gaseous hydrogen chloride through a well-cooled solution of 50 grams of methyl ethyl ketone in 100 grams of ether, 82 grams of amyl nitrite being added drop by drop. After a few hours the monoxime is extracted by caustic soda solution (150 c.c. iced water and 50 c.c. 33 p.c. caustic soda), the ethereal layer extracted a few times with dilute caustic soda, the alkaline solutions united, extracted with a little ether and somewhat evaporated. After cooling the solution is carefully neutralised with dilute sulphuric acid, and 50 grams of hydroxylamine hydrochloride dissolved in 75 c.c. of water is added. The dioxime crystallises out on standing over-night, and is purified by recrystallisation. The yield amounts to 45–50 grams (*v.* DIMETHYLGLYOXIME).

Benzil $C_6H_5{\cdot}CO{\cdot}CO{\cdot}C_6H_5$ is obtained by the oxidation of benzoïn $C_6H_5{\cdot}CO{\cdot}CH(OH)C_6H_5$, which may be prepared by heating for a short time 200 grams of pure benzaldehyde with 20 grams of potassium cyanide dissolved in 800 grams of 50 p.c. alcohol under reflux. The solution is allowed to cool, benzoïn separates, and is collected, the filtrate yields a further quantity of benzoïn when heated with more potassium cyanide (Zincke, Annalen, 1879, 198, 151). The benzoïn is then heated with twice its weight of nitric acid (sp.gr. 1·4) until red fumes are no longer evolved, the whole is poured into water, and the benzil, which then solidifies, purified by crystallisation from alcohol (Zinin, Annalen, 1840, 34, 188).

Benzil crystallises in six-sided prisms; m.p. 95°; b.p. 346°–348° (corr. with slight decomposition). Easily soluble in alcohol and ether. Is reduced to benzoïn by iron and acetic acid, or zinc and hydrochloric acid (Zinin, Annalen, 1861, 119, 177) and to hydrobenzoïn

$$C_6H_5{\cdot}CH(OH)CH(OH)C_6H_5$$

by sodium amalgam (Zincke and Forst, Ber. 1875, 8, 797). Other reactions have already been mentioned under 1 : 2-diketones.

Benzil yields substitution products with difficulty, it may be nitrated by boiling with fuming nitric acid. Two dinitrobenzils (m.p.'s 131° and 147°) are produced; these may be mechanically separated as crystals. The mixture of dinitrobenzils can be reduced, the resulting diamino-compound (? a mixture), though not isolated, can be used as a component in the preparation of azo dyestuffs (Poirrier and Rosenstiehl, D. R. PP. 44269 and 45789).

OPEN CHAIN TRI- AND TETRA-KETONES.

Triketones. *Preparation.*—(1) F. Sachs and H. Barschall (Ber. 1901, 34, 3047) obtained triketopentane by condensation of nitrosodimethylaniline with acetylacetone and hydrolysis of the resulting azomethine compound:

$$\begin{aligned} &CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CH_3+ON{\cdot}C_6H_4{\cdot}N(CH_3)_2 \\ &\qquad =H_2O+CH_3{\cdot}CO{\cdot}C[:N{\cdot}C_6H_4N(CH_3)_2]CO{\cdot}CH_3 \\ &CH_3{\cdot}CO{\cdot}C[:N{\cdot}C_6H_4N(CH_3)_2]CO{\cdot}CH_3+H_2O \\ &\qquad =H_2N{\cdot}C_6H_4{\cdot}N(CH_3)_2+CH_3{\cdot}CO{\cdot}CO{\cdot}CO{\cdot}CH_3. \end{aligned}$$

(Later papers by Sachs, Ber. 1902, 35, 3307; 1903, 36, 3221; 1907, 40, 2714.)

(2) Aromatic triketones with open chain have been obtained by Wieland and Bloch (Ber. 1904, 37, 1524). By the action of nitrous gases evolved from a mixture of arsenious oxide and nitric acid (sp.gr. 1·38) on an ethereal solution of dibenzoylmethane, the bisnitroso derivative of the latter compound and diphenyltriketone are obtained. The latter crystallises with water, probably of constitution; in fact the colourless hydrates give coloured triketones by loss of water. The same behaviour is observed in the case of cyclic triketones: Ruhemann (Chem. Soc. Trans. 1910, 2025; 1911, 792, 1306, 1486) finds that the coloured triketohydrindene not only forms a colourless monohydrate, but also gives colourless addition products with guanidine, benzamidine, and hydrogen cyanide.

Tetraketones are also known.

2 : 4 : 5 : 7-*Octanetetrone*

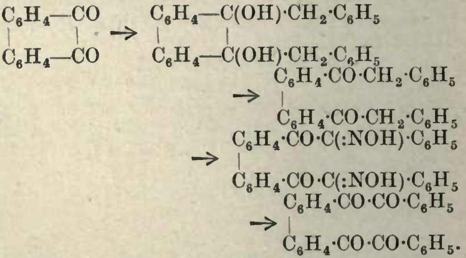
$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CH_3$$

is obtained by adding sodium ethoxide (free from alcohol) to an ethereal solution of acetone and diethyl oxalate (Claisen and Stylos, Ber. 1888, 21, 1142). With acetophenone, &c., corresponding aromatic compounds can be prepared.

o-o'-**Dibenzil**

$$C_6H_5{\cdot}CO{\cdot}CO{\cdot}C_6H_4{\cdot}C_6H_4{\cdot}CO{\cdot}CO{\cdot}C_6H_5$$

has been obtained by Zincke and Tropp (Annalen, 1908, 363, 302). Phenanthraquinone is treated with magnesium benzyl halide, the resulting di-tertiary alcohol oxidised to dibenzyldiphenylene diketone, the latter converted into a di*iso*nitroso compound and hydrolysed:



$$\begin{array}{l} C_6H_4{-}CO \\ |\qquad\quad | \\ C_6H_4{-}CO \end{array} \rightarrow \begin{array}{l} C_6H_4{-}C(OH){\cdot}CH_2{\cdot}C_6H_5 \\ | \\ C_6H_4{-}C(OH){\cdot}CH_2{\cdot}C_6H_5 \end{array}$$

$$\rightarrow \begin{array}{l} C_6H_4{\cdot}CO{\cdot}CH_2{\cdot}C_6H_5 \\ | \\ C_6H_4{\cdot}CO{\cdot}CH_2{\cdot}C_6H_5 \end{array} \rightarrow \begin{array}{l} C_6H_4{\cdot}CO{\cdot}C(:NOH){\cdot}C_6H_5 \\ | \\ C_6H_4{\cdot}CO{\cdot}C(:NOH){\cdot}C_6H_5 \end{array} \rightarrow \begin{array}{l} C_6H_4{\cdot}CO{\cdot}CO{\cdot}C_6H_5 \\ | \\ C_6H_4{\cdot}CO{\cdot}CO{\cdot}C_6H_5. \end{array}$$

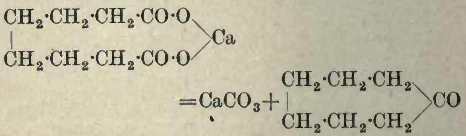
Possessing two 1 : 2-diketo- groups, the compound condenses with 2 molecules of *o*-phenylenediamine to form the corresponding *di*quinoxaline.

CYCLIC KETONES.

In the cyclic ketones the carbonyl groups form members of a closed ring; the properties are very similar to those of the aliphatic ketones as a rule, but in the case of the ortho- and paraquinones, such special characteristics are exhibited that they will be treated in a separate article (*q.v.*).

Preparation.—The cyclic ketones may frequently be prepared by the general methods already given; the following syntheses, or special methods, resulting in the formation of closed chain ketones, may be mentioned.

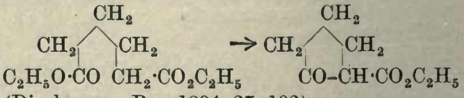
(1) The distillation of the calcium salts of certain dibasic acids gives cyclic ketones. The earliest example is the preparation of suberone from calcium suberate:



$$\begin{array}{l} CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}O \\ | \\ CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}O \end{array} \!\!> Ca \;=CaCO_3+\begin{array}{l} CH_2{\cdot}CH_2{\cdot}CH_2 \\ | \\ CH_2{\cdot}CH_2{\cdot}CH_2 \end{array}\!\!> CO$$

(Boussingault, Annalen, 1836, 19, 308; Tilley, *ibid.* 1841, 39, 166; Dale and Schorlemmer, *ibid.* 1879, 199, 147). *Cyclo*pentanone, *cyclo*hexanone, and *cyclo*octanone can be obtained by similar methods from the calcium salts of adipic, pimelic, and azelaïc acids (Wislicenus, Annalen, 1893, 275, 312, 364; v. Baeyer, *ibid.* 1875, 178, 112; Ber. 1893, 26, 229).

(2) The esters of certain dicarboxylic acids undergo intramolecular condensation when acted on by sodium:

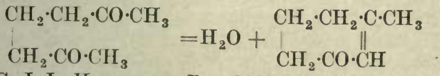


(Dieckmann, Ber. 1894, 27, 102).

(3) *Cyclo*hexanone and its derivatives may be obtained by the reduction of phenols. When

phenol vapour mixed with an excess of hydrogen is passed over reduced nickel at 215°–230°, *cyclo*hexanol and *cyclo*hexanone are obtained. The mixed product may be entirely converted into the latter compound by passing the vapour over copper heated to 330° (Sabatier and Senderens, Compt. rend. 1904, 137, 1025; 138, 457, 1257).

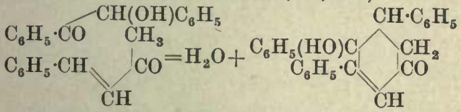
(4) 3-Methyl-Δ^2-*cyclo*hexenone is a product of the interaction of ethyl sodioacetoacetate and methylene iodide. Apparently the first formed 2 : 6-heptanedione undergoes intramolecular condensation:



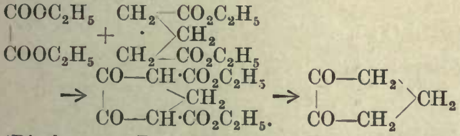
(C. J. L. Hagemann, Ber. 1893, 26, 876).

*iso*Butylidene *di*acetoacetic ester undergoes a similar internal condensation, giving an ester from which 3-methyl-5-*iso*propyl-Δ^2-*cyclo*-hexenone may be obtained (Knoevenagel, Annalen, 1896, 289, 131).

(5) Open chain ketones will condense with unsaturated aldehydes or unsaturated ketones of the type of benzalacetone. Thus the latter compound, condensed with benzoïn, gives 3 : 4 : 5-triphenyl-4-hydroxy-Δ^2-*cyclo*hexenone (Garner, Amer. Chem. J. 1904, 31, 143):

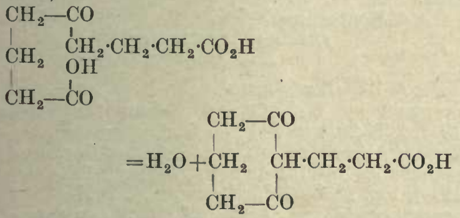


(6) Cyclic 1 : 2-diketones may be obtained by the condensation of diethyl glutarate and its derivatives with diethyl oxalate in presence of sodium ethoxide:

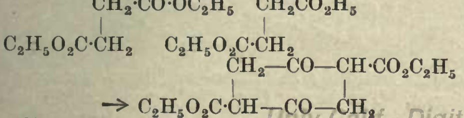


(Dieckmann, Ber. 1897, 30, 1470; 1899, 32, 1933; *cf.* papers by W. H. Perkin, jun., and co-workers, Chem. Soc. Trans. 1906, 89, 1640; 1908, 93, 1943; 1909, 95, 2010).

(7) A derivative of *cyclo*hexane-1 : 3-dione is obtained by dehydration of acetonedipropionic acid (v. Pechmann and Sidgwick, Ber. 1904, 37, 3816):



(8) Two molecules of diethyl succinate are condensed by Claisen's reaction (Herrmann, Annalen, 1882, 211, 311):



The resulting ester yields *cyclo*hexanedione (*vide infra*).

Individual Cyclic Ketones.

I. *Monocyclic Monoketones.*

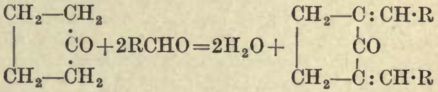
*cyclo***Pentanone** $CH_2<\begin{matrix}CH_2\cdot CO\\ CH_2\cdot CH_2\end{matrix}$ occurs in raw wood spirit, and may be obtained by the distillation of calcium adipate (J. Wislicenus and Hentzschel, Annalen, 1893, 275, 312, 318). The oil of wood spirit is distilled, and the fraction boiling at 120°–140° shaken with syrupy sodium bisulphite. The resulting crystalline bisulphite compound is well pressed, decomposed with warm saturated sodium carbonate solution, and the oil freed from pyridine bases by shaking with a saturated solution of oxalic acid. The compound obtained is identical with the 'Dumasin' obtained by Kane from acetone oil (J. pr. Chem. 1838, 13, 69).

Mobile oil smelling like peppermint; b.p. 130°–130·5°; sp.gr. 0·9416 at 21·5°/4°. *Oxime* $C_5H_8 : NOH$, m.p. 56·5°; b.p. 196°. Condenses with 2 molecules of aromatic aldehydes in presence of alkalis (Vorländer and Hobohm, Ber. 1896, 29, 1836):



Since the resulting compounds crystallise well, and ketones and aliphatic aldehydes do not react with *cyclo*pentanone, Mentzel recommends the reaction for the recognition of aromatic aldehydes (Ber. 1903, 36, 1499). Vorländer and Hobohm have shown that the 'pyroxanthin' obtained by Scanlan, Apjohn and Gregory (Annalen, 1837, 21, 143), by the action of alkalis on raw wood spirit is difural-*cyclo*pentanone.

Camphophorone $\begin{matrix}CH_2-C=C(CH_3)_2\\ |\qquad\qquad >CO\\ CH_2-CH-CH_3\end{matrix}$, first obtained by Gerhardt and Lies-Bodart (Annalen, 1849, 72, 293) by distillation of calcium camphorate, smells like peppermint; b.p. 200°–205°; sp.gr. 0·9305 at 20°/4°.

Pulegenone is isomeric with camphophorone, both compounds give 2-methyl-5-*iso*propyl*cyclo*pentanone (dihydrocamphorone, dihydropulegenone) on reduction. *Dihydrocamphorone*, b.p. 184°–185°; *oxime*, m.p. 77°–78°; *semicarbazone*, m.p. 193°–195° (Semmler, Ber. 1902, 35, 1022; Wallach, Annalen, 1903, 327, 125).

Dihydrocamphoketone $\begin{matrix}C(CH_3)_2-CH\cdot CH_3\\ |\qquad\qquad >CO\\ CH_2-CH\cdot CH_3\end{matrix}$, results on fusion of camphoric acid with potash (W. H. Perkin, jun., and A. W. Crossley, Chem. Soc. Trans. 1898, 73, 26). Smells like peppermint, b.p. 180°–181°; *semicarbazone*

$C_9H_{16} : N\cdot NH\cdot CO\cdot NH_2$,

m.p. 202°–203°.

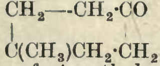
*cyclo***Hexanone** $\begin{matrix}CH_2\cdot CH_2\cdot CO\\ CH_2\cdot CH_2\cdot CH_2\end{matrix}$ occurs with other cyclic ketones in wood oil (Looft, Ber. 1894, 27, 1544); it may be obtained by distillation of calcium pimelate (*v.s.*); by the oxidation of synthetic *cyclo*hexanol (v. Baeyer, Ber. 1893,

26, 229; Annalen, 1894, 278, 88); or by the reduction of phenol by alternate current (Drechsel, J. pr. Chem. 1888, [ii.] 38, 65); or by reduction in presence of nickel (*v.s.*), the last method being used technically.

Mobile oil, somewhat soluble in water, smells like peppermint; b.p. 155·4°; sp.gr. 0·9471 at 22°/4°. Gives a bisulphite compound; condenses with 2 molecules of benzaldehyde (Vorländer and Hobohm, Ber. 1896, 29, 1840); yields a di*iso*nitroso derivative (W. Borsche, Festschrift Otto Wallach, 1909, 31).

Oxime $C_6H_{10}:NOH$, m.p. 88°; *phenylhydrazone* $C_6H_{10}:N\cdot NH\cdot C_6H_5$, m.p. 74°–77°.

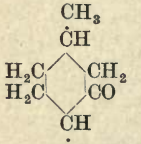


$\begin{array}{l} CH_2\text{—}CH_2\cdot CO \\ | \\ C(CH_3)CH_2\cdot CH_2 \end{array}$

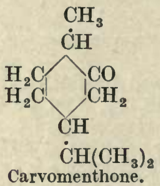
4-Methyl*cyclo*hexanone is obtained by the oxidation of 4-methyl*cyclo*hexanol with nitric acid. Oxidation of methylcyclohexanone with alkaline permanganate gives β-methyladipic acid, a compound which finds employment in the manufacture of dyes and pharmaceutical products (Farbenf. vorm. Fr. Bayer & Co., D. R. P. 221849).

Menthanones $C_{10}H_{18}O$. Ordinary menthone was first obtained in an inactive form by Moriya (Chem. Soc. Trans. 1881, 39, 77) by the oxidation of natural menthol; Atkinson and Yoshida obtained a strongly dextrorotatory variety (*ibid.* 1882, 41, 50). Beckmann has examined the stereochemistry of the menthones at length (Annalen, 1889, 250, 325; 1896, 289, 362; J. pr. Chem. 1897, [ii.] 55, 14).

Carvomenthone (tetrahydrocarvone) was discovered nearly simultaneously by v. Baeyer (Ber. 1893, 26, 822; 1895, 28, 1588; 1896, 29, 27) and Wallach (Annalen, 1893, 277, 133; 1895, 286, 102; 1899, 305, 266; 1900, 312, 302; Ber. 1895, 28, 1961). Ordinary menthone and carvomenthone can each exist in four stereoisomeric forms, their structures are given by:



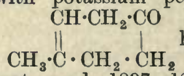
Ordinary menthone.



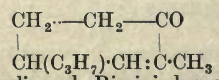
Carvomenthone.

Δ²-*cyclo*Hexenone C_6H_8O has been obtained from *cyclo*hexanone (A. Kötz and T. Grethe, J. pr. Chem. 1909, [ii.] 80, 473).

Methyl*cyclo*hexenone $CH_3\cdot C_6H_7O$. In addition to the compound synthesised from ethyl sodioacetoacetate by methylene iodide (Hagemann, Ber. 1893, 26, 876), and formaldehyde (Knoevenagel, *ibid.* 1090), an isomeride (m.p. 12°, b.p. 192°) has been discovered in wood tar. Since this gives acetic and lævulic acids on oxidation with potassium permanganate the constitution has been deduced (Béhal, Compt. rend. 1897, 125, 1036; 1901, 132, 342).

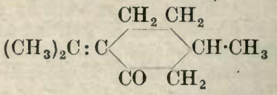


$\begin{array}{l} CH\cdot CH_2\cdot CO \\ \| \qquad\qquad | \\ CH_3\cdot C\cdot CH_2\cdot CH_2 \end{array}$



$\begin{array}{l} CH_2\text{—}CH_2\text{—}CO \\ | \qquad\qquad\qquad | \\ CH(C_3H_7)\cdot CH:C\cdot CH_3 \end{array}$

*iso***Camphor** was obtained by Angeli and Rimini by acting on camphoroxime with nitrous acid and decomposing the resultant nitrimine with ice-cold sulphuric acid (Gazz. chim. ital. 1896, ii. 26, 34).



Pulegone ($\Delta^{4(8)}$-3-menthenone) is the most important of the seven possible structurally different *p*-menthenones. (Each of these exhibits stereoisomerism.) Beckmann and Pleissner (Annalen, 1891, 262, 1) obtained pulegone from oil of pennyroyal (*Mentha Pulegium* [Linn.]) of which it constitutes about 80 p.c. It is also found in the ethereal oils of *Hedeoma pulegioides* (Pers.) and *Pycnanthemum lanceolatum* (Pursh.). It is isolated from oil of pennyroyal by fractional distillation and conversion into the sodium bisulphite derivative. The synthesis from citronellal has been effected by Tiemann and Schmidt (Ber. 1897, 30, 22); b.p. 221°–222°; sp.gr. 0·936: $[\alpha]_D +22{\cdot}89°$.

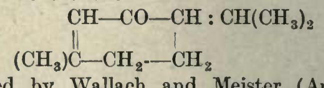
The crystalline hydrochloride $C_{10}H_{17}OCl$ (m.p. 24°–25°) and hydrobromide $C_{10}H_{17}OBr$ (m.p. 40·5°) give pulegone on treatment with alcoholic potash.

Semicarbazone $C_{10}H_{16}:N\cdot NH\cdot CO\cdot NH_2$, m.p. 172°; *oxime* $C_{10}H_{16}:NOH$, m.p. 118°–119°. Addition of hydroxylamine at the double linkage gives 8-*hydroxylaminomenthone* (m.p. 157°, $[\alpha]_D$ −83·44°) which may be successively oxidised to 8-*nitrosomenthone* (chromic acid) and 8-*nitromenthone*, m.p. 80° (nitric acid, sp.gr. 1·16) (Harries and Roeder, Ber. 1899, 32, 3364). The so-called pulegone dioxime, m.p. 118°, has the constitution (Semmler, Ber. 1905, 38, 147).

$(CH_3)_2C(NH\cdot OH)\cdot CH\left\langle\begin{array}{l} CH_2\cdot CH_2 \\ CO\cdot CH_2 \end{array}\right\rangle CH\cdot CH_3$

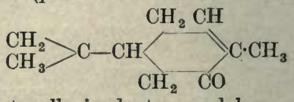
$(CH_3)_2C(NH\cdot OH)CH\left\langle\begin{array}{l} CH_2\text{——}CH_2 \\ C(:NOH)CH_2 \end{array}\right\rangle CH\cdot CH_3$

For the identification of pennyroyal, v. Baeyer and Henrich recommend conversion into the *bis*nitroso compound $(C_{10}H_{15}O_2N)_2$. 2 c.c. pulegone, 2 c.c. petroleum spirit, and 1 c.c. amyl nitrite are mixed, and very little concentrated hydrochloric acid added; the mixture becomes milky in 20–25 seconds, and solidifies to a paste of fine long needles of the nitroso compound. This compound cannot be recrystallised, it dissolves in cold ammonia with a yellow colour (Ber. 1895, 28, 654).



$\begin{array}{l} CH\text{—}CO\text{—}CH:CH(CH_3)_2 \\ \qquad \| \qquad\qquad\quad | \\ (CH_3)C\text{—}CH_2\text{—}CH_2 \end{array}$

Δ′-3-Menthenone prepared by Wallach and Meister (Annalen, 1908, 362, 261) from 1:3:4-trihydroxyterpane has been identified as a constituent of Japanese peppermint oil (Schimmel's Bericht, October, 1910), b.p. 235°–237°. *Oxime*, m.p. 107°–109°; *oxaminooxime*, m.p. 164°–165°; two *semicarbazones* α, m.p. 224°–226°; β, m.p. 171°–172°.



Carvone (p-$\Delta^{6,\,8(9)}$-menthadiene-2-one) occurs naturally in dextro- and lævo- rotatory forms. The former (b.p. 224°, sp.gr. 0·9598 at

20°/4° $[\alpha]_D +62{\cdot}07°$) occurs in the oils of carraway (*Carum Carvi* [Linn.]), fennel (*Fœniculum vulgare* (Mill.), and dill (*Peucedanum graveolens* [Benth. et Hook.]). The lævorotatory form (b.p. 223°–224°; sp.gr. 0·9593 at 20°/4°; $[\alpha]_D -62{\cdot}41°$) occurs in spear mint (*Mentha viridis* [Linn.]) and kuromoji (*Lindera sericea* [Blume]). The isolation of carvone from oils is effected by conversion into the compound with hydrogen sulphide $(C_{10}H_{14}O)_2H_2S$, and subsequent decomposition with alcoholic potash. When heated, carvone yields carvacrol $C_6H_3(OH)(CH_3)(i\text{-}C_3H_7)$. The active *carvoximes* melt at 72°, the inactive at 93°. Carvoxime was first obtained by Tilden by the action of alcoholic potash on limonene nitrosochloride (J. 1877, 428). *d*-α- and *d*-β-Limonene nitrosochlorides correspond to *l*-carvone, the *l*α- and *l*-β-nitrosochlorides to *d*-carvone, whilst α- and β-dipentene nitrosochlorides give the oxime of *r*-carvone (Wallach, Annalen, 1888, 245, 256; 246, 226; 1892, 270, 171).

Harries has described a method for preparation of the carvoximes (Meyer-Jacobson's Lehrbuch, 1902, II. 939).

Hydrochlorocarvoxime $C_{10}H_{15}Cl : NOH$ melts at 135° (*d*- or *l*-) or 125·5° (*r*-). The melting-points of the *hydrobromocarvoximes*

$$C_{10}H_{15}Br : NOH$$

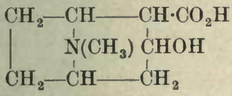
are 133°–134° (*d*- or *l*-) and 128°–129° (*r*-).

d-Carvone yields *m*- and *p*-nitrophenylhydrazones $C_{10}H_{14} : N{\cdot}NH{\cdot}C_6H_4{\cdot}NO_2$, which melt at 105°–106° and 174°–175° respectively (W. Borsche, Annalen, 1908, 359, 49).

Suberone $C_7H_{12}O$ (Preparation, General Method 1), smells like peppermint; b.p. (742 mm.) 178·5°, sp.gr. 0·9685 at 0°.

Oxime $C_7H_{12} : NOH$, m.p. 23·3°, b.p. 230°; *semicarbazone*, $C_7H_{12}:N{\cdot}NH{\cdot}CO{\cdot}NH_2$, m.p. 163°; *dibenzal derivative* $C_7H_8O(:CH{\cdot}C_6H_5)_2$, m.p. 107°–108°; *sulphonal* $C_7H_{12}(SO_2C_2H_5)_2$ (by the action of mercaptan in presence of hydrogen chloride and oxidation of the resultant mercaptol), m.p. 136°–139°. Suberone gives ζ-hydroxyœnanthoïc acid by oxidation with Caro's acid (v. Baeyer, Ber. 1900, 33, 862).

Willstätter obtained suberone as a degradation product of ecgonine :

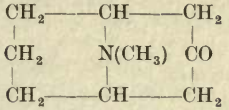


(Ber. 1898, 31, 2498).

Tropilene  CO, an oil of high refractive power and odour of bitter almonds, is difficultly soluble in water, and boils at 186°–188°. It is obtained from tropine by exhaustive methylation (Ladenburg, Ber. 1881, 14, 2403; Annalen, 1883, 217, 132, 138; Merling, Ber. 1891, 24, 3123); its constitution was correctly recognised by Willstätter (Ber. 1898, 31, 1545; 1901, 34, 133).

*cyclo***Octanone** $C_8H_{14}O$ was obtained by Mager (Annalen, 1893, 275, 363) by distilling the calcium salt of azelaïc acid, b.p. about 205°.

*pseudo***Pelletierine** or *methylgranatonine* is an alkaloid obtained from the pomegranate tree (*Punica Granatum* [Linn.]). Its constitution has been determined as:



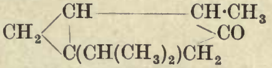
by Willstätter and Veraguth (Ber. 1905, 38, 1975, 1984).

II. *Bicyclic Monoketones.*

Of the numerous monoketones derived from bicyclic hydrocarbons only a few can be mentioned.

Thujone (Tanacetone) $C_{10}H_{16}O$ is known in stereoisomeric forms, it occurs in *Arbor vitæ* (*Thuya occidentalis* [Linn.]), tansy (*Tanacetum vulgare* [Linn.]), *Artemisia* and *Salvia*. α-Thujone predominates in thuja oil, $[\alpha]_D -10{\cdot}23°$; *oxime* $C_{10}H_{16} : NOH$, $[\alpha]_D -25{\cdot}25°$ in ethereal solution, *semicarbazone* $C_{10}H_{16} : N{\cdot}NH{\cdot}CO{\cdot}NH_2$ $[\alpha]_D +59{\cdot}9°$ in methyl alcoholic solution. β-Thujone is found in tansy oil $[\alpha]_D$ about +70°, *oxime*, m.p. 54°–55°, $[\alpha]_D +105{\cdot}1°$ in methyl alcoholic solution; *semicarbazone*, dimorphic, hexagonal, m.p. 174°–175°, rhombic, m.p. 170°–172°. Other derivatives *v.* Kijner, J. Russ. Phys. Chem. Soc. 1910, 42, 1198; 1911, 43, 577, 951, 1132.

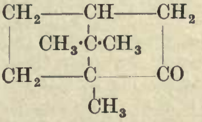
Artemisia oil seems to contain a third feebly dextro-rotatory thujone (Wallach, Annalen, 1893, 275, 179; 1894, 279, 383; 1895, 286, 90; 1904, 336, 247). Thujone probably possesses the structure :

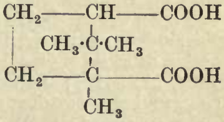


(Tschugaeff, Ber. 1900, 33, 3122; Semmler, *ibid.* 1900, 33, 275; 1903, 36, 4367; D. Thomson, Chem. Soc. Trans. 1910, 97, 1502).

Carone $C_{10}H_{16}O$, obtained by the action of alcoholic potash on the hydrobromide of dihydrocarvone, is also probably bicyclic (v. Baeyer, Ber. 1894, 27, 2715; 1895, 28, 639, 1586; 1896, 29, 3, 2796; 1898, 31, 1401, 2067).

Camphor $C_{10}H_{16}O$ (*q.v.*) occurs in the dextrorotatory form ($[\alpha]_D +44{\cdot}22°$ in 20 p.c. alcoholic solution) in *Cinnamomum Camphora* (Nees and Eberm.) and other plants, m.p. 178·4°, b.p. 209°. The lævo- form occurs in the oils of *Matricaria*, *Salvia*, and *Tanacetum*. Bredt gives the following formulæ for camphor and its oxidation product, camphoric acid (Ber. 1893, 26, 3047; Annalen, 1896, 292, 55):—

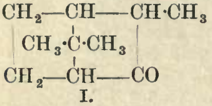




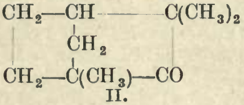
Camphor has been obtained by distillation of the lead (Haller) and calcium (Bredt and Rosenberg) salts of homo- camphoric acid; respecting the synthesis of camphoric acid see Kommpa (Ber. 1903, 36, 4332), Blanc and Thorpe (Chem. Soc. Trans. 1910, 97, 836), and Kommpa (Chem. Soc. Trans. 1911, 99, 29).

Fenchone $C_{10}H_{16}O$ occurs in nature as optical antipodes. The dextro-rotatory modification was found by Wallach and Hartmann (Annalen, 1890, 259, 324) in the portion of fennel oil boiling at 190°–195°, whilst *l*-fenchone is a constituent of the corresponding fraction of thuja oil. The two fenchones melt at 5°–6°, boil at 192°–193°; sp.gr. 0·9465 at 19°. *d*-Fenchone gives $[\alpha]_D + 71{\cdot}97^\circ$, the *l*-fenchone a slightly lower value (*see* also Bertram and Helle, J. pr. Chem. 1900, [ii.] 61, 293). Fenchone does not combine with sodium bisulphite; the *oximes* melt at 161°. Many derivatives have been prepared by Wallach; much *m*-cymene is produced on heating to 115°–130° with phosphorus pentoxide (Annalen, 1891, 263, 129; 1892, 269, 326; 1893, 272, 99; 1893, 275, 145; 1895, 284, 324; 1901, 315, 291).

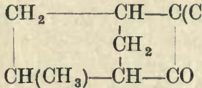
Of the following formulæ for fenchone:



I.



II.



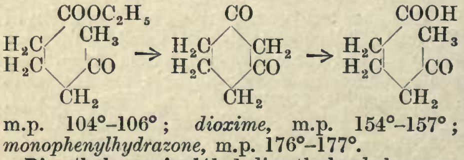
III.

the first was proposed by Wallach, the other two by Semmler (Ber. 1906, 39, 2577). L. Bouveault and F. Levallois prefer formula II. above (Semmler's first formula), and have brought forward considerable evidence in its favour (Compt. rend. 1908, 146, 180; 1909, 148, 1399, 1524; Bull. Soc. chim. 1910, [iv.] 7, 542, 683, 736, 807, 963, 968; Wallach, Annalen, 1911, 379, 182, 215).

III. *Monocyclic Diketones, &c.*

1 : 2-*cyclo*Pentanedione  $CH_2<\begin{array}{l}CH_2-CO\\ \quad\ |\\ CH_2-CO\end{array}$ (preparation, *v.s.*) is easily soluble in water, the solution reddens litmus, and is coloured violet by ferric chloride. In some respects it behaves as if one $\cdot CH_2\cdot CO\cdot$ group were enolised, giving a phenylurethane $C_5H_5O{\cdot}O{\cdot}CO{\cdot}NH{\cdot}C_6H_5$, m.p. 122°, and benzoyl ester $C_5H_5O{\cdot}O{\cdot}CO{\cdot}C_6H_5$, m.p. 72°–73°. As a 1 : 2-diketone it yields a *dioxime* $C_5H_6(:NOH)_2$, m.p. 210°; an *osazone* $C_5H_6(:N{\cdot}NH{\cdot}C_6H_5)_2$, m.p. 146°; and a *quinoxaline*  $CH_2<\begin{array}{l}CH_2-C=N\\ \qquad\ |\\ CH_2-C=N\end{array}>C_6H_4$, m.p. 102°–103°.

1 : 3-*cyclo*Hexanedione (Dihydroresorcinol) $C_6H_8O_2$ was obtained by Merling by the reduction of resorcinol in boiling alcoholic solution with sodium amalgam, carbon dioxide being led in during the operation (Annalen, 1894, 278, 28). Vorländer synthesised the diketone by the action of sodium on ethyl γ-acetobutyrate (Ber. 1895, 28, 3428); barium hydroxide breaks the ring, giving γ-acetobutyric acid:



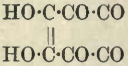
m.p. 104°–106°; *dioxime*, m.p. 154°–157°; *monophenylhydrazone*, m.p. 176°–177°.

Dimethylresorcinol (1 : 1-dimethyl*cyclo*-hexanedione-3 : 5 has been obtained by D. Vorländer (Annalen, 1898, 304, 15) and A. W. Crossley (Chem. Soc. Trans. 1899, 75, 771); the latter chemist has examined it exhaustively (*see* later papers).

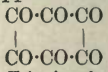
1 : 4-*cyclo*Hexanedione $C_6H_8O_2$ is obtained in small quantity by the dry distillation of calcium succinate (Feist, Ber. 1895, 28, 738). v. Baeyer (Annalen, 1894, 278, 91) obtains a good yield of the ketone in the following manner: 100 grams of diethyl diacetosuccinate are dissolved in 420 c.c. of concentrated sulphuric acid, the solution being meanwhile cooled and then poured on to ice (1450 grams). After addition of 40 c.c. of alcohol the mixture is boiled for 16 hours, the alcohol distilled off and the residue nearly neutralised with calcined sodium carbonate. The sodium sulphate is frozen out, the filtrate saturated with ammonium sulphate, and the diketone extracted with chloroform, m.p. 78°; *dioxime*, m.p. 192°; *dicyanhydrin*, m.p. 180°.

Phloroglucinol $C_6H_3(OH)_3$1 : 3 : 5 behaves tautomerically as *cyclo*hexanetrione, giving a *trioxime* $C_6H_6(:NOH)_3$, m.p. 155°.

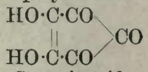
A few cyclic polyketones may be mentioned. The potassium carboxide $(KCO)_n$ prepared by Liebig (Annalen, 1834, 11, 182), and which forms a by-product in Brunner's method of manufacturing potassium (Brodie, Annalen, 1860, 113, 358), is the potassium derivative of hexahydroxybenzene (Nietzki and Benckiser, Ber. 1885, 18, 499; 1886, 19, 293, 772). Treatment with dilute alcohol gives rhodizonic acid $C_6H_2O_6$ (Heller, Annalen, 1837, 24, 1; 1840, 34, 232; 1862, 124, 32; Will, *ibid.* 1861, 118, 189). Rhodizonic acid, as well as hexahydroxybenzene, when oxidised, give triquinoyl $C_6H_{16}O_{14}$ or $C_6O_6{\cdot}8H_2O$. Alkalis convert rhodizonic acid into croconic acid $C_5H_2O_5$ (*see* Zincke, Ber. 1887, 20, 1267, footnote), and the latter compound can be oxidised to leuconic acid. All four compounds appear to be cyclic polyketones:



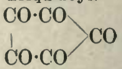
Rhodizonic acid.



Triquinoyl.



Croconic acid.



Leuconic acid.

IV. *Aromatic Cyclic Ketones.*

Only the briefest reference can be made to the cyclic ketones, in which both ends of the closed chain containing carbonyl groups are united to aromatic nuclei.

Hydrindene  $C_6H_4<\begin{array}{l}CH_2\\ CH_2\end{array}>CH_2$ gives rise to two hydrindones, two diketohydrindenes, and one triketohydrindene. The properties of these compounds are those to be expected of monoketones, α- and β-diketones and triketones respectively.

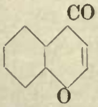
Fluorene ketone  $\begin{array}{l}C_6H_4\\ \ |\\ C_6H_4\end{array}>CO$ is obtained by the distillation of calcium diphenate with lime (Fittig and Ostermayer, Annalen, 1873, 166, 373); by oxidation of phenanthraquinone with alkaline permanganate (Anschütz and Japp, Ber. 1878, 11, 212); and by oxidation of fluorene alcohol. Yellow rhombic tablets, m.p. 83·5°–84°.

Pyrene ketone  $C_{10}H_6<\begin{array}{l}CH\\ \ |\\ CH\end{array}>CO$ was obtained by Bamberger and Philip by distillation of pyrenic acid $C_{15}H_8O_5$ with slaked lime, m.p. 83°, b.p. 235°–250° (Annalen, 1887, 240, 178).

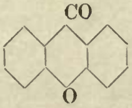
The ketonic properties of the carbonyl group are usually profoundly modified when it forms one of the members of a heterocyclic chain. This is observed in the following well-known examples :—

Pyridone.

Pyrone.



Chromone.



Xanthone.

Ketonic Acids and Esters.

Whilst a few ketonic acids (*e.g.* pyruvic and lævulic) are obtained by special reactions, these substances are generally obtained as esters by condensation of simpler esters or esters and ketones under the influence of sodium, sodium ethoxide, &c.

α-Ketonic Monobasic Acids.

Pyruvic acid (*Pyroracemic* or *Propanonic acid*) $CH_3{\cdot}CO{\cdot}CO_2H$ can be obtained by the distillation of tartaric or racemic acids (Berzelius, Pogg. Ann. 1835, 36, 1) ; of glyceric acid (Moldenhauer, Annalen, 1864, 131, 338) ; and from α-dichloro- or α-dibromopropionic acids or their esters by the action of moist silver oxide (Beckurts and Otto, Ber. 1877, 10, 264 ; 1885, 18, 228). Claisen and Shadwell hydrolysed acetyl cyanide with hydrochloric acid (Ber. 1878, 11, 620, 1563), and Beilstein and Wiegand oxidised calcium lactate with potassium permanganate (*ibid.* 1884, 17, 840) (*v.* Pyruvic acid).

Pyruvic acid is prepared by distilling 500 grams of tartaric acid and 780 grams of commercial potassium bisulphate from a copper retort of 2 litres capacity. The process is complete in 30 minutes, and a 60 p.c. yield is obtained after rectifying the product under reduced pressure, b.p. 59°–60° at 12 mm. (A. Wohl and R. Maag, Ber. 1910, 43, 2188).

The salts crystallise when prepared in the cold ; the solutions, if boiled, only yield gummy masses.

Pyruvic acid shows the reaction of a (methyl) ketone as well as an acid, *e.g.*

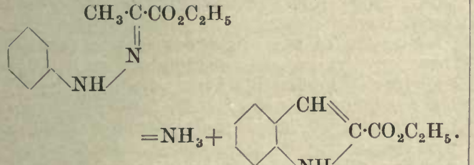
$$CH_3{\cdot}C(OH)(SO_3Na)CO_2H$$

and $CH_3{\cdot}C(OH)(SO_3Na)CO_2Na,H_2O$ are known.

Pyruvic acid phenylhydrazone

$$CH_3{\cdot}C(:N{\cdot}NH{\cdot}C_6H_5)CO_2H$$

forms shining needles, m.p. 192°. The *ethyl ester* $C_9H_9O_2N_2{\cdot}C_2H_5$, m.p. 116°–117°, when heated 3 or 4 minutes with its own weight of zinc chloride, yields ethyl indole carboxylate (E. Fischer, Annalen, 1886, 236, 142) :



Benzoylformic acid $C_6H_5{\cdot}CO{\cdot}CO_2H$ is obtained by the hydrolysis of benzoyl cyanide with hydrochloric acid (Claisen, Ber. 1877, 10, 845), m.p. 65°–66° ; easily soluble in water ; reduced by sodium amalgam to mandelic acid, and by hydriodic acid and amorphous phosphorus to α-toluic acid. *Phenylhydrazone*

$$C_6H_5{\cdot}C(:N{\cdot}NH{\cdot}C_6H_5)CO_2H,$$

m.p. 153° (with decomposition into carbon-dioxide and benzalphenylhydrazone).

β-Ketonic Monobasic Acids.

The β-ketonic acids are extremely unstable, decomposing very readily into carbon dioxide and a ketone :

$$R{\cdot}CO{\cdot}CH_2{\cdot}COOH = CO_2 + R{\cdot}CO{\cdot}CH_3.$$

Owing to the reactivity of the methylene group, the esters of these acids are valuable synthetic agents ; they are prepared by the action of sodium (sodium ethoxide, &c.) on esters or mixtures of esters and decomposition of the resultant sodium derivatives with dilute acetic acid :

$$R{\cdot}COOC_2H_5 + CH_3{\cdot}COOC_2H_5 + NaOC_2H_2$$
$$= 2C_2H_5OH + R{\cdot}C(ONa):CH{\cdot}COOC_2H_5.$$
$$R{\cdot}C(ONa):CH{\cdot}COOC_2H_5 + H{\cdot}C_2H_3O_2$$
$$= Na{\cdot}C_2H_3O_2 + R{\cdot}CO{\cdot}CH_2{\cdot}COOC_2H_5.$$

Ethyl acetoacetate $CH_3{\cdot}CO{\cdot}CH_2{\cdot}COOC_2H_5$ is obtained by the action of sodium on ethyl acetate (Geuther, J. 1863, 323 ; Zeitsch. Chem. 1866, 5 ; Wislicenus, Annalen, 1877, 186, 161 ; Matthews and Hodgkinson, Ber. 1882, 15, 2679) ; b.p. 180·6°–181·2° ; sp.gr. at 20°/4° 1·0256 (Brühl, Annalen, 1880, 203, 27) ; b.p. 71° at 12·52 mm. (Kahlbaum). Free acetoacetic acid is described by Ceresole as a thickish liquid, miscible with water, reacting strongly acid, and decomposing violently below 100° into carbon dioxide and acetone. Ceresole obtained the acid by allowing 4·5 parts of ethyl acetoacetate, 2·1 parts of caustic potash, and 80 parts of water to stand for 24 hours, then acidifying with sulphuric acid and extracting with ether (Ber. 1882, 15, 1327, 1872).

Ethyl acetoacetate reacts tautomerically as :

$$CH_3{\cdot}C(OH):CH{\cdot}CO_2C_2H_5 \text{ and } CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO_2C_2H_5.$$

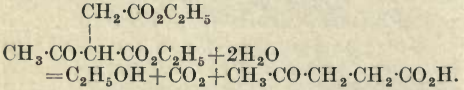
The question of this tautomerism has been much discussed, some of the papers bearing on this matter which have appeared since 1890 are as follows :—

J. U. Nef (Annalen, 1891, 266, 52 ; 1893, 276, 239) ; W. H. Perkin, sen. (Chem. Soc. Trans. 1892, 61, 800) ; J. W. Brühl (Ber. 1894, 27, 2378 ; J. pr. Chem. 1894, [ii.] 50, 119) ; L. Claisen (Annalen, 1893, 277, 162 ; Ber. 1892, 25, 1763) ; A. Michael (Amer. Chem. J. 1892, 14, 481 ; Ber. 1905, 38, 22 ; *cf.* H. Goldschmidt, *ibid.* 1096) ; A. Lapworth (Chem. Soc. Trans. 1902, 81, 1491, 1499 ; 1903, 83, 1114 : 1904, 85, 46) ; E. C. C. Baly and C. H. Desch (*ibid.* 1904, 85, 1029 ; 1905, 87, 766) ; R. S. Morrell (Chem. Soc. Proc. 1898, 14, 121 ; Chem. Soc. Trans. 1903, 83, 1292) ; R. Schenck and E. Ellenberger (Ber. 1904, 37, 3443) ; F. Giolitti (Gazz. chim. ital. 1904, 34, ii. 208) ; S. F. Acree (Amer. Chem. J. 1907, 37, 71) ; A. E. Dunstan and J. A. Stubbs (Chem. Soc. Trans. 1908, 93, 1919) ; A. Hantzsch (Ber. 1910, 43, 3049) ; Knorr (*ibid.* 1911, 44, 1138, 2767) ; Kurt Meyer (Annalen, 1911, 380, 212 ; Ber. 1911, 44, 2718, 2725, 2729).

In addition to the use of acetoacetic ester in the laboratory, it is employed in the preparation of pyrazolone derivatives, *e.g.* antipyrine and pyrazolone dyestuffs (*see* Farbenfab. vorm. Fr. Bayer & Co., Eng. Pat. 532 of 1910) (*v.* PYRAZOLONE).

γ-Ketonic Monobasic Acids.

Lævulic acid $CH_3\cdot CO\cdot CH_2\cdot CH_2\cdot CO_2H$ is obtained synthetically from diethyl acetosuccinate (b.p. 254°–256°, sp.gr. 1·08809 at 15°), produced from ethyl chloroacetate and the sodium derivative of ethyl acetoacetate by boiling with twice its volume of dilute hydrochloric acid (Conrad, Annalen, 1877, 188, 222):



$$\begin{array}{l} \quad CH_2\cdot CO_2C_2H_5 \\ \quad | \\ CH_3\cdot CO\cdot CH\cdot CO_2C_2H_5+2H_2O \\ \qquad =C_2H_5OH+CO_2+CH_3\cdot CO\cdot CH_2\cdot CH_2\cdot CO_2H. \end{array}$$

It is obtained from various carbohydrates by boiling with acids, *e.g.* lævulose, glucose, cane sugar, milk sugar, inulin (Tollens, Annalen, 1875, 175, 181; 1881, 206, 231; 1885, 227, 228); pine shavings, Carragheen moss and gum arabic (Bente, Ber. 1875, 8, 416, 1157). Conrad and Guthzeit (*ibid.* 1885, 18, 1442) recommend warming 20 grams of cane sugar with 50 grams of water containing 9·43 grams of hydrogen chloride for 17 hours on the water-bath. The liquid is filtered, evaporated on the water-bath, and extracted with ether; the ethereal extract is concentrated and distilled under reduced pressure.

W. A. van Ekenstein and J. J. Blanksma find the conversion of hexoses into lævulic acid takes place in two stages, hydroxyfurfuraldehyde which is first formed, giving lævulic and formic acids subsequently (Chem. Weekblad. 1910, 7, 387).

Lævulic acid has m.p. 33·5°, b.p. 250° (with slight decomposition); sp.gr. 1·135 at 15°. Easily soluble in water, alcohol, and ether. Reduced by sodium amalgam in alcoholic solution to γ-hydroxyvaleric acid. Yields iodoform with iodine and caustic soda in the cold and forms *oxime* and *phenylhydrazone*, m.p. 108°. The latter compound loses water above 160°, giving phenylmethylpyridazolone

The *methyl* and *ethyl esters* are liquid, and boil at 191°–191·5° (743 mm.) and 205·2° (corr. 756 mm.) respectively.

Lævulic acid is used in cotton printing.

A number of ε-ketonic acids have been prepared, starting with adipic acid (E. E. Blaise and A. Kochler, Bull. Soc. chim. 1910, [iv.] 7, 215).

Carboxylic acids of cyclic ketones are also known, *e.g. cyclo*hexanone-2-carboxylic acid, and *l*-methyl*cyclo*hexane-2-one-3-carboxylic acid (H. D. Gardner, W. H. Perkin, jun., and H. Watson, Chem. Soc. Trans. 1910, 97, 1756).

Dibasic Ketonic Acids.

Mesoxalic acid (dihydroxymalonic acid) $C(OH)_2(COOH)_2$ or $CO(COOH)_2,H_2O$ was obtained by Liebig and Wöhler by the hydrolysis of alloxan (Annalen, 1838, 26, 298); from aminomalonic acid by Baeyer (*ibid.* 1864, 131, 298) and from dibromomalonic acid by Petriew (J. Russ. Phys. Chem. Soc. 1878, 10, 72). M. Conrad and C. Brückner (Ber. 1891, 24, 2993) obtained the diethyl ester (m.p. 57°) by the action of bromine on diethyl acetyltartronate $CH_3CO\cdot O\cdot CH(CO_2C_2H_5)_2$, whilst H. Filippo, jun., obtained a practically quantitative yield of the ester by the action of bromine on diethyl tartronate (Rec. trav. chim. 1910, [ii.] 14, 113).

Mesoxalic acid melts at 119°–120° (E. Fischer), is easily soluble in water, fairly so in alcohol and ether. The aqueous solution, when boiled, gradually decomposes into carbon dioxide and glyoxylic acid.

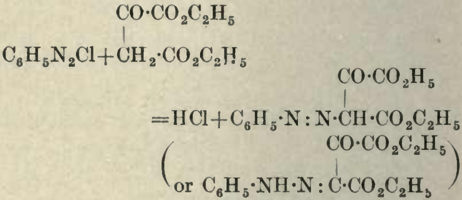
Diethyl oxalacetate

$$C_2H_5O_2C\cdot CO\cdot CH_2\cdot CO_2C_2H_5$$

is obtained by Claisen's method from diethyl oxalate and ethyl acetate, and by the action of concentrated sulphuric acid on diethyl acetonedicarboxylate. It is a colourless oil giving an intense dark red colouration with ferric chloride, and is sufficiently acid in character to be titrated with phenolphthaleïn as indicator (H. Gault, Compt. rend. 1910, 150, 1608; L. J. Simon, *ibid.* 1760).

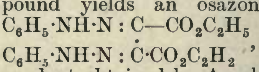
Hydrolysis with dilute sulphuric acid gives alcohol, carbon dioxide, and pyruvic acid (ketonic fission); with alkalis, salts of oxalic and acetic acids are produced.

The ester reacts with phenyldiazonium chloride, giving a product identical with the monophenylhydrazone of diethyl diketosuccinate (m.p. 72°–73°):



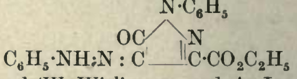
$$\begin{array}{l} \qquad\qquad CO\cdot CO_2C_2H_5 \\ \qquad\qquad | \\ C_6H_5N_2Cl+CH_2\cdot CO_2C_2H_5 \\ \qquad\qquad\qquad\qquad\qquad\qquad CO\cdot CO_2H_5 \\ \qquad\qquad\qquad\qquad\qquad\qquad | \\ \qquad\qquad =HCl+C_6H_5\cdot N:N\cdot CH\cdot CO_2C_2H_5 \\ \qquad\qquad \left(\begin{array}{r} CO\cdot CO_2C_2H_5 \\ | \\ \text{or } C_6H_5\cdot NH\cdot N:C\cdot CO_2C_2H_5 \end{array}\right) \end{array}$$

The action of phenylhydrazine on this compound yields an osazone (m.p. 119°–120°)



$$\begin{array}{l} C_6H_5\cdot NH\cdot N:C\text{—}CO_2C_2H_5 \\ C_6H_5\cdot NH\cdot N:C\cdot CO_2C_2H_2 \end{array}$$

, identical with the product obtained by Anschütz and Geldermann from phenylhydrazine and diethyl diketosuccinate (Annalen, 1891, 261, 130). When this osazone is boiled with three or four parts of glacial acetic acid, ethyl alcohol is eliminated, and ethyl phenylketopyrazolonephenylhydrazone carboxylate



is produced (W. Wislicenus and A. Jensen, Ber. 1892, 25, 3448). Orange needles, m.p. 152°–153°; also obtained by Anschütz and Parlato (*ibid.* 1892, 25, 1975).

The pyrazolone compound described is of tartrazine type, and it is evident that mixed tartrazines may be prepared from ethyl oxalacetate, using hydrazines and diazo compounds derived from different aromatic amines. The constitution of the original tartrazine derived from phenylhydrazine-*p*-sulphonic and dihydroxytartaric acids has been fully investigated by Anschütz (Annalen, 1897, 294, 219), who recognised definitely the existence of the pyrazolone ring in the dyestuff. In the preparation of this colouring matter from diethyl oxalacetate, 9·4 kilos. of the ester, 9·5 kilos. of phenylhydrazine sulphonic acid, and 7·5 kilos. of crystallised sodium acetate are stirred with 50 litres of water at 50° until complete solution is effected. The solution is cooled to ordinary temperature, 8–10 kilos. of calcined soda are added (reaction alkaline), and after completion of the pyrazolone condensation, the tartrazinogen ester sulphonic acid precipitated by dilute sulphuric acid, pressed and dried. After the hydrolysis with caustic soda, diazotised sulphanilic acid is added, and the tartrazine salted out when coupling is completed (B. A. S. F., Eng. Pats. 5693 of 1893 and 765 of 1897; *cp.* R. Grehm and L. Benda, Annalen, 1898, 299, 100, and Farbenfab. vorm. Fr. Bayer & Co., Eng. Pat. 532 of 1910).

Dihydroxytartaric acid (Diketosuccinic acid) $HO_2\cdot C\cdot C(OH)_2C(OH)_2\cdot CO_2H$ or

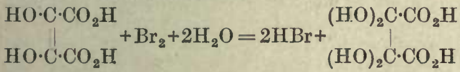
$$HO_2C\cdot CO\cdot CO\cdot CO_2H+2H_2O$$

was first obtained from protocatechuic acid (Gruber, Ber. 1879, 12, 514) and catechol (Barth, Monatsh. 1880, 1, 869) by the action of nitrous gases (N_2O_3). Kekulé obtained it from dinitrotartaric acid

$$HO_2\cdot C\cdot CH(O\cdot NO_2)\cdot CH(O\cdot NO_2)\cdot CO_2H$$

(Annalen, 1883, 221, 247). The dinitrotartaric acid is obtained by dissolving tartaric acid in 4½ parts of fuming nitric acid, shaking with an equal volume of concentrated sulphuric acid, and drying the precipitate on porous earthenware. This compound is then mixed with an equal amount of ether, some crude ethyl nitrite added, and the mixture allowed to stand for some days. On shaking with water and adding sodium carbonate, the nearly insoluble sodium dihydroxytartrate is precipitated.

H. J. H. Fenton and E. S. St. B. Sladen (Eng. Pat. 27032 of 1897) obtain the acid by adding to a mixture of 1 part of dihydroxymaleïc acid and 4 parts of glacial acetic acid, bromine and water drop by drop in quantities slightly greater than that required by the equation:



$$\begin{array}{l}HO\cdot C\cdot CO_2H\\ \quad|\\ HO\cdot C\cdot CO_2H\end{array}+Br_2+2H_2O=2HBr+\begin{array}{l}(HO)_2C\cdot CO_2H\\ \quad|\\ (HO)_2C\cdot CO_2H\end{array}$$

During the addition the mixture is well cooled.

Dihydroxytartaric acid generally reacts as diketosuccinic acid, and is very unstable; its employment in the production of tartrazines has already been mentioned.

Acetonedicarboxylic acid

$$HO_2C\cdot CH_2\cdot CO\cdot CH_2\cdot CO_2H$$

is obtained by heating citric and sulphuric acids on the water-bath until carbon dioxide begins to be evolved:

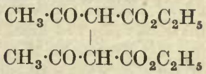
$$HO_2C\cdot CH_2\cdot C(OH)(CO_2H)CH_2\cdot CO_2H$$
$$=HO_2C\cdot CH_2\cdot CO\cdot CH_2\cdot CO_2H+H\cdot COOH(CO+H_2O).$$

The mixture is then diluted with water, and the acetonedicarboxylic acid extracted with ether (v. Pechmann, Ber. 1884, 17, 2543).

Heated with phenylhydrazine and hydrochloric acid in aqueous solution, methylphenylpyrazolone carboxylic acid is produced. The latter compound, when heated to 160°, and then distilled under reduced pressure, gives Knorr's phenylmethylpyrazolone (Ber. 1883, 16, 2597; Annalen, 1887, 238, 147; v. Pechmann and Jenisch, Ber. 1891, 24, 3252).

Acetonedicarboxylic acid is obtained crystalline from ethyl acetate; it decomposes on fusion into carbon dioxide and acetone, the same reaction occurring on boiling with water or warming with acids or alkalis. Ferric chloride gives a violet colouration.

Diethyl diacetosuccinate



$$\begin{array}{c}CH_3\cdot CO\cdot CH\cdot CO_2C_2H_5\\ |\\ CH_3\cdot CO\cdot CH\cdot CO_2C_2H_5\end{array}$$

is obtained by the action of iodine on the sodium derivative of ethyl acetoacetate (Rugheimer, Ber. 1874, 7, 892; Harrow, Annalen, 1880, 201, 144); rhombic tables, m.p. 78°. The free acid seems incapable of existence; when boiled with 20 p.c. sodium carbonate solution carbon dioxide escapes and acetonylacetone is produced. Like the latter compound, the ester readily condenses with ammonia, giving pyrrolderivatives.

Ethyl oxalyl-succinate, b. p. 170°–175°/12–13 mm. Blaise a. Gault. Bull. Soc. Chim. 1911, 9, 451, 458, 588. J. T. H.

KHAYA or **KAYA** *v.* Caïl-cedra.

KIDNEY IRON ORE *v.* Iron.

KIESELGUHR, *Diatomite*, *Diatomaceous earth*, *Infusorial earth*, or *Tripolite*. A white or greyish, pulverulent material of low sp.gr., consisting chiefly of the minute silicious shields of diatomaceæ. Large deposits of fossil diatoms have been traced in many parts of the world, but the chief amount of kieselguhr is obtained from Naterleuss, between Hamburg and Hanover. It is found there from the surface down to a depth of about 150 feet. The upper stratum supplies the white kieselguhr. It contains very little organic matter, but some sand; on washing, it gives a very pure and porous product. The second stratum produces grey kieselguhr, containing very little sand, but sufficient organic matter for calcining it. After calcination it forms kieselguhr of the highest quality. The lowest and by far the largest stratum, varying from 50 to 100 feet in thickness, supplies the green kieselguhr, which contains up to 30 p.c. of organic matter. When dry this material glows when heated like peat. It is calcined in small furnaces about 15 feet high and 6 feet wide; these are filled and lighted at the bottom, and no additional fuel is needed. The furnaces are continually replenished at the top, and the calcined product, which has a reddish colour due to ferric oxide, is taken out from the grates underneath.

Deposits of diatomite are found with peat at several places in Scotland (W. I. Macadam, Min. Mag. 1884, 6, 87; 1886, 7, 30, 35; 1889, 8, 135), and beds up to 40 feet in thickness are now being worked in the Isle of Skye. (On the kieselguhr of County Antrim, *see* J. H. Pollok, Sci. Proc. R. Dublin Soc. 1899, 9, 33.) Enormous deposits, sometimes as much as 1000 feet in thickness, are found at several places in the United States. The more compact, laminated variety known as tripolite is from Tripoli and from Bilin in Bohemia.

Kieselguhr varies much in composition, containing silica, 70–80 p.c.; water and organic matter, 10–20 p.c.; together with small amounts of alumina, ferric oxide, lime, &c. The silica is largely in the soluble form of opal (hydrated silica).

The high degree of porosity of the material makes it very valuable as an absorbent of nitroglycerin in the manufacture of dynamite. Its high non-conducting power makes it useful for the coating of steam boilers and pipes. It is used by safe makers, cooking stove and kitchener manufacturers, for making fireproof rooms, and for filling up bulkheads in steamships, &c. It has been made into fireproof bricks of low sp.gr. for the setting of steam boilers, the lining of blast furnaces and the hot-air pipes connected with them, and for the backs of fireplaces. It has also been suggested as an absorbent for bromine to be used for disinfecting purposes, and for sulphuric acid. What is termed ‘ dry sulphuric acid ’ is prepared by saturating calcined kieselguhr with three or four times its weight of sulphuric acid. The product, containing 75 p.c. of its weight of sulphuric acid, is said to retain the pulverulent form, and can be transported by land or sea in iron vessels without damage or breakage. Kieselguhr is used by manufacturers of ultramarine and by soap makers. A composition for preventing rot and fungus in buildings is made of it; it is also used for polishing metals, &c., and for the manufacture of imitation meerschaum.

KILLAS. A local name used by Cornish miners for the clay-slates of their country (*v.* SLATE).

KINETITE *v.* EXPLOSIVES.

KING’S BLUE, KING’S YELLOW, *v.* PIGMENTS.

KINO. Kino is the red, astringent, jelly-like juice obtained by incisions made in the trunks of several trees, and dried without the application of artificial heat. The variety originally introduced by Fothergill in 1757 (Med. Observ. and Inq. 1, 358) came from the river Gambia in tropical West Africa, where it was derived from the *Pterocarpus erinaceus* (Lam.). This *African* or *Gambia kino* was, however, soon replaced by other similar products from Jamaica, the East Indies, and Australia. *Jamaica, West Indian,* or *Caracas kino* is obtained from the *Coccoloba uvifera* (Linn.), a tree inhabiting Florida and the West Indian Islands. The only important kinos at the present day are, however, those which come from India and Australia. The *official, East Indian,* or *Malabar kino* is the product of the *Pterocarpus Marsupium* (Roxb.) (Corom. Pl. plate 116; Bentl. a. Trim. plate 81), a tree which attains a height of 40 to 80 feet, and occurs throughout Southern India and Ceylon. In the Madras Presidency it is one of the trees the felling of which is restricted by the Government. It affords valuable timber. The allied *P. indicus* (Willd.) was the source of the kino exported from Moulmein in Lower Burma. Another variety of Indian kino is that furnished by the *Butea frondosa* (Roxb.) and other allied species of *Butea*, and known as *Butea kino, Butea guru, Bengal kino, Palas* or *Pulas kino,* or *Dhak gum.* It closely resembles official kino, and is largely substituted for it in India. *Australian, Botany Bay,* or *Eucalyptus kino* is the product of numerous species of *Eucalyptus* (Mueller, Pharm. J. [iii.] 16, 898; Maiden, J. Soc. Chem. Ind. 1888, 38; Pharm. J. [iii.] 20, 221, 321). Eucalyptus kino is gradually becoming more important, and the better varieties are quite equal in all respects to the kino of Malabar (*cf.* Flück a. Hanb. 199).

The dried juices from the bark of several Asiatic species of *Myristica* show but little difference from official Malabar kino, but the crude inspissated fresh juice contains calcium tartrate suspended in and depositing from it, which serves to distinguish it from other kinos of commerce (Schaer, Pharm. J. [iv.] 3, 117).

Kino consists of small glistening, angular, brittle, garnet-like fragments, heavier than water, and transparent when in thin layers. When chewed it tastes astringent and colours the saliva blood-red. It is partly soluble in water, entirely soluble in rectified spirit, and almost insoluble in ether. The weak spirituous solution of kino used in medicine sometimes becomes gelatinous. Methods to obviate this have been much discussed (*v.* Indexes Ph.). Fused with potash it yields the trihydroxybenzene *phloroglucinol* (Hlasiwetz, Annalen, 134, 122), and the dihydroxybenzoic acid, *protocatechuic acid* (Stenhouse, *ibid.* 177, 187). When it is distilled alone, *o*-dihydroxybenzene or *catechol* is formed (Eisfeldt, *ibid.* 92, 101).

Treatment of Malabar, Butea, or Eucalyptus kino with ether extracts a small quantity of *catechol*, and perhaps in the case of Eucalyptus kino traces also of *catechin* (Eisfeldt, Annalen, 92, 101; Flückiger, Ber. 5, 1; Flück. a. Hanb.; Wiesner, Pharm. J. [iii.] 2, 102). When dilute mineral acids are added to an aqueous solution of kino, a bulky precipitate falls of a substance which has been described as *kinotannic acid.* This compound constitutes the greater part of kino, but it has not hitherto been isolated in a state of purity. It differs from other tannins in its behaviour towards reagents. It is sparingly soluble in water, soluble in alcohol, and insoluble in ether (*v.* Berzelius, Lehrbuch, 3 Aufl. 6, 258; Gerding, Arch. Pharm. [ii.] 65, 283; Hennig, *ibid.* 73, 129; 77, 260; 85, 150; Eisfeldt). By boiling kino with dilute hydrochloric acid (1 in 5), a crystalline compound, *kinoïn*, $C_{14}H_{12}O_6$, is extracted, which is taken up by ether from the acid solution and may be purified by recrystallisation from water (Etti, Ber. 11, 1879; 17, 2241; Flück. a. Hanb. 197). It forms colourless prisms which are sparingly soluble in cold, easily soluble in hot water, very soluble in alcohol, and less so in ether. With ferric chloride it gives a red colour. It does not precipitate gelatin solution. Heated with concentrated hydrochloric acid at 120°–130°, it breaks up into *methyl chloride, gallic acid,* and *catechol*, which indicates that kinoïn is probably *methylcatechol gallic ether*, $C_{14}H_{12}O_6$ or $C_6H_2(OH)_3CO\cdot OC_6H_4\cdot OMe$. Heated at 120°–130°, two molecules of kinoïn lose a molecule of water, and are converted into the anhydride *kino red* $C_{28}H_{22}O_{11}$, identical with that described by Gerding, and which is also obtained from the residue after extraction of the kinoïn from kino by treatment with dilute acid (Etti). Kino red is a resinous compound difficultly soluble in water, easily so in alcohol and in alkalis. Ferric chloride colours it dirty green. It gives a precipitate with gelatin solution. It melts at 160°–170°, losing a molecule of water, and forming the *anhydride*, $C_{28}H_{20}O_{10}$, a compound resembling kino red. Among the products of the dry distillation of kino red are *catechol* and *phenol* (*cf.* Catechu). A. S.

KINO RED, KINOÏN, KINOTANNIC ACID, *v.* Kino.

KIRSCHWASSER or **KIRSCH** is a strong spirituous liquor made by distillation of the fermented juice of ripe Morella or wild cherries. It is prepared chiefly in Germany (particularly in the Black Forest), in Switzerland, and in the Vosges district in France.

The cherries are crushed and the juice collected in vats, the kernels added and the whole allowed to ferment for about 5 days, when the liquor is drawn off and distilled by steam.

The strength of the spirit is usually about 50 p.c. alcohol by volume or approximately 10 under proof; and its peculiar taste and flavour are due largely to the presence of hydrocyanic (prussic) acid derived from the kernels of the cherry stones.

In properly made kirschwasser, the hydrocyanic acid does not exceed 0·015 gram per litre, but in crude varieties, made by prolonged fermentation of unripe or unsound fruit, and distilled over an open fire, it occasionally reaches almost poisonous proportions.

Kirschwasser is sometimes made from grain, grape, molasses, or other spirit flavoured with ‘essence of kirschwasser’ or with peach blossom, oil of bitter almonds or its substitute nitrobenzene. Traces of copper are frequently found as an impurity, due no doubt to the copper vessels used for distillation.

Genuine kirschwasser improves greatly by keeping, either in flasks or bottles with porous stoppers or in casks. The latter are made of ash in preference to oak, as the liquor should remain perfectly bright and colourless.

Various imitations of kirschwasser are made, the characteristic flavour being derived from the kernels of stone fruit, apricots, peach kernels or oil of bitter almonds. The following recipe (Spon's Encyclopædia) is one of the best: cherry seeds, 9 kilos; apricot seeds, 3 kilos; dried peach leaves, 625 grams; myrrh, 150 grams; alcohol at 85°, 62 litres. The seeds are bruised and digested with about 30 litres of water for 24 hours, and the whole distilled until about 60 litres have come over, when the distillate is reduced to about 50° alcohol. A little glycerin or sugar (not more than 15 grams per 100 litres) is usually added to soften the flavour.

Kirschwasser is occasionally heavily sweetened, when it greatly resembles ‘noyeau’ (*v.* Liqueurs and Cordials). J. C.

KISH. An ironworker's name for the masses of impure graphite which are occasionally found in blast furnaces, and which separate out from molten cast iron.

KLIACHITE *v.* Bauxite.

KOHLRABI. *Brassica oleracea* f. *caulo-rapa.* A plant of the cabbage tribe producing a great enlargement on the stem. This ‘bulb,’ which sometimes weighs as much as 12 or 15 lbs., is the valued portion of the crop, and furnishes an excellent substitute for swedes or turnips as food for cattle and sheep.

It is very hardy and more resistant to drought and frost than the turnip.

König gives as the average composition of the “bulb”—

Water	Protein	Fat	Sugar	Other *N*-free subst.	Crude fibre	Ash	Organic sulphur
86·9	2·9	0·2	0·4	7·8	1·7	1·2	0·06

Of the total nitrogen, from which the “protein” in the above analysis is calculated, only about 44 p.c. is present as true proteid, about 8 p.c. as amides, and the remainder in other forms of combination.

The leaves and stalks contain—

Water	Protein	Fat	Sugar	Other *N*-free subst.	Crude fibre	Ash	Organic sulphur
86·0	3·0	0·4	0·5	6·8	1·6	1·7	0·08

The ash contains—

	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl	
‘Bulb’	35·3	6·5	11·0	6·8	3·0	21·9	8·8	2·5	4·9	p.c.
Leaves	18·5	4·9	30·1	4·6	6·0	8·3	10·9	9·0	8·0	,,

H. I.

KOLA. Kola nuts, the fruit of *Cola acuminata,* (Schott and Endl.) are imported from the West Coast of Africa, and are made into a paste which contains about 2 p.c. of caffeïne, in addition to betaïne (Polstorff, Chem. Zentr. 1909, ii. 1014; *cf.* Desvignes, J. Pharm. Chim. 1910, 2, 20; Allard, *ibid.* 2, 122). According to Heckel and Schlagdenhauffen, the fruit of *Heritiera littoralis* (Dryand), a tree growing in India, in the Philippines, and Molucca, is often found mixed with kola nuts. This fruit belongs to the same family (*Sterculiaceæ*) as those which give the kola nuts, and is said to possess the same waste-repairing properties as the kola nut, although it contains no caffeïne. It is used as a foodstuff in India.

KORALLENERZ *v.* Cinnabar.

KOSIN or **KOUSSEIN RESIN** *v* Resins.

KOUMISS *v.* Milk.

KRANTZITE. A variety of retinite (*v.* Resins).

KREMS or **KREMSER WHITE, CREMNITZ WHITE,** *v.* Pigments.

KREOSAL, KREOTOSAL, KRESALOL, KRYOGENIN *v.* Synthetic drugs.

KREOSOL *v.* *Guaiacum,* art. Resins.

KRYOFINE. Trade name for phenetidine-methyl-glycollate $CH_3OCH_2CONH{\cdot}C_6H_4OC_2H_5$. Used as an antipyretic and anti-neuralgic. White crystalline needles, m.p. 98°, odourless and tasteless, sparingly soluble in water (*v.* Synthetic drugs).

KRYPTON. Sym. Kr. At.wt. 82·9 (Moore, Watson, *v. infra*).

An inert gas, discovered by Ramsay and Travers (Proc. Roy. Soc. 1898, 63, 405; British Assoc. Rep. 1898, 828) in the last portions of gas collected after evaporating considerable quantities of liquid air. When the latter is allowed to evaporate quietly in a vacuum vessel, the last traces of liquid consist almost entirely of oxygen, with small quantities of nitrogen, argon, krypton, and xenon. The liquid is allowed to evaporate, the gas is mixed with hydrogen and passed through a heated iron tube to remove oxygen. Nitrogen is absorbed by means of lime and magnesium (*cf.* ARGON), and after removing traces of hydrogen and carbon monoxide by means of heated copper oxide, the mixture of argon, krypton, and xenon is separated into its components by liquefaction and fractional evaporation. At the temperature of liquid air, krypton has a vapour pressure of 17 mm., whilst that of xenon is only 0·17 mm. (*v.* Travers, Study of Gases, 218; Ladenburg and Krügel, Sitzungber K. Preuss. Akad. Wiss. 1900, 212, 727; Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329; Moore, Chem. Soc. Trans. 1908, 93, 2181). The separation of a mixture of argon, krypton, and xenon has been effected by absorbing the gases in charcoal cooled in liquid air, allowing the temperature to rise slowly and collecting the evolved gas in fractions (Valentiner and Schmidt, Sitzungber. K. Akad. Wiss. Berlin, 1905, 38, 816).

The proportion of krypton in the atmosphere is about 1 part in twenty millions by volume (Ramsay, Proc. Roy. Soc. 1903, 71, 421; 1908, 80, A. 599). Krypton also occurs in the gases evolved from many thermal springs (Moureu and Lepape, Compt. rend. 1909, 149, 1171).

Krypton is a colourless, odourless, tasteless gas. It is only slightly soluble in water, the absorption coefficient at 20° being 0·0729 (Antropoff, Proc. Roy. Soc. 1910, 83, A. 474). One litre of the gas at N. T. P. weighs 3·708 grams; its density is therefore 41·506 (O=16) (Moore, Chem. Soc. Trans. 1908, 93, 2181; Watson, *ibid.* 1910, 97, 833). Krypton boils at −151·7° and melts at −169°; its critical temperature is −62·5°, and the critical pressure is 54·3 atmospheres. One cub. cm. of liquid krypton at its boiling-point weighs 2·155 grams; the molecular volume is 37·84 (Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329). At N. T. P. the refractive index of the gas for the green mercury line ($\lambda=5461$) is 1·0004287 (Cuthbertson and Cuthbertson, Proc. Roy. Soc. 1908, 81, A. 440; 1910, 84, A. 13). (For the viscosity of krypton, *v.* Rankine, *ibid.* 1910, 83, A, 516; for its spectrum, *v.* Baly, Phil. Trans. 1903, 202, A. 183; Liveing and Dewar, Proc. Roy. Soc. 1901, 68, 389.)

Krypton is completely inactive, no compounds of the element being known. The gas is monatomic, since the ratio of its specific heats is 1·66 (Ramsay and Travers).

KUNKUR. An argillaceous limestone used in India for the preparation of mortar. It forms an excellent hydraulic mortar (E. Nicholson, Chem. News, 32, 82).

KUNZITE. A transparent, violet, or lilac-coloured variety of the mineral spodumene, $LiAlSi_2O_6$ (*q.v.*), used as a gem-stone. It is found with pink tourmaline in the gem-mines of San Diego Co., California, and in Madagascar.

L. J. S.

KUS-KUS ROOT. The rhizome of *Andropogon squarrosus* (Linn.), a marsh plant of the Gramineæ, growing in India, the Philippines, &c., and cultivated in Jamaica; gives an ethereal oil, *oleum æther vetiveriæ*, used in perfumery.

KUTEERA GUM *v.* GUMS.

KYANISING. A process for preserving timber, due to Kyan, of New York, in which a solution of mercuric chloride is forced into the pores of the wood.

KYANITE or **CYANITE.** An aluminium silicate $Al_2O_3 \cdot SiO_2$ found in triclinic prisms; generally of a pale blue colour, sometimes white, or blue with white edges; also grey, green, and black. Occurs usually in gneiss or mica schist.

KYANOL. Runge's term for aniline.

KYNITE *v.* EXPLOSIVES.

L

LABDANUM or **LADANUM** *v.* OLEO-RESINS.

LABEL VARNISH *v.* VARNISH.

LABRADORITE *v.* FELSPAR.

LAC DYE. Lac dye is produced by an insect, the *Coccus lacca* or *ficus*, living on the twigs of various kinds of trees, particularly the *Ficus religiosa* (Linn.), the *Zizyphus Jujuba* (Lam.), and the *Butea frondosa* (Roxb.). These insects appear usually in November, and subsequently fasten themselves to the fleshy portions of the young branches. Gradually the abdomen of the insects becomes covered by a viscous fluid, which slowly forms a cellule surrounding the animal. The substance composing this cellule is the *stick lac.* The cellule attains its full size in March, and the insect then exhibits the appearance of a red oval-shaped, smoothly polished lifeless sack entirely filled with a beautifully red liquid; its size is then the same as the full-grown cochineal (Crookes, Dyeing and Calico Printing, 354). Commercial stick lac is chiefly gathered on the hilly banks of the Ganges in India, that for dyeing purposes possessing a deep red colour, whereas the pale perforated kind in which no insects exist is employed for varnish making, and constitutes the material for *shellac.*

Of *lac*, the following varieties occur: *stick lac*, the crude product together with the twigs upon which it is formed; *grained lac*, the material removed from the twigs; and *caked lac* the latter variety fused and cast into moulds.

Such a resinous material is not suitable for dyeing purposes, and a simple process is adopted to remove the colouring matter from the resin, or at least to obtain it in a more concentrated form. This consists in extracting stick lac with hot dilute sodium carbonate, evaporating the extract, and moulding the residue into square cakes. The product, which is *lac dye*, according to Crookes (*l.c.*) contains on an average about 50 p.c. of colouring matter, 25 p.c. of resin, and 22 p.c. of earthy impurities.

Lac dye is an extremely ancient dyestuff, and was employed by the East Indians for many centuries before it was known in Europe. It appears to have been introduced into this country about 1790. Early in the last century, lac dye was a very important article of commerce, so much so that at that time shellac was practically a bye-product of its manufacture. The position of these products has now been reversed, for whereas the dyestuff is almost defunct, the shellac industry is of considerable importance.

According to the older writers, the colouring matter of lac dye was considered to be identical with that of cochineal, but that this is not the case has been clearly indicated by Schmidt (Ber. 20, 1285).

Laccaic acid. Finely powdered lac dye, after treatment with dilute hydrochloric acid to remove mineral matter, is extracted with boiling water, and the colouring matter is precipitated from this solution by means of lead acetate. The lead precipitate suspended in water is decomposed with sulphuretted hydrogen, and the filtrate which contains the free colouring matter is evaporated to dryness. The residue thus obtained is extracted with alcohol and ether is then added to the solution until a precipitate no longer separates. The filtered liquid on gradual evaporation deposits crystals of laccaic acid. According to Schmidt, the amount of pure colouring matter which can be isolated by this method from a kilo. of lac dye is 20 grams.

Thus prepared, laccaic acid consists of a brownish-red crystalline powder, soluble in water with a blood-red colour, and insoluble in ether. When heated it decomposes at about 180°. Schmidt's analyses indicate $C=58{\cdot}00$, $H=41$ p.c., and correspond to the formula $C_{16}H_{12}O_8$. When heated with concentrated hydrochloric acid at 180°, *methyl chloride* and a red-brown amorphous substance, $C_{26}H_{16}O_{11}$, are produced. Dilute nitric acid at 160° gives *picric acid*, but no crystalline compounds resembling the α- and β-bromcarmines so readily prepared from carminic acid are produced from it by the action of bromine. On the other hand, although no distinction is to be observed in the absorption spectra of the aqueous and alkaline solutions of laccaic and carminic acids, it is possible when the colouring matters are dissolved in sulphuric acid to thus discriminate between them. When fused with potassium hydroxide, laccaic acid gives, in addition to a substance (*a*) volatile in steam, colourless needles, m.p. 142°–143°; a compound (*b*) $C_{10}H_6O_6$ or $C_{10}H_8O_6$, m.p. 285°, readily soluble in water; a compound (*c*) $C_8H_8O_3$, m.p. 169°, possibly a *hydroxytoluic acid*; and (*d*) an easily soluble substance, the aqueous solution of which gives with ferric chloride a black colouration.

Dyeing properties.—The dyeing properties of lac dye are practically identical with those of cochineal, although the shades obtained are somewhat faster. Owing to the resinous and mineral impurities accompanying the colouring matter, it is not readily dissolved by water, and before use it is therefore ground to a paste with the requisite quantity of tin spirit together with a little hydrochloric acid, and allowed to stand overnight. Cochineal and lac dye can be used together with advantage, or after the wool is dyed with lac it may be entered into a fresh bath with cochineal. Its employment at the present time is, however, extremely limited.

A. G. P.

LACMOID $C_{12}H_9NO_4$ (?)

Preparation.—(1) A mixture of resorcinol (20 parts), sodium nitrite (1 part), and water (1 part) is slowly heated to 110°, when a vigorous reaction sets in; the mass is then kept at 115°–120° until it has become quite blue and no more ammonia is evolved. The product is dissolved in water and the lacmoid precipitated with hydrochloric acid (Traub and Hock, Ber. 1884, 17, 2615). (2) By fusing resorcinol (5 parts) with potassium nitrite (6 parts) (Benedict and Julius, Monatsh. 1884, 5, 534). (3) By the action of H_2O_2 on ammoniacal resorcinol solution (Wurster, Ber. 1887, 20, 2938).

To purify the substance, extract it almost completely with boiling water, cool, filter, and acidify the blue solution with hydrochloric acid. Filter off the precipitated lacmoid, wash with cold water and dry it below 100°. An alternative method is to warm gently powdered lacmoid (8 parts) with 20 p.c. alcohol (100 parts) for 15 minutes, cool and filter (Foerster, Zeitsch. angew. Chem. 1890, 3, 163).

Properties.—A glistening brown powder, easily soluble in methyl, ethyl, or amyl alcohol, acetone, acetic acid, or phenol, less easily in ether or water, insoluble in benzene or petroleum spirit. It dissolves in concentrated HCl or H_2SO_4, yielding a blue solution. Heated below 200° it decomposes.

Lacmoid differs from the colouring matter of litmus in being soluble in strong alcohol. Its absorption spectrum resembles that of azolitmin (Hartley, Proc. Roy. Dublin Soc. 5, 159).

For the use of lacmoid as an indicator, *v.* Thomson (Chem. News, 1885, 52, 18, 29) and ACIDIMETRY AND ALKALIMETRY.

LACQUER (*Urushi, Ki-urushi*). A varnish obtained from the juice of *Rhus vernicifera* (DC.), a tree indigenous to China, whence in early times it was introduced into Japan (Bull. Imp. Inst. 1910, 8, 32; J. Soc. Chem. Ind. 1910, 639).

Chinese lacquer. The tree is abundant in Central China, growing wild or under cultivation at altitudes of 3000 to 7500 feet. It is tapped in June or early July; shallow incisions are made in the bark of the stem and the greyish-white, milky juice collected in shells, bamboos, &c., and covered with oiled paper to prevent oxidation. The tapping is repeated seven times at intervals of 7 days, and the tree is then left for 5–7 years to recover. Much of the varnish is sent to Japan. The lacquer is frequently adulterated with tung oil.

Japanese lacquer. The lacquer tree grows abundantly all over Japan, and is cultivated largely in the district north of Tokyo. Tapping takes place when the tree is 10 years old and is continued from June to October, each tree yielding from 27 to 54 grams of lacquer. Usually the tree is left to recover, but sometimes it is cut down. In the latter case, a further yield of lacquer is obtained from the branches by steeping them in water for 10–20 days, and then making incisions and heating the water to cause the sap to exude. The varnish thus obtained, called *seshine-urushi*, is harder and of poorer quality, and is used only for groundwork and for cheap articles. The best quality is obtained from between the inner and outer bark of trees from 14 to 15 years old. It is called *ki-urushi* (Pudor, Zeitsch. öffentl. Chem. 1910, 16, 315). A very inferior quality, known as *Moku-yshi*, is used mixed with the better kinds in varying proportions.

The raw varnish is packed in wooden tubs and covered with oiled paper to prevent oxidation. It is prepared for use by various processes, the quality and value of the varnish and of the lacquered ware produced depending upon the time and care spent upon the purification.

The juice is strained from particles of bark, &c., and is allowed to stand in wooden vessels until it separates into various layers, when the lighter and finer qualities are decanted from the heavier and inferior varnish. The product is finally filtered through hempen or cotton cloth and exposed in shallow wooden pans to the heat of the sun or to artificial warmth. It thus becomes syrupy and of a dark-brown colour, the change being due principally to loss of water. It is thinned with camphor or oil of turpentine or other suitable solvent.

Coloured lacquers are prepared from *ki-urushi* during the exposure to the sun (*v.s.*) by mixing in appropriate pigments, those most commonly employed being as follows (Miyama, J. Coll. Engineering, Imp. Univ. Tokyo, 1908, 4, 201; J. Soc. Chem. Ind. 1909, 318):—

White.—Barium sulphate; bismuth oxychloride.

Red.—Cinnabar; rouge.

Blue.—Prussian blue; ultramarine.

Yellow.—Cadmium sulphide; lead chromate; orpiment.

Green.—Chromic oxide (or by the addition of indigo from *Polygonum tinctorum* (Ait.) to the yellow lacquer).

Black.—Lampblack; iron powder or compounds of iron.

Brown.—Mixture of red and black.

The so-called 'pear-ground' lacquer, used with gold-dust, is prepared with gamboge.

Use of the lacquer.—The prepared surface of the article to be lacquered first receives several coats of the poorer quality mixed with a special clay called *ching-chu*, or in some cases with an inferior clay or with pottery dust. After each coat, the article is kept for several days in a moist atmosphere until the lacquer has set, and it is then rubbed down with pumice to a dull, smooth surface before another coat is given. The final coat is of the better quality lacquer, and the article may be further decorated with a pattern in coloured lacquer. Any joint in the wood is scraped down below the general level of the surface and then filled up with alternate layers of silk and lacquer.

Lacquering is applied to small articles, *e.g.* card-cases, vases, images, &c., either for ornamental purposes or for practical use. Hollow articles of lacquer are made by building up a layer of lacquer and silk on a clay model which is afterwards washed out with water through a hole left for that purpose. (For full details of the manufacture of lacquered ware, *see* Nightingale, J. Indust. and Engineering Chem. 1911, 3, 59; also Workshop Receipts, 3rd series, 306.)

The drying of lacquer at ordinary temperatures is caused by an enzyme (an oxydase) called *laccase*, contained in the sap (Tschirch and Stevens, Arch. Pharm. 1905, 243, 504; J. Soc. Chem. Ind. 1906, 81). During the drying it absorbs 5·75 p.c. of oxygen.

It may also be dried by heat, this process being specially applicable to lacquered articles of glass, porcelain, and papier-mache (Miyama, J. Soc. Chem. Ind. 1909, 318). At 100° it dries in 4–5 hours, at 150° in 30 minutes, and at 180° in 10 minutes. The drying by heat is attended by absorption of oxygen and some decomposition, giving a dark-coloured coating which is harder and more durable than the cold-dried lacquer. Coloured lacquers cannot usually be dried by heat because of the darkening of the lacquer. For a similar reason it is not the practice to use 'driers' in lacquers.

Composition of lacquer.—The main constituent of lacquer, to which its peculiar properties are due, is an unsaturated polyhydric phenol, *urushiol*, having the formula $C_{20}H_{28}O_2$ (Majima, Ber. 1909, 42, 3664).

Miyama gives the following analyses of typical specimens of the juice (J. Coll. Eng. Tokyo, 1908, 4, 89; J. Soc. Chem. Ind. 1908, 456):—

	Japanese	Chinese	Indian
Moisture .	17·81–27·62 p.c.	—	—
Urushiol .	64·14–77·63 ,,	36·88 p.c.	26·39 p.c.
Gum .	2·62–7·57 ,,	23·5 ,,	37·78 ,,
Nitrogenous matter .	1·78–2·47 ,,	—	—

Sun-dried Japanese lacquer contains 94·5 p.c. urushiol.

Urushiol forms a compound with barium hydroxide, and is estimated by titrating with a solution of that base, using phenolphthalein as indicator.

Urushiol may be obtained from lacquer by repeated extraction with alcohol, and is purified by treatment with petroleum spirit. It is a light-brown, viscous fluid, sp.gr. 0·9687 at 21·5°/4°, and is readily soluble in most organic solvents. It forms a dimethyl ether and an easily hydrolysable acetyl derivative. On dry distillation it yields various hydrocarbons and polyhydric phenols, but no simple alicyclic hydrocarbon or ordinary terpene (Majima and Cho, Ber. 1907, 40, 4390; Majima, *ibid.* 1909, 42, 1418, 3664). Tschirch and Stevens (*l.c.*) found in the lac an irritant poison, named by them *verniciferol.*

LAC RESIN *v.* Resins.

LACTANIN *v.* Synthetic drugs.

LACTARIC ACID $C_{14}H_{29}COOH$ is obtained by extracting the fungus *Agaricus integer* with alcohol (Chuit, Bull. Soc. chim. [iii.] 2, 153); m.p. 69·5°–70°.

LACTASE is the enzyme decomposing lactose (milk sugar) to dextrose and galactose. The distribution in animals is limited, being confined entirely to the intestine and generally of young animals only. Plimmer (J. physiol. 1906, 35, 20) found lactase in the cat and the pig during the whole of their lives, but only in the young guinea pig. The gastro-intestinal sac of snails contains a lactase (Bierry, Compt. rend. 1909, 148, 949). It is present in a few torula (*S. fragilis*, *S. kayser*, *S. adametz*, &c.) and in kephir. Lactose is also hydrolysed by the emulsin derived from almonds, which accordingly contains a lactase. There is apparently a difference between kephir and almond lactase, since the hydrolytic activity of the former is restricted mainly by galactose, that of the latter mainly by glucose (Armstrong, Proc. Roy. Soc. 1908, B, 80, 321). Lactase also hydrolyses β-methylgalactoside and melibiose. The optimum activity is about 37°. Lactase is precipitated by alcohol, and behaves very similarly to emulsin: its rate of action is governed by the same laws. It has not been fully investigated.

E. F. A.

LACTIC ACID or α-**HYDROXYPROPIONIC ACID** (Ger. *Milchsäure*) $CH_3CH(OH)COOH$ was first obtained by Scheele in 1780 from sour milk. Its exact constitution was, however, first ascertained by Liebig and Mitscherlich (Annalen, 7, 47) and by Gay-Lussac and Pelouze (*ibid.* 7, 40). It is widely distributed in nature, occurring in the lesser centaury (*Erythræa Centaurium* [Pers.]) (Habermann, Chem. Zeit. 30, 40); in the sap of the vine; and in most fermented liquids of vegetable origin, especially in sour milk; it is not, however, present in fresh milk. It is found in beet molasses, and owes its origin to the boiling of the sucrose solution with lime in the process of defecation (Schöne and Tollens, J. Soc. Chem. Ind. 1901, 54; Weisberg, *ibid.* 375; Beythien, Parcus and Tollens, Annalen, 255, 228). It has also been found in small quantities in saliva; in the brain and under certain conditions in the gastric juice; in the blood and in urine. The acid obtained by Braconnot, and termed *nanceic acid*, as well as the *thebolactic* acid obtained from opium, have been proved to be identical with common lactic acid. On the other hand, the acid obtained by Berzelius from flesh, and further investigated by Liebig, differs from the ordinary lactic acid in certain of its properties, and is therefore distinguished as *paralactic acid.* This will be described later on.

Lactic acid is formed in the fermentation of various sugars, of mannitol, and of dextrin (*v.* FERMENTATION), and also by the action of caustic alkalis on the sugars. It has also been obtained synthetically in a number of ways, the three most important of which are the following:—

(1) Aldehyde unites with hydrogen cyanide, forming the nitrile

$$CH_3{\cdot}CHO+HCN=CH_3{\cdot}CH(OH)CN,$$

and this on treatment with acids is converted into lactic acid (Wislicenus, Annalen, 128, 13, 22).

(2) By the action of alkalis on α-chloropropionic acid (Friedel and Machuca, Annalen, 120, 285)

$$CH_3{\cdot}CHCl{\cdot}COOH+2KOH \\ =CH_3{\cdot}CH(OH)COOH+KCl+H_2O.$$

(3) By the reduction of pyruvic acid with sodium amalgam, hydriodic acid (Wislicenus, Annalen, 126, 227), zinc (Debus, *ibid.* 127, 332), or electrolytically (Tafel and Friedrichs, Ber. 1904, 3187)

$$CH_3{\cdot}CO{\cdot}COOH+H_2=CH_3{\cdot}CH(OH)COOH.$$

These syntheses clearly show that the acid is α-hydroxypropionic acid.

In order to distinguish lactic acid from the allied acids it is frequently called *ethylidene-lactic* or *fermentation lactic acid.*

Preparation.—Lactic acid is usually prepared by the fermentation of sugar. McLauchan (J. Soc. Chem. Ind. 1909, 734) recommends the following method: 400 grams of commercial glucose are dissolved in 1200 c.c. of hot water, and to this is added 170 grams of whitening or well powdered calcium carbonate and 20 grams of malt, previously boiled for a few minutes with 100 c.c. of water. The solution is kept simmering for 30 minutes, then cooled to 60°–70°, and after stirring is poured into a narrow-necked bottle, of 2½ litres capacity. The calcium carbonate is rinsed out with water and the solution made up to 1800 c.c. The bottle is placed in an air-bath at 45°, a small quantity of sour milk or caseïn added to start fermentation, and a wad of cotton used to stopper the bottle. The bottle is shaken every few hours for 6 days and when the unfermented sugar is less than 0·4 p.c. the solution is filtered. The final filtrate after concentration should be one litre of 25 p.c. acid. Kassner (Chem. Zentr. 1897, ii. 20) dissolves 300 grams of cane sugar and 15 grams of tartaric acid in 1700 grams of boiling water and allows the solution to stand for several days, the temperature being maintained at 60°; 100 grams of old cheese and a little more than the calculated quantity of finely powdered chalk are then added and fermentation is allowed to proceed with daily stirring for about 3 weeks. Brensch (Annalen, 61, 177) proceeds in a similar manner, but during fermentation keeps the temperature at 30°–35°. Lautemann (*ibid.* 113, 142) replaces the chalk in the original mixture by 2 kilos. zinc white. After about 10 days a magma of zinc lactate together with some mannitol is formed, which may be recrystallised from water. The purified salt obtained by any of these methods is dissolved in boiling water, and precipitated with H_2S, the filtrate evaporated to a syrup, cooled, and separated from mannitol and any undecomposed salt by extraction with ether. The syrup which remains after evaporation of the ether is then warmed on the water-bath.

A large number of micro-organisms are capable of causing lactic fermentation of sugar, one of which has, however, a much greater intensity of action than the remainder, and is known therefore as *Bac. acid. lactici.* The solution must be kept neutral, and access of air must be allowed, as well as the necessary nitrogenous food. Its form in a highly nitrogenous saccharine solution, is a double truncated cone, and it has the tendency of all lactic bacteria to link itself together in pairs or short chains (Claflin, J. Soc. Chem. Ind. 1897, 516). (For further particulars of the micro-organisms, *v.* Andreasch, J. Soc. Chem. Ind. 1897, 53; Leichmann and Bazarewski, *ibid.* 1900, 698; Harden, Chem. Soc. Trans. 1901, 624; J. Soc. Chem. Ind. 1901, 921; Hashimoto, *ibid.* 1902, 506; Beijerinck, *ibid.* 1903, 106; Henneberg, *ibid.* 1904, 332; Buchner and Meisenheimer, Annalen, 349, 125; Wehmer, Chem. Zeit. 30, 1033; Heinemann, J. Biol. Chem. 1907, 2, 603.) Lactolase is an enzyme which causes the formation of lactic acid in plant cells (Stoklasa, Chem. Zentr. 1905, i. 265; 1907, i. 828). Malic, succinic, tartaric, and citric acids are all readily converted into lactic acid by certain moulds such as *Pencillium glaucum*, *Aspergillus niger*, and *Botrytis cinera* (Bied. Zentr. 1908, 37, 215).

For the preparation of the acid from sugar by the action of caustic alkalis, Kiliani (Ber. 1882, 699) recommends the following method. 500 grams cane sugar are mixed with 250 c.c. water, and 10 c.c. of the sulphuric acid employed later on, and warmed in a flask of 2 litres capacity to 50° for 2 hours. To the well-cooled solution 400 c.c. of caustic soda solution (1 part of caustic to 1 part water) are gradually added, the mixture being constantly cooled. The exact quantity of sulphuric acid necessary is then allowed to flow in; the acid is prepared by adding 3 parts H_2SO_4 to 4 parts water, and previously directly compared with the caustic soda solution by titration. A crystal of Glauber's salt is added to facilitate crystallisation, the whole being cooled and well shaken, and allowed to stand 24 hours. The mass is then extracted with 93 p.c. alcohol, filtered on the pump, and half the filtrate neutralised with $ZnCO_3$ on the water-bath, then mixed with the other portion, and the whole allowed to stand 36 hours. The separated zinc salt is filtered off, well pressed, recrystallised from water, and converted into the acid as before.

Just as lactic acid may be obtained by boiling hexoses and hexobioses with caustic alkalis, so it may be obtained from pentoses such as arabinose and xylose (Katsuyama, Ber. 1902, 669; Araki, Zeitsch. physiol. Chem. 19, 463) and from cane sugar and raffinose (Beythien, Parcus, and Tollens, Annalen, 255, 222). Meisenheimer (Ber. 1908, 1009) states that lactic acid is formed in small quantities when glucose, fructose, or galactose are allowed to stand in dilute sodium hydroxide for many months in the dark.

Manufacture.—There are three stages in the manufacture of lactic acid, the preparation of the saccharine solution, the fermentation process, and the conversion of the fermented liquid into commercial lactic acid. The saccharine solution, which should have a sp.gr. of about 1·075, *i.e.* a saccharine content of 7½–11 p.c., and which should be faintly alkaline or neutral but not acid, is sterilised either by boiling for an hour, or by blowing live steam into the solution for one hour at 95°. It is advantageous to have about 10–15 p.c. of the saccharine matter in the form of cane sugar and the remainder as glucose. After sterilisation, the liquid is conveyed to the fermentation tank, cooled to between 45° and 55°, and impregnated. Where continuous manufacture of lactic acid is carried on, impregnation takes place from a previously fermented liquor where a lively fermentation is in progress; for an original fermentation, milk, which has been kept until it is slightly sour, is used. For efficient working, the lactic acid ferment must be well nourished with nitrogenous matter, the most convenient sources being vegetable matter, *e.g.* as extracted from bran by the action of boiling water and dilute acid. If mineral food is employed, ammonium salts should be in excess of nitrates. As the fermentation proceeds, the temperature is allowed to decrease and the solution is neutralised with milk of lime or chalk in suspension, as the lactic acid bacteria are only healthy in solutions containing between 0·02 and 0·5 p.c. of acid: the fermentation is best completed in from 3 to 6 days. The fermented liquid, which contains calcium lactate with a layer of dead bacteria floating on it, is evaporated and filtered. For a commercial acid, decomposition of the syrupy solution of calcium lactate with sulphuric acid gives an acid of sufficient purity. If a pure acid is required, the solution of calcium lactate is set to crystallise; the solid crystals are pressed to remove mother liquor, and may be recrystallised if required (Claflin, J. Soc. Chem. Ind. 1897, 516; Dreher, *ibid.* 1898, 1070; McLauchan; *ibid.* 1907, 734; *cf.* Just, U.S. Pat. 868444; J. Soc. Chem. Ind. 1907, 1211; D. R. P. 203306; Chem. Zentr. 1908, ii. 1843). Various methods have been patented for the manufacture of lactic acid, differing mainly as to the source of the saccharine solution. Mislin and Lewin (Eng. Pat. 10436; Fr. Pat. 355520; J. Soc. Chem. Ind. 1905, 1248) place alternate layers of malt and rye in a suitable apparatus until saccharification of the starch is complete. The must is removed by pressure and fermented as in above method (*cf.* Brookes, Eng. Pat. 5780; J. Soc. Chem. Ind. 1885, 116; Avery, Pharm. J. Aug. 5, 1882). Jean and Bougard obtain lactic acid from powdered grain or oil-free cake (Fr. Pats. 315325, 315326, 321374; J. Soc. Chem. Ind. 1903, 225), and Claflin uses as the starting material a wort containing about 10 p.c. of fermentable material (U.S. Pat. 861163; J. Soc. Chem. Ind. 1907, 985). Boullanger acts on starch or sugar containing substances with a mould such as *Rumex acetosella*, and then proceeds as above (D. R. P. 118083; Chem. Zentr. 1901, i. 650).

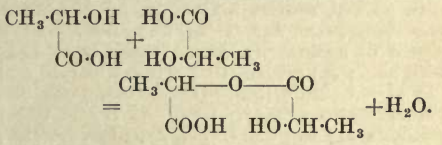
Boehringer states that calcium lactate and sulphuric acid form a paste which is very difficult to work up. The method recommended is to take 300 litres of calcium lactate solution (10° B.), obtained from fermentation process, and evaporated to 50 litres; 50 kilos. of a 50 p.c. solution of lactic acid is added and then the calcium lactate is decomposed by sulphuric acid. The solution of lactic acid thus obtained is 50 p.c. (Eng. Pat. 7094; Fr. Pat. 401395; D. R. P. 221112; J. Soc. Chem. Ind. 1909, 674).

Patents have been granted for processes to recover lactic acid from brewers' and distillers' slop and from the waste water of jam factories. One such method consists in neutralising the liquid with milk of lime, partly evaporating and causing the albuminoid substances to coagulate, filtering and allowing the calcium lactate to separate out from the filtrate (Beckers, D. R. P. 104281; Chem. Zentr. 1899, ii. 926; *v.* also Beckers, D. R. P. 113383; Chem. Zentr. 1900, ii. 702; Roehr, U.S. Pat. 823366; J. Soc. Chem. Ind. 1906, 901).

Several processes have been patented for the purification of the acid thus obtained. Waite (Eng. Pat. 13403; D. R. P. 140319; J. Soc. Chem. Ind. 1901, 931) washes the crude acid with amyl alcohol and distils off the solvent from the alcoholic solution of the acid, or washes this solution with water and concentrates the aqueous solution. Blumenthal and Chain (D. R. P. 169992; J. Soc. Chem. Ind. 1907, 279) mix the crude acid with aniline (150 parts 60 p.c. acid with 93 of aniline) and cool to —5°; the precipitate is recrystallised from a small quantity of water, decomposed with steam, and the acid concentrated *in vacuô*. Noerdlinger (Eng. Pat. 26415; Fr. Pat. 364468; D. R. P. 221786; U. S. Pat. 924494; J. Soc. Chem. Ind. 1908, 245) distils the crude acid in a current of inert gas. The water is first expelled and then pure lactic acid passes over. Erdmann (D. R. P. 217846; Chem. Zentr. 1910, i. 701) obtains pure lactic acid from copper lactate and water, heated at 150°–250°.

Properties.—The acid thus obtained forms a syrup of sp.gr. 1·21–1·24, and is soluble in all proportions in water and alcohol, less readily in ether. It is hygroscopic, colourless, and inodorous, but has a very sharp acid taste. The syrup is, however, not the pure acid, but a mixture of the latter with small quantities of water and the anhydride. The pure acid cannot be obtained by evaporation of the aqueous solution, as formation of the anhydride commences before all the water is driven off. Krafft and Dyës (Ber. 1895, 2589; Chem. Zentr. 1896, i. 742) have obtained lactic acid in the form of very hygroscopic white crystals, m.p. 18°, by the distillation of the commercial acid under reduced pressure. Lactic acid is slightly volatile at the ordinary temperatures, lactide is less volatile, and lactic anhydride practically non-volatile (Müller, Bull. Soc. chim. 1896, 15, 1206); lactic acid is volatile in steam, but not sufficiently volatile to be quantitatively separated from aqueous solutions by this means (Utz, Chem. Zeit. 1905, 29, 363). Lactic acid contains an asymmetric carbon atom, and hence can exist in two optically active modifications (*v. infra*). The fermentation lactic acid is optically inactive, but the acid obtained from the works is sometimes optically active. According to McKenzie (Chem. Soc. Trans. 1905, 1377), this is due to the fact that the action of the pure culture on sugar is to produce equal amounts of *d*- and *l*-isomerides. On converting these into the calcium salts and recrystallising, the crop of crystals which separate are mostly calcium *r*- salt, the active salt remaining in solution. If crystallisation takes place from a concentrated solution and the precipitate is not washed free from mother liquor, the acid obtained will be optically active. This would also be the case if the bacterial action had been such as to produce an excess of one isomeride (*cf.* Pottevin, J. Soc. Chem. Ind. 1899, 700). Wehmer recommends the use of *Oidium lactis* and two mycoderma to decompose lactic acid in liquids where its presence is not desirable (Chem. Zentr. 1903, i. 891). An aqueous solution of lactic acid decomposes in sunlight into acetaldehyde, pyruvic acid, carbon dioxide, and water (Ganassini, Boll. Chim. Farm. 48, 785). Oxidation of lactic acid with hydrogen peroxide yields pyruvic acid (Fenton and Jones, Chem. Soc. Trans. 1900, 71); with potassium permanganate, pyruvic acid (Aristoff, J. Russ. Phys. Chem. Soc. 1884, 2, 249), acetaldehyde and malic acid (Schoorl, Zeitsch. angew. Chem. 1900, 15, 367); with dilute sulphuric acid at 130°, or by heating alone at 440°–460°, acetaldehyde and formic acid (Nef, Annalen, 335, 296); with chromic acid, acetic acid, and carbon dioxide (Dossios, Zeitsch. Chem. 1866, 451; Chapman and Smith, *ibid.* 1867, 477.) Oxidation of the ammonium salt with hydrogen peroxide yields acetaldehyde, acetic acid, and carbon dioxide (Dakin, J. Biol. Chem. 4, 91). Reduction with hydriodic acid yields propionic acid. Electrolysis of the sodium salt results in the production of acetaldehyde and carbon dioxide (Walker, Chem. Soc. Trans. 1896, 1278; Ber. 1894, 467; Kolbe, Annalen, 113, 244). Phosphorus pentachloride converts lactic acid into α-chlorpropionic acid (Walden, Ber. 1895, 1293; Le Bel, *ibid.* 1895, 1923); bleaching powder converts it into chloroform and formic acid (Eberhard, Chem. Soc. Abstr. 1901, i. 357). Lactic acid reduces the nitrates of the heavy metals, *e.g.* bismuth, silver, mercury, cadmium, &c.; cobalt and nickel yield strongly magnetic powders (Vanino and Hauser, Zeitsch. anal. Chem. 1900, 29, 506). When the silver salt is treated with alkyl iodides, the hydrogen of the hydroxyl and carboxyl groups are both attacked (Purdie and Lander, Chem. Soc. Trans. 1898, 296, 300). For thermo-chemical data, *v.* Berthelot and Delépine, Compt. rend. 1899, 129, 920; dielectric constant, electrical conductivity, Drude, Zeitsch. physikal. Chem. 23, 349; Walden, *ibid.* 46, 103; 54, 129.

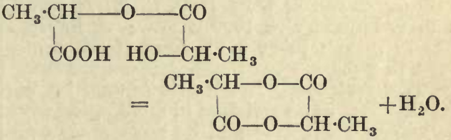
Lactic anhydride, which has been mentioned above, is formed by the elimination of a molecule of water from two molecules of the acid in the following manner, the one molecule acting as an alcohol and the other as an acid:—



$$\begin{array}{l}\mathrm{CH_3{\cdot}CH{\cdot}OH\quad HO{\cdot}CO}\\ \quad | \qquad\quad + \qquad\ | \\ \quad\mathrm{CO{\cdot}OH\quad HO{\cdot}CH{\cdot}CH_3}\end{array} = \begin{array}{l}\mathrm{CH_3{\cdot}CH—O—CO}\\ \quad | \qquad\qquad\ \ | \\ \mathrm{COOH\quad HO{\cdot}CH{\cdot}CH_3}\end{array} + \mathrm{H_2O}.$$

This compound, *lactic anhydride* or *lactolactic acid*, is at the same time an alcohol, an acid, and an ethereal salt. It is a light-yellow amorphous mass, easily soluble in alcohol and ether, insoluble in water, and is decomposed by alkalis, forming salts of lactic acid.

On further heating, another molecule of water is driven off, forming a second anhydride called lactide



$$\begin{array}{l}\mathrm{CH_3{\cdot}CH—O—CO}\\ \quad | \qquad\qquad\ \ | \\ \mathrm{COOH\quad HO—CH{\cdot}CH_3}\end{array} = \begin{array}{l}\mathrm{CH_3{\cdot}CH—O—CO}\\ \quad | \qquad\qquad\ \ | \\ \mathrm{CO—O—CH{\cdot}CH_3}\end{array} + \mathrm{H_2O}.$$

This substance, which is a double ethereal salt, is very slightly soluble in water, and forms white needles melting at 124·5° (Bischoff and Walden, Annalen, 279, 71; Nef, *ibid.* 335, 296; Raper, J. Physiol. 32, 216).

Detection and estimation.—On heating lactic acid with potassium chromate and sulphuric acid it is decomposed into formic acid and acetaldehyde. The mixture is distilled and vapours collected in Nessler's solution, giving a yellow precipitate or opalescence (Lassar-Cohn, Annalen, 284, 226; Windisch, J. Soc. Chem. Ind. 1887, 262). Thoms (Apoth. Zeit. 1907, 22, 206) recommends treating a few cc. of the liquid with 3 or 4 drops of 30 p.c. solution of chromic acid sufficient to impart a bright-yellow tint. In the presence of free lactic acid a reddish-brown colouration is produced on warming the solution on the water-bath for 10 minutes. Denigès (Ann. Chim. Phys. 18, [viii.] 191) treats the solution with bromine water, and then after the addition of acetic acid a red-violet colour is produced on adding sodium nitroprusside. Other methods, *v.* Denigès, Bull. Soc. chim. 1909, 5, 647; Croner and Cronheim, J. Soc. Chem. Ind. 1905, 1258; Herzog, Annalen, 1907, 351, 263. The following process has been recommended by Jean (Ann. Chim. Anal. Appl. 1900, 5, 285) for estimating the commercial acid. (i.) Total acidity is determined as H_2SO_4; (ii.) free acids by evaporating three times to dryness on the water-bath; (iii.) lactic acid by evaporating 10 c.c. to dryness several times, and dissolving the residue in water. The solution is heated to boiling, neutralised with barium carbonate, and then filtered and evaporated to dryness in a platinum dish. The residue is incinerated to carbonate, extracted with boiling water, collected on a filter, well washed, and dissolved in a known volume of decinormal hydrochloric acid. The solution is heated to remove the carbon dioxide, titrated with decinormal alkali, and the volume of N/10-hydrochloric acid neutralised by the carbonate formed by subtraction. This number of c.c. × 0·009 gives weight of lactic acid originally present. To estimate the amount of lactic acid and lactic anhydride present in a sample of lactic acid, the following process is used: (i.) dilute sample with water and titrate with normal sodium hydroxide, using phenolphthalein as an indicator; (ii.) add a known excess of sodium hydroxide and titrate back with acid; (i.) gives actual amount of acid and (ii.) of anhydride (Philip, Collegium, 1906, 88; Kunz, Chem. Zentr. 1901, i. 791). Other methods, *v.* Ulzer and Seidel, Monatsh. 18, 138; Paessler, Collegium, 1907, 388, 396. Estimation in wines, *v.* Kunz, Chem. Soc. Abstr. 1901, ii. 700; 1903, ii. 701; Sostegni and Prandi, Chem. Zentr. 1903, ii. 469; Müller, Bull. Soc. chim. 1896, 15, [iii.] 1203; Parthiel, Chem. Soc. Abstr. 1903, ii. 189; Arch. Pharm. 241, 401; Paris, Chem. Zentr. 1908, i. 773; Trummer, Chem. Zentr. 1908, ii. 101; Heiduschka and Quincke, Arch. Pharm. 245, 458. In milk, *v.* Thörner, Chem. Zeit. 16, 1469, 1519. In urine, *v.* Proc. Physiol. Soc. 1909, v.–vii.; J. Physiol. 39. In gastric juice, *v.* De Jong, Chem. Zentr. 1896, ii. 806.

Technical uses.—Lactic acid is used by the woollen dyer as an assistant in mordanting with potassium dichromate and its advantages over tartaric and oxalic acids are its greater reducing power, the greater solubility of itself and its salts, and the fact that it is less corrosive. It gives the wool a very fine, soft 'handle' and a beautiful lustre. *Lactolin,* which consists of equal parts of lactic acid and potassium lactate is stated to be superior to lactic acid, which is in itself superior to tartar (Claflin, *l.c.*; Norton and Tuttle, J. Soc. Chem. Ind. 1891, 362; Hoffmann, *ibid.* 1896, 196, 540; Dreher, *ibid.* 1896, 448; 1898, 1070; 1899, 491; Kielmeyer, *ibid.* 1899, 368; Kapff, *ibid.* 1900, 659; Fuchs, Chem. Zentr. 1897, i. 1183; Archer, J. Soc. Chem. Ind. 1897, 140; Düring, Bull. Soc. Ind. Mulhouse, 1902, [v.] 3; Paessler and Appelius, Collegium, 1903, 152, 153, 164, 169). Aniline lactate is used in producing aniline black on cotton (Goldovsky, Bull. Soc. Ind. Mulhouse, Jan. 9, 1900; Schener and Schoellkopf, *ibid.* 1901, 102; Düring, Chem. Zentr. 1905, i. 1515; D. R. P. 96600; J. Soc. Chem. Ind. 1899, 1119). The double lactate of calcium and antimony is used in mordanting cotton, and as a substitute for glycerin and tartaric acid in printing fabrics (Dreher, J. Soc. Chem. Ind. 1898, 919, 921). For methods of obtaining double lactates of antimony and calcium or of antimony and alkalis or alkaline earths, *v.* Moritz, Zeitsch. angew. Chem. 17, 1143; Akt. Ges. Revaler Chem. Fab. R. Mayer, D. R. P. 136135; Chem. Zentr. 1902, ii. 1286; Ch. Fab. von Heyden, D. R. P. 184202; Chem. Soc. Abstr. 1907, i. 888; Boehringer, D. R. P. 98939; Chem. Zentr. 1898, ii. 1231; Ch. Werke Schuster and Wilhelmj, D. R. PP. 216158, 217806; Chem. Zentr. 1909, ii. 1908; 1910, i. 701.

A solution containing the lactates of aluminium, calcium, and tin has been used instead of the above (Oswald, Bull. Soc. Ind. Mulhouse, 1900, 343), whilst Boehringer (D. R. P. 91230; Chem. Zentr. 1897, i. 1189) employs zinc lactate for the same purpose. Lactolin and sulphuric acid are used in hat dyeing (Düring, J. Soc. Chem. Ind. 1900, 660; 1901, 470) and lactic acid, free from traces of iron, is used as a discharge for Turkey red (Düring, *ibid.* 1900, 1013). It has also been used as a solvent for dyestuffs insoluble in water (Dreher, *ibid.* 1897, 1014; 1898, 919, 921).

Lactic acid is used in tanning for colouring, bating, and plumping. In preparing the skins it completely removes the lime, ensures a fine even grain, and does not dissolve the hide substance. It is easier to control than the bran drench, which is also used for this purpose, and which owes its efficiency to the lactic acid produced during the fermentation of the bran (Claflin, J. Soc. Chem. Ind. 1901, 210, 596, 730, 913; Paessler and Appelius, *ibid.* 1902, 1461, 57; 1903, 1201). It is also used in the preparation of yeast (Büchler, *ibid.* 1901, 376) and in the distillery, *e.g.* to check the bacterial development in the 'Hefengut' mash (Moritz, *ibid.* 1899, 778).

Lactic acid is also used for medicinal purposes in cases of laryngeal tuberculosis and of infantile diarrhœa. It dissolves false membrane and a solution of 1 part of acid in 6 parts of water is employed in the local treatment of diphtheria and croup. Local applications are used in stopping the growth of venereal worts and in treatment of tuberculous ulcers, lupus, and epithelioma. Calcium lactate is used in the treatment of rheumatism. For pharmaceutical purposes, the acid must be colourless and inodorous, and have a sp.gr. of at least 1·21, and should leave scarcely any residue on ignition. It should not be affected by NH_3 and $(NH_4)_2S$, and should give, at most, only a faint opalescence with $BaCl_2$, $AgNO_3$, $(NH_4)_2C_2O_4$, and should give no precipitate on boiling with Fehling's solution.

Esters. The esters of lactic acid may be prepared by treating a salt of lactic acid with sulphuric acid or gaseous hydrogen chloride and the corresponding alcohol. The product is distilled *in vacuô,* whereby the pure ester is obtained. By treating the pure ester with steam, distilling off the alcohol and concentrating, the pure acid is obtained (Ch. Fab. Güstrow, Hillringhaus and Heilmann, D. R. P. 171835; Chem. Zentr. 1906, ii. 470).

Methyl ester. Colourless liquid, b.p. 144·8°; sp.gr. 1·0898 at 19° (Schreiner, Annalen, 197, 12).

Ethyl ester. Colourless liquid, b.p. 154–5°; sp.gr. 1·0308 at 19° (Schreiner, *l.c.*; Friedel and Wurz, Ann. Chim. Phys. [iii.] 63, 102; Brüggen, Annalen, 148, 227).

Ethylidene ester. Prepared by heating acetaldehyde and lactic acid at 120°–170° for some hours: colourless liquid, b.p. 150°–151·5° (Leipen, Monatsh. 9, 45).

Glyceryl mono- and di-lactates (*v.* Kalle & Co. D. R. P. 216917; Chem. Zentr. 1910, i. 214).

Salts. The salts of lactic acid are all soluble in water, many so readily that they are very difficult to obtain crystalline. They are obtained by direct neutralisation of the free acid, or by double decomposition from the calcium salt.

The K, Na, NH_4 salts are very hygroscopic, and only the last two have been obtained crystalline (Wislicenus, Annalen, 125, 49; Engelhardt and Maddrell, *ibid.* 63, 88; Brüning, *ibid.* 104, 192).

Calcium lactate $(C_3H_5O_3)_2Ca,5H_2O$ is usually obtained direct from sugar in the preparations of lactic acid (*v. supra*). In small quantities it is sometimes prepared by neutralising lactic acid with chalk. It forms cauliflower-like aggregates of microscopic rhombic needles, which are soluble in 9·5 parts of cold, much more readily in hot water, and also soluble in alcohol. It loses its water of crystallisation at 100°, and at 250°–275° loses another molecule of water, forming *calcium dilactate* $(CH_3{\cdot}CH)_2{\cdot}O(CO_2)_2Ca$. The product is a vesicular mass, from which alcohol extracts some unaltered calcium lactate, and leaves the new compound behind as a very slightly soluble substance (Friedel and Würtz, Ann. Chim. Phys. [iii.] 63, 114).

Barium lactate $(C_3H_5O_3)_2Ba,4H_2O$ crystallises with great difficulty, forming cauliflower-like aggregates. It does not lose all its water of crystallisation at 100° (Meyer, Ber. 1886, 2454).

Magnesium lactate $(C_3H_5O_3)_2Mg,3H_2O$ is prepared by dissolving lactic acid syrup in 10 times its bulk of water, and neutralising with basic magnesium carbonate. The solution is evaporated until a skin forms, and then allowed to crystallise. It forms small light prismatic crystals, which frequently unite to form crusts. It dissolves in 28 parts of cold and 6 parts of hot water, forming a neutral very bitter solution. It loses its water of crystallisation at 100°.

Zinc lactate $(C_3H_5O_3)_2Zn,3H_2O$ is best obtained direct from sugar by neutralising the lactic acid produced with zinc carbonate or zinc white (Lautemann, Annalen, 113, 142; Kiliani, Ber. 1882, 659). It crystallises better than any other lactate, and forms colourless, well-developed, four-sided rhombic prisms. It loses its water of crystallisation *in vacuô* or at 100°. It dissolves in 53 parts of water at 15°, and in 6 parts at 100°, forming an acid, bitter-tasting solution. It is very slightly soluble in alcohol (Strecker, Annalen, 105, 316).

Ferrous lactate $(C_3H_5O_3)_2Fe,3H_2O$. This salt was introduced into pharmacy by Gélis and Conté in 1840, and was again recommended in 1847 by Engelhardt and Maddrell (*l.c.*). It is best prepared from crude calcium lactate in the following manner. The crude salt is recrystallised from water to which a little lime has been added, and if necessary the operation repeated. To the conc. aqueous solution of the purified salt the theoretical quantity of ferrous chloride is added, and the mixture allowed to stand for 3 days in a cool place. When no more crystals form the precipitated salt is filtered off, washed with a little alcohol, and dried at 50°.

Ferrous lactate forms greenish-white crusts of needles, or a similarly coloured crystalline powder. It dissolves at the ordinary temperature in 48 parts, and at 100° in 12 parts of water, forming an acid solution with a sweetish chalybeate taste. The solution becomes yellow, and then brown, in the air, ferric lactate being formed, and also undergoes alteration on evaporation in the air, leaving a hygroscopic residue containing ferrous and ferric lactates and some free acid. The dry salt is unaltered in the air, and loses its water of crystallisation when heated at 100° in a current of hydrogen.

Silver lactate $C_3H_5O_3Ag,\frac{1}{2}H_2O$ is prepared by treating freshly prepared lactic acid, after cooling, with silver oxide, evaporating the solution in the dark *in vacuô* at the ordinary temperature. It forms colourless needles, soluble in 20 parts of cold water, insoluble in cold, but readily soluble in hot alcohol. On heating the salt in the dark for 3 hours at 80°, anhydrous silver lactate is obtained (Klimenko, J. Russ. Chem. Soc. 12, 97; Berthelot and Delépine, Compt. rend. 129, 920).

Bismuth lactate $BiC_6H_9O_6,7H_2O$ is prepared by the slow dissolution of freshly precipitated bismuth hydroxide in lactic acid slightly diluted with water. The solution gradually deposits needles of the hydrated salt; on heating to 105° this yields the anhydrous salt, which is very sparingly soluble in water. The latter may be obtained by digesting freshly precipitated bismuth hydroxide in lactic acid at 100°. It forms rhombic tablets which decompose slightly when boiled with water for some time (Telle, Arch. Pharm. 1908, 246, 484).

Mercury lactates. *Mercurous lactate*

$$(C_3H_5O_3)_2Hg,HgO$$

is prepared by dissolving freshly precipitated mercurous oxide in dilute lactic acid, which has previously been heated with water to destroy the anhydride which it contains. The solution is allowed to evaporate in a desiccator over sulphuric acid, when the salt separates in short white prismatic needles. It is not completely soluble in water, hydrolysis occurring with the formation of a basic lactate, which then decomposes into mercuric lactate and mercury. *Mercuric lactate* $(C_3H_5O_3)_2Hg$, prepared in a similar manner from lactic acid and mercuric oxide, forms colourless prismatic needles, readily soluble in water. On boiling the aqueous solution, mercurous lactate, acetaldehyde, lactic acid, and carbon dioxide are produced (Guerbet, Bull. Soc. chim. 1902, 27, [iii.] 803).

Glucinium lactate (*v.* Tanatar and Kurowski, J. Russ. Phys. Chem. Soc. 39, 936; Glassmann, Ber. 1908, 33).

Cerous lactate (*v.* Morgan and Cahen, Pharm. J. 1907, 78, 428).

Optically active acids. As has already been stated, lactic acid can be resolved into two optically active components. This resolution has been effected by the fractional crystallisation of zinc ammonium lactate (Purdie and Walker, Chem. Soc. Trans. 1893, 1143; 1895, 616); of the strychnine salts (Purdie and Walker, *ibid.* 1892, 754); morphine salts (Irvine, *ibid.* 1906, 935); and of the quinine salts (Jungfleisch, Compt. rend. 1904, 139, 56, 203; 1905, 140, 719; 1906, 142, 515). Asymmetric syntheses have been made by the reduction of the *l*-menthyl (McKenzie, Chem. Soc. Trans. 1905, 1373), *l*-bornyl (McKenzie and Wren, *ibid.* 1906, 688), and *d*-amyl (McKenzie and Müller, *ibid.* 1909, 544) salts of pyruvic acid.

Paralactic acid (Sarcolactic acid, *d*-lactic acid) is present in flesh, in the blood, in muscles, in the thymus and thyroid and other animal organs (Berlinbauer, Chem. Zentr. 1888, 757; Salomon, Chem. Soc. Abstr. 1889, 64; Asker and Jackson, Zeit. Biol. 41, 393; Moscatelli, Zeitsch. physiol. Chem. 12, 416; Griffiths, Chem. News, 91, 147; Werther, Chem. Soc. Abstr. 1890, 348; Inouye and Kondo, Zeitsch. physiol. Chem. 54, 481; Frew, *ibid.* 60, 15; Moriya, *ibid.* 43, 397).

It is obtained from extract of meat by dissolving in 4 parts of warm water, adding 3 times the volume of 90 p.c. alcohol, and evaporating the filtrate to a syrup. This is again precipitated with alcohol, filtered, and evaporated, then acidified with H_2SO_4, and extracted with ether (Wislicenus, Annalen, 167, 302). The crude acid may be purified by conversion into the zinc salt. If *Penicillium glaucum* is allowed to grow in the solution of the inactive ammonium lactate, the *d*- modification alone will remain (Lewkowitsch, Ber. 1883, 2720; Linossier, Bull. Soc. chim. [iii.] 6, 10). *Micrococcus acidi paralacti*, an anaërobic micrococcus formed in the preparation of the *Rauschbrand bacillus*, is found to convert sugar into paralactic acid (Nencki and Sieber, Monatsh. 10, 532).

Paralactic acid is a syrup which can only be distinguished from lactic acid by the fact that it rotates the plane of polarisation to the right, whereas lactic acid is inactive. The salts strongly resemble the lactates, but are somewhat more soluble in water. The methyl ester boils at 143°–145° and has sp.gr. 1·1017 at 15°/16°; and the ethyl ester, b.p. 152°–154°, sp.gr. 1·0414 at 15°/16° (Frankland, Chem. Soc. Proc. 1895, 54). Further details as to rotatory power of acid and derivatives, *v.* Walker, Chem. Soc. Trans. 1895, 914; Purdie and Williamson, *ibid.* 1896, 827; Guye and Melikian, Compt. rend. 123, 1291; Henderson and Prentice, Chem. Soc. Trans. 1902, 658; 1903, 259; Wassmer and Guye, J. Phys. Chem. 1903, i. 257; Purdie and Irvine, Chem. Soc. Trans. 1899, 484; Walker, J. Phys. Chem. 13, 574.

l-**Lactic acid** has not been found in nature. It is prepared by the resolution of the inactive acid (*q.v.*); by the fermentation of sugar with *Bacillus acidi lævolacti* (Schardinger, Monatsh. 11, 545) or with a lævolactic ferment obtained from pears (Tate, Chem. Soc. Trans. 1893, 1263). It is similar in properties to *d*-lactic acid, with the exception that it rotates the plane of polarisation to the left.

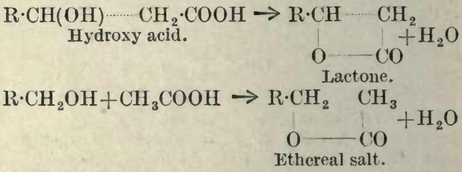
Besides these acids, another isomeric acid remains to be described. *Hydracrylic acid, ethylene-lactic acid* or *β-hydroxypropionic acid* $CH_2(OH)CH_2CO_2H$ is prepared by the action of moist silver oxide on β-iodopropionic acid (Sokolow, Annalen, 150, 167; Wislicenus, Annalen, 166, 10); by heating the sodium salt of acrylic acid with sodium hydroxide at 100° (Linnemann, Ber. 1875, 1095); and by the action of prussic acid on ethylene chlorhydrin and saponification of the resulting nitrile (Wislicenus, Annalen, 128, 1; 167, 346; Erlenmeyer, *ibid.* 191, 268). It forms a syrup which decomposes into water and acrylic acid on heating. Chromic acid oxidises it into oxalic acid and carbon dioxide, and silver oxide converts it into glycollic acid. Wislicenus also obtained from flesh, in addition to paralactic acid, an acid which he believed to be identical with this ethylene-lactic acid, but it has been shown (Siegfried, Ber. 1889, 2713) that this is in reality *acetyllactic acid.*

Atrolactinic acid (*αα-phenylhydroxypropionic acid*) $CH_3{\cdot}C(C_6H_5)OH{\cdot}CO_2H$. Prepared by the action of fuming hydrochloric acid on acetophenone hydrocyanide (Spiegel, Ber. 1881, 14, 1353; Tiemann and Köhler, *ibid.* 1980); colourless needles, m.p. (anhydrous) 93°–94°.

LACTIC FERMENTATION GUM *v.* GUMS.

LACTOLIN. Trade name for potassium di-lactate used as a mordant.

LACTONES. Generally speaking a lactone is formed by the elimination of water from a hydroxyl group and a carboxyl group present in the same molecule. They may therefore be regarded as internal salts corresponding with the external salts which are known as the ethereal salts or esters:



$$R{\cdot}CH(OH)\text{······}CH_2{\cdot}COOH \rightarrow \begin{array}{c} R{\cdot}CH\text{······}CH_2 \\ |\qquad\quad| \\ O\text{——}CO \end{array} + H_2O$$

$$R{\cdot}CH_2OH + CH_3COOH \rightarrow \begin{array}{c} R{\cdot}CH_2\quad CH_3 \\ |\qquad\quad| \\ O\text{——}CO \end{array} + H_2O$$

The lactones are therefore derived from that class of organic compounds known as the hydroxy acids. The hydroxy acids are divided into several series depending on the position of the hydroxyl group in respect to the carboxyl group and are named α-, β-, γ-, &c., hydroxy acids according as the hydroxyl group is in the α-, β-, γ-, &c., position in respect to the acid group, thus:

$R{\cdot}CH(OH){\cdot}COOH$
(α) — α-Hydroxy acid

$R{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$
(β) (α) — β-Hydroxy acid

$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}COOH$
(γ) (β) (α) — γ-Hydroxy acid

$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$
(δ) (γ) (β) (α) — δ-Hydroxy acid

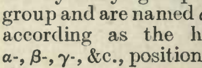
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$
(ε) (δ) (γ) (β) (α) — ε-Hydroxy acid

$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2COOH$
(ζ) (ε) (δ) (γ) (β) (α)—ζ-Hydroxy acid

The lactones derived from these acids are named accordingly α-, β-, γ-, &c., lactones and thus a γ-lactone would be constituted

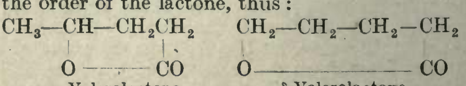
$$\begin{array}{c} R{\cdot}CH{\cdot}CH_2CH_2 \\ |\qquad\qquad| \\ O\text{——}CO \end{array}$$

and a δ-lactone would have the structure



$$\begin{array}{c} R{\cdot}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2. \\ |\qquad\qquad\qquad| \\ O\text{————}CO \end{array}$$

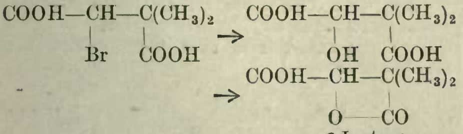
Nomenclature.—The name of the lactones is usually taken from the trivial name of the acid from which the corresponding hydroxy acid is derived, as for example, butyrolactone from γ-hydroxybutyric acid, valerolactone from γ-hydroxyvaleric acid. In those cases where the formation of two isomeric lactones is possible the prefix γ- or δ- is added to indicate the order of the lactone, thus:



$$\begin{array}{c} CH_3\text{—}CH\text{—}CH_2CH_2 \\ |\qquad\quad| \\ O\text{——}CO \end{array} \qquad \begin{array}{c} CH_2\text{—}CH_2\text{—}CH_2\text{—}CH_2 \\ |\qquad\qquad\qquad\qquad| \\ O\text{————————}CO \end{array}$$

γ-Valerolactone. δ-Valerolactone.

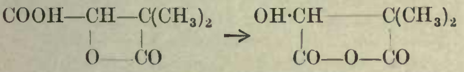
α-Lactones are not known, and in only a few exceptional cases has the formation of β-lactones been observed. Thus Baeyer and Villiger (Ber. 1897, 30, 1954; compare also Fichter and Hirsch, *ibid.* 1900, 33, 3273) have shown that when α-bromo-α′α′-dimethylsuccinic acid is treated with moist silver oxide the β-lactone of dimethylmalic acid is formed:



$$\underset{\mathrm{Br}\quad\ \mathrm{COOH}}{\mathrm{COOH{-}CH{-}C(CH_3)_2}} \rightarrow \underset{\mathrm{OH}\quad\ \mathrm{COOH}}{\mathrm{COOH{-}CH{-}C(CH_3)_2}} \rightarrow \underset{\mathrm{O}\ \text{——}\ \mathrm{CO}}{\mathrm{COOH{-}CH{-}C(CH_3)_2}}$$

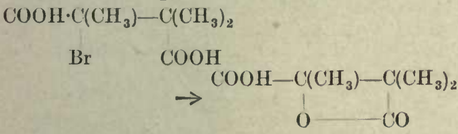
β-Lactone.

This compound crystallises in rhombic plates containing 1 mol. of water, and melts at 54°–55°; it loses this water of crystallisation at 45° in a vacuum. When distilled under diminished pressure it passes by rearrangement into the anhydride of αα-dimethylmalic acid



$$\underset{\mathrm{O}\ \text{—}\ \mathrm{CO}}{\mathrm{COOH{-}CH{-}C(CH_3)_2}} \rightarrow \underset{\mathrm{CO{-}O{-}CO}}{\mathrm{OH{\cdot}CH\ \text{——}\ C(CH_3)_2}}$$

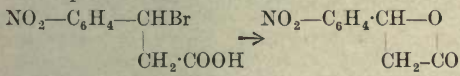
In the same way, trimethylbromosuccinic acid is converted into the β-lactone of trimethylmalic acid (Komppa, Ber. 1902, 35, 534)



$$\underset{\mathrm{Br}\qquad\quad \mathrm{COOH}}{\mathrm{COOH{\cdot}C(CH_3){-}C(CH_3)_2}} \rightarrow \underset{\mathrm{O}\ \text{———}\ \mathrm{CO}}{\mathrm{COOH{-}C(CH_3){-}C(CH_3)_2}}$$

The formation of a similar compound has been recorded by Meldrum (Chem. Soc. Trans. 1908, 93, 598) who finds that when acetone is condensed with malonic acid in the presence of acetic anhydride containing a little sulphuric acid, the β-lactone of β-hydroxy*iso*propylmalonic acid  $\underset{\mathrm{O{-}CO}}{\mathrm{(CH_3)_2C{-}CH{\cdot}COOH}}$ is formed. This substance crystallises from acetone in transparent four-sided plates melting at 97°.

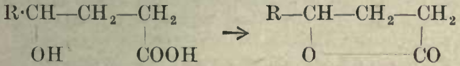
β-Lactone formation occurs in the aromatic series from β-hydroxy acids having a phenyl-group, in which strongly negative groups are present, attached to the β-carbon atom. Thus the lactones of *o*-, *m*-, and *p*-nitrophenyl-β-lactic acids are formed when the corresponding nitrophenyl-β-bromopropionic acids are treated with cold aqueous sodium carbonate



$$\underset{\mathrm{CH_2{\cdot}COOH}}{\mathrm{NO_2{-}C_6H_4{-}CHBr}} \rightarrow \underset{\mathrm{CH_2{-}CO}}{\mathrm{NO_2{-}C_6H_4{\cdot}CH{-}O}}$$

o-Nitrophenyllactic acid lactone readily passes into indigo when boiled with glacial acetic acid.

γ-Lactones. The remarkable tendency which exists for the formation of the five-membered ring causes the γ-hydroxy acids to be, usually, unstable at the ordinary temperature and to pass, with elimination of water, into the γ-lactone

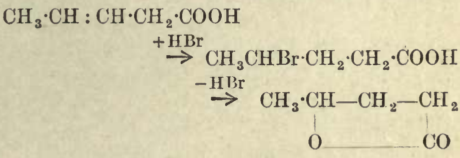


$$\underset{\mathrm{OH}\qquad\quad \mathrm{COOH}}{\mathrm{R{\cdot}CH{-}CH_2{-}CH_2}} \rightarrow \underset{\mathrm{O}\ \text{———}\ \mathrm{CO}}{\mathrm{R{-}CH{-}CH_2{-}CH_2}}$$

γ-Hydroxy acid. γ-Lactone.

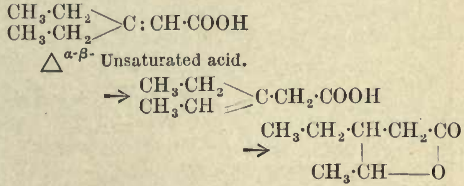
The tendency for the formation of the inner anhydride is so great that the change from the hydroxy acid to the lactone is usually effected by merely raising the temperature of an aqueous solution of the acid and in many cases the lactone exists in aqueous solution at the ordinary temperature. The simplest member of the class, butyrolactone  $\underset{\mathrm{O}\ \text{——}\ \mathrm{CO}}{\mathrm{CH_2{\cdot}CH_2{\cdot}CH_2}}$, was discovered by Saitzew in 1873, although certain naturally occurring lactones, such as coumarin and meconine (*q.v.*), were known before that time. (For a general description of the lactones, compare E. Hzelt, Ahrens' Samm. 1903, 8, 83.)

Formation.—The methods usually adopted for the preparation of γ-hydroxy acids, that is of the γ-lactones, may be briefly summarised as follows: (1) The transformation of the $\Delta^{\beta.\gamma.}$ unsaturated acids by the addition of halogen hydride and its subsequent elimination thus:



$$\mathrm{CH_3{\cdot}CH:CH{\cdot}CH_2{\cdot}COOH} \xrightarrow{+\mathrm{HBr}} \mathrm{CH_3CHBr{\cdot}CH_2{\cdot}CH_2{\cdot}COOH} \xrightarrow{-\mathrm{HBr}} \underset{\mathrm{O}\ \text{————}\ \mathrm{CO}}{\mathrm{CH_3{\cdot}CH{-}CH_2{-}CH_2}}$$

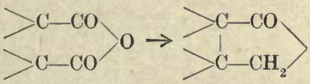
The $\Delta^{\beta.\gamma.}$ unsaturated acids are also transformed into the γ-lactones either by merely heating them alone or by warming them with a mixture of equal volumes of concentrated sulphuric acid and water at 140° (Fittig, Ber. 1894, 27 2667; Annalen, 1894, 283, 51). In the latter instance, the same change is shown by those $\Delta^{\alpha.\beta.}$ unsaturated acids which have two alkyl groups on the β-carbon atom. Thus Fichter, Kiefer, and Bernoulli (Ber. 1909, 42, 4710) find that when ββ-diethylacrylic acid is warmed for a short time with 60 p.c. aqueous sulphuric acid, it is converted into β-ethyl-γ-valerolactone



$$\begin{matrix}\mathrm{CH_3{\cdot}CH_2}\\ \mathrm{CH_3{\cdot}CH_2}\end{matrix}\!\!>\mathrm{C:CH{\cdot}COOH} \quad \Delta^{\alpha\text{-}\beta\text{-}}\ \text{Unsaturated acid.} \rightarrow \begin{matrix}\mathrm{CH_3{\cdot}CH_2}\\ \mathrm{CH_3{\cdot}CH}\end{matrix}\!\!>\mathrm{C{\cdot}CH_2{\cdot}COOH} \rightarrow \underset{\mathrm{CH_3{\cdot}CH}\ \text{——}\ \mathrm{O}}{\mathrm{CH_3{\cdot}CH_2{\cdot}CH{\cdot}CH_2{\cdot}CO}}$$

γ-Lactone.

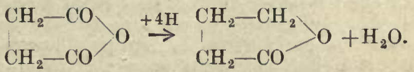
(2) The relation between the anhydrides of the dibasic acids and the γ-lactones, which is illustrated by the expression:



$$\begin{matrix}>\mathrm{C{-}CO}\\ >\mathrm{C{-}CO}\end{matrix}\!\!>\mathrm{O} \rightarrow \begin{matrix}>\mathrm{C{-}CO}\\ >\mathrm{C{-}CH_2}\end{matrix}\!\!>$$

Anhydride. γ-Lactone.

indicates that the last-named compounds can be derived from the anhydrides by reduction. Thus butyrolactone is formed when succinic anhydride is reduced by sodium amalgam (Fichter and Herbrand, Ber. 1896, 29, 1192):

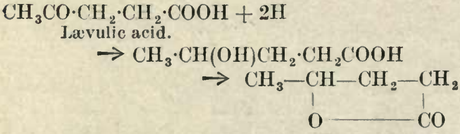


$$\begin{matrix}\mathrm{CH_2{-}CO}\\ \mathrm{CH_2{-}CO}\end{matrix}\!\!>\mathrm{O} \xrightarrow{+4\mathrm{H}} \begin{matrix}\mathrm{CH_2{-}CH_2}\\ \mathrm{CH_2{-}CO}\end{matrix}\!\!>\mathrm{O} + \mathrm{H_2O}.$$

Succinic anhydride. Butyrolactone.

(3) The sodium salts of γ-hydroxy acids are also formed when γ-ketonic acids, such as

lævulic acid, are reduced by sodium amalgam, thus:



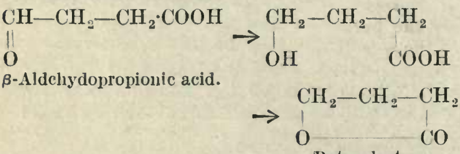
$$\underset{\text{Lævulic acid.}}{\mathrm{CH_3CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH}} + 2\mathrm{H}$$

$$\rightarrow \mathrm{CH_3{\cdot}CH(OH)CH_2{\cdot}CH_2COOH}$$

$$\rightarrow \begin{array}{ccccccc}\mathrm{CH_3}&—&\mathrm{CH}&—&\mathrm{CH_2}&—&\mathrm{CH_2}\\ &&|&&&&|\\ &&\mathrm{O}&—&—&—&\mathrm{CO}\end{array}$$

γ-Valerolactone.

In a similar manner, β-aldehydo acids, for example, β-aldehydopropionic acid, yield γ-lactones when reduced.



$$\begin{array}{l}\mathrm{CH—CH_2—CH_2{\cdot}COOH}\\ \|\\ \mathrm{O}\end{array} \rightarrow \begin{array}{ccccc}\mathrm{CH_2}&—&\mathrm{CH_2}&—&\mathrm{CH_2}\\ |&&&&|\\ \mathrm{OH}&&&&\mathrm{COOH}\end{array}$$

β-Aldehydopropionic acid.

$$\rightarrow \begin{array}{ccccc}\mathrm{CH_2}&—&\mathrm{CH_2}&—&\mathrm{CH_2}\\ |&&&&|\\ \mathrm{O}&—&—&—&\mathrm{CO}\end{array}$$

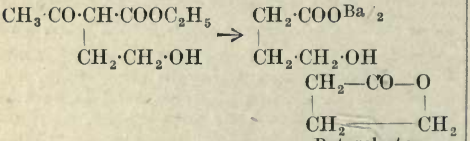
Butyrolactone.

(4) The alkyl salts of γ-hydroxy acids may be formed by the condensation of chlorhydrins of the type $\mathrm{CH_2Cl\,CH_2OH}$ with the sodium compounds of ethyl acetoacetate and its homologues, thus:

$$\mathrm{CH_3{\cdot}CO{\cdot}CHNa{\cdot}COOC_2H_5 + CH_2Cl{\cdot}CH_2OH}$$

$$\rightarrow \mathrm{CH_3{\cdot}CO\,CH(COOC_2H_5)CH_2{\cdot}CH_2OH + NaCl}$$

When this ethyl salt is hydrolysed with baryta, the acetyl group is eliminated and the barium salt of the hydroxy acid, which is then formed, is converted into the γ-lactone by the action of dilute mineral acids:

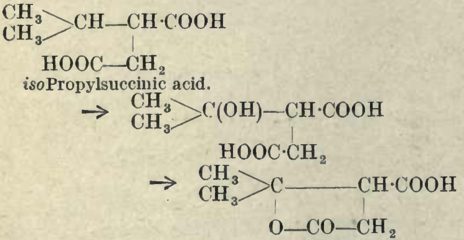


$$\begin{array}{l}\mathrm{CH_3{\cdot}CO{\cdot}CH{\cdot}COOC_2H_5}\\ \qquad\quad |\\ \qquad\mathrm{CH_2{\cdot}CH_2{\cdot}OH}\end{array} \rightarrow \begin{array}{l}\mathrm{CH_2{\cdot}COO^{Ba}/_2}\\ |\\ \mathrm{CH_2{\cdot}CH_2{\cdot}OH}\end{array}$$

$$\begin{array}{ccccc}\mathrm{CH_2}&—&\mathrm{CO}&—&\mathrm{O}\\ |&&&&|\\ \mathrm{CH_2}&—&—&—&\mathrm{CH_2}\end{array}$$

Butyrolactone.

(5) The formation of certain γ-lactones may also be effected by taking advantage of the fact that the tertiary hydrogen atom of the system $\begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3}\end{matrix}\!\!>\!\overset{*}{\mathrm{C}}\mathrm{H}—$ is readily oxidised to hydroxyl by alkaline permanganate. Thus *iso*propyl-succinic acid passes on oxidation into terebic acid (Lawrence, Chem. Soc. Trans. 1899, 75, 527).



$$\begin{array}{l}\begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3}\end{matrix}\!\!>\!\mathrm{CH—CH{\cdot}COOH}\\ \qquad\qquad\quad |\\ \qquad\mathrm{HOOC—CH_2}\end{array}$$

*iso*Propylsuccinic acid.

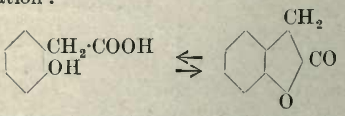
$$\rightarrow \begin{array}{l}\begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3}\end{matrix}\!\!>\!\mathrm{C(OH)—CH{\cdot}COOH}\\ \qquad\qquad\qquad\quad |\\ \qquad\quad\mathrm{HOOC{\cdot}CH_2}\end{array}$$

$$\rightarrow \begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3}\end{matrix}\!\!>\!\begin{array}{ccccc}\mathrm{C}&—&—&—&\mathrm{CH{\cdot}COOH}\\ |&&&&|\\ \mathrm{O}&—&\mathrm{CO}&—&\mathrm{CH_2}\end{array}$$

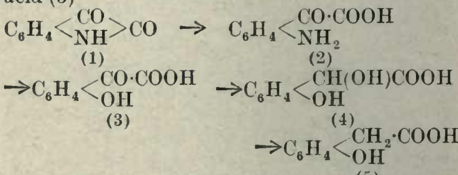
Terebic acid.

(6) The methods of formation of γ-lactones of the aromatic series are similar to those employed with aliphatic compounds, but for the sake of convenience the substances belonging to this class may be divided into three sections. (*a*) The γ-lactones which are derived from hydroxy acids having the hydroxyl group in the ortho- position in the benzene nucleus to a side chain bearing a carboxyl group. (*b*) The γ-lactones which are formed when both the hydroxyl and carboxyl groups are attached to the side chain. (*c*) The γ-lactones formed from compounds having the hydroxyl group in the side chain and the carboxyl group attached to the ortho- position in the benzene nucleus.

o-Hydroxyphenylacetic acid may be given as an illustration of compounds included under section (*a*). This acid, unlike the γ-hydroxy acids of the aliphatic series, can be isolated in the free state, but passes into the γ-lactone on distillation:



The lactone is again converted into the acid on shaking with water. The method employed for the preparation of *o*-hydroxyphenylacetic acid is as follows (Baeyer and Fritsch, Ber. 1884, 17, 973; compare also Stoermer, Annalen, 1900, 313, 83; Ber. 1901, 34, 1807). Isatin (1) is converted into *o*-aminobenzoylformic acid, (2) by the action of alkali, and this substance is then converted into *o*-hydroxybenzoylformic acid (3) by the aid of the diazo reaction. Reduction with sodium amalgam converts this compound into α-hydroxy-α-*o*-hydroxyphenylacetic acid, (4) which, on reduction with hydriodic acid, yields *o*-hydroxyphenylacetic acid (5)



$$\underset{(1)}{\mathrm{C_6H_4}\!<\!\begin{matrix}\mathrm{CO}\\ \mathrm{NH}\end{matrix}\!>\!\mathrm{CO}} \rightarrow \underset{(2)}{\mathrm{C_6H_4}\!<\!\begin{matrix}\mathrm{CO{\cdot}COOH}\\ \mathrm{NH_2}\end{matrix}}$$

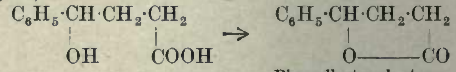
$$\rightarrow \underset{(3)}{\mathrm{C_6H_4}\!<\!\begin{matrix}\mathrm{CO{\cdot}COOH}\\ \mathrm{OH}\end{matrix}} \rightarrow \underset{(4)}{\mathrm{C_6H_4}\!<\!\begin{matrix}\mathrm{CH(OH)COOH}\\ \mathrm{OH}\end{matrix}}$$

$$\rightarrow \underset{(5)}{\mathrm{C_6H_4}\!<\!\begin{matrix}\mathrm{CH_2{\cdot}COOH}\\ \mathrm{OH}\end{matrix}}$$

Under section (*b*) may be given, as illustration, the example of γ-phenyl-γ-hydroxybutyric acid, $\mathrm{C_6H_5{\cdot}CH(OH)CH_2{\cdot}CH_2{\cdot}COOH}$, which can be produced by the reduction of β-benzoylpropionic acid

$$\mathrm{C_6H_5{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH},$$

and by other methods. Although this substance is more stable than the corresponding γ-hydroxy acids of the aliphatic series, and can be isolated in the free state, it nevertheless passes into the γ-lactone when heated above its melting-point (75°).

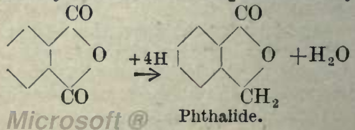


$$\begin{array}{ccc}\mathrm{C_6H_5{\cdot}CH}&\mathrm{{\cdot}CH_2{\cdot}}&\mathrm{CH_2}\\ |&&|\\ \mathrm{OH}&&\mathrm{COOH}\end{array} \rightarrow \begin{array}{ccc}\mathrm{C_6H_5{\cdot}CH}&\mathrm{{\cdot}CH_2{\cdot}}&\mathrm{CH_2}\\ |&&|\\ \mathrm{O}&—&\mathrm{CO}\end{array}$$

Phenylbutyrolactone.

The hydroxy acid may be recrystallised from warm water, but at 80° lactone formation slowly occurs, and when the acid is treated with very dilute hydrochloric acid the transformation into the lactone (m.p. 37°) is complete even at low temperatures.

The γ-lactones included under section (*c*) are known as the *phthalides*, a name which is derived from that of the first member of the series, phthalide. Phthalide itself may be conveniently prepared by the reduction of phthalic anhydride



Phthalide.

Other methods of preparation will be found under the head of *Meconine* (*q.v.*).

General properties of γ-lactones.—As already mentioned, the γ-hydroxy acids of the aliphatic series are, for the most part, unstable, and therefore cannot be isolated in the free state. The corresponding γ-lactone separates in almost every case when the aqueous solution of the salt of the acid is acidified even at low temperatures, and in only one or two instances has it been found possible to isolate the hydroxy acid in the free condition. Thus Fittig and Chanlarow (Annalen, 1884, 226, 325, 334) found that γ-hydroxybutyric acid as well as its ethyl derivatives are stable at very low temperatures. The lactones titrate as monobasic acids, and the salts of the corresponding hydroxy acids can usually be isolated in the crystalline condition; the silver salts, which are mostly well-defined crystalline substances, can be readily obtained by double decomposition from the potassium salt.

The γ-lactones derived from the monohydroxy-mono-carboxylic acids of the aliphatic series, and which therefore have the general formula $C_nH_{2n-2}O_2$, are neutral, colourless liquids or low-melting solids which are volatile with steam, and can be distilled without decomposition under ordinary atmospheric pressure. The lower members of the series are miscible with water in all proportions, but the solubility decreases with increase of molecular weight. The less soluble γ-lactones are frequently characterised by possessing the curious property of being varyingly soluble in water; thus when a concentrated solution of the lactone is warmed, the solution becomes cloudy owing to the partial separation of the dissolved substance; the emulsion again clears above 80°. When the γ-lactones are dissolved in water, a partial conversion into the hydroxy acid takes place, and a state of equilibrium between the two compounds is attained. Thus it has been found by P. Henry (Zeitsch. physikal. Chem. 1892, 10, 96) that a boiling 1 p.c. solution of butyrolactone contains 80 p.c. of the lactone and 20 p.c. of the hydroxy acid. γ-Lactones frequently react with halogen hydrides, yielding the γ-halogen derivatives of the acid, thus:

$$\begin{array}{l} CH_2{\cdot}CH_2{\cdot}CH_2 \\ \vert \qquad\qquad \vert \;\; +HBr \rightarrow CH_2Br{\cdot}CH_2{\cdot}CH_2{\cdot}COOH \\ O\text{———}CO \end{array}$$

but the breaking of the lactone ring in this manner is usually more easily effected by heating the compound with an alcoholic solution of the halogen hydride, whereby the corresponding ester is formed (Henry, Compt. rend. 1886, 102, 368; Cloves, Annalen, 1901, 319, 362). When treated with aqueous ammonia in the cold, the γ-lactones yield the amide of the hydroxy acid, thus:

$$\begin{array}{l} CH_2\text{—}CH_2\text{—}CH_2 \\ \vert \qquad\qquad\quad \vert \;\; +NH_3 \\ O\text{————}CO \\ \qquad\qquad \rightleftarrows CH_2OH{\cdot}CH_2{\cdot}CH_2{\cdot}CONH_2. \end{array}$$

These compounds readily split off ammonia and pass again into the lactone (Fittig and Rasch, Annalen, 1890, 256, 151; Fittig and Dubois, *ibid.* 1890, 256, 153). The γ-lactones react with hydrazine (Blanc and Luttringer, Bull. Soc. chim. 1905, [iii.] 33, 1095) also with potassium cyanide (Wislicenus, Annalen, 1886, 233, 113; Blanc, Bull. Soc. chim. 1905, [iii.] 33, 886, 904).

The more important γ-lactones of the formula $C_nH_{2n-2}O_2$ are:

Butyrolactone $\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}CH_2 \end{array}$ Preparation method (3): boils at 204° and solidifies at −42°. It has sp.gr. 1·129 at 16°.

Valerolactones. γ-*Methylbutyrolactone* (*n-valerolactone*) $\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}CH{\cdot}CH_3 \end{array}$ Preparation from lævulic acid method (3); occurs in pyroligneous acid (crude acetic acid from the distillation of wood). It boils at 206°–207°, solidifies at −31°, and has sp.gr. 1·072 at 0°. The reduction of lævulic acid to the lactone is very readily effected by hydrogen at 250° (method of Sabatier and Senderens).

α-*Methylbutyrolactone* $\begin{array}{l} CH_3{\cdot}CH\text{—}CO \\ \vert \qquad\qquad >O \\ CH_2\text{—}CH_2 \end{array}$ is a pungent-smelling oil, boiling at 200°–202°.

Caprolactones. γ-*Ethylbutyrolactone* (*n-caprolactone*) $\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}CH.C_2H_5 \end{array}$ boils at 220°. α-*Ethylbutyrolactone* $\begin{array}{l} C_2H_5{\cdot}CH\text{—}CO \\ \vert \qquad\qquad >O, \\ CH_2\text{—}CH_2 \end{array}$ boils at 215°. αα-*Dimethylbutyrolactone* $\begin{array}{l} (CH_3)_2C\text{—}CO \\ \vert \qquad\qquad >O \\ CH_2CH_2 \end{array}$ boils at 200°–201°. αγ-*Dimethylbutyrolactone* $\begin{array}{l} CH_3{\cdot}CH\text{—}CO \\ \vert \qquad\qquad >O \\ CH_2\text{—}CH{\cdot}CH_3, \end{array}$ boils at 206°. βγ-*Dimethylbutyrolactone* $\begin{array}{l} CH_2\text{———}CO \\ \vert \qquad\qquad\quad >O \\ CH(CH_3)\text{—}CH{\cdot}CH_3, \end{array}$ boils at 213°, and γγ-*Dimethylbutyrolactone* (*isocaprolactone*) $\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}C(CH_3)_2, \end{array}$ boils at 95° (20 mm.), and at 206°–207° under ordinary atmospheric pressure. It melts at +6° and dissolves in 20 parts of water at 0°.

Stearolactone (γ-*tetradecylbutyrolactone*)

$$\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}CH(CH_2)_{13}CH_3 \end{array}$$

is formed, in yield of 30–40 p.c., when oleic acid, elaïdic acid, or *iso*-oleic acid is warmed with zinc chloride or concentrated sulphuric acid at 80°–85°. It crystallises from alcohol as leaflets melting at 47°–48°.

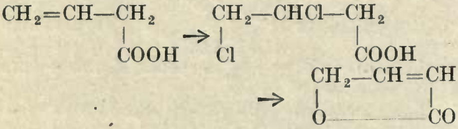
Behenolactone (γ-*octodecylbutyrolactone*)

$$\begin{array}{l} CH_2\text{—}CO \\ \vert \qquad\quad >O \\ CH_2\text{—}CH(CH_2)_{17}CH_3 \end{array}$$

which is formed from erucic acid by the action of sulphuric acid, crystallises from alcohol or ether as plates melting at 63·5°.

The unsaturated monohydroxymonocarboxylic acids also yield γ-lactones, and the following are important members of this series:—

Crotonolactone $\begin{array}{l} CH_2\text{—}CH:CH \\ \vert \qquad\qquad\quad \vert \\ O\text{————}CO \end{array}$ is formed from vinylacetic acid by converting it into βγ-dichlorobutyric acid by the addition of chlorine and then eliminating hydrogen chloride by heating at 200°–215°. It melts at 4° and boils at 95°–96° (13 mm.):

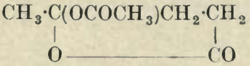


$$\begin{array}{l}\mathrm{CH_2{=}CH{-}CH_2}\\ \qquad\qquad |\\ \qquad\quad \mathrm{COOH}\end{array} \rightarrow \begin{array}{l}\mathrm{CH_2{-}CHCl{-}CH_2}\\ |\qquad\qquad\quad |\\ \mathrm{Cl}\qquad\quad\ \ \mathrm{COOH}\end{array} \rightarrow \begin{array}{l}\mathrm{CH_2{-}CH{=}CH}\\ |\qquad\qquad |\\ \mathrm{O}\text{———}\mathrm{CO}\end{array}$$

Crotonolactone.

$\Delta^{\beta\gamma}$-Angelicalactone 
$$\begin{array}{l}\mathrm{CH_3{\cdot}C{=}CH{-}CH_2}\\ |\qquad\qquad\ |\\ \mathrm{O}\text{————}\mathrm{CO}\end{array}$$

is formed, unaccompanied by the $\Delta^{\alpha\beta}$-lactone (*see* below), when acetyllævulic acid



$$\begin{array}{l}\mathrm{CH_3{\cdot}C(OCOCH_3)CH_2{\cdot}CH_2}\\ \quad |\qquad\qquad\qquad |\\ \quad \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

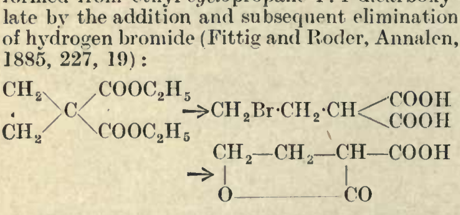
is distilled under 200–230 mm. pressure. It melts at 18°–18·5°, and distils at 55°–56° (12 mm.).

$\Delta^{\alpha\beta}$-*Angelicalactone* 
$$\begin{array}{l}\mathrm{CH_3{\cdot}CH{-}CH{=}CH}\\ \quad |\qquad\qquad |\\ \quad \mathrm{O}\text{————}\mathrm{CO}\end{array}$$

is formed from the $\Delta^{\beta\gamma}$ compound by warming it with triethylamine. It does not solidify at −17°, and boils at 89° (15 mm.). The $\Delta^{\alpha\beta}$-lactone is partially converted into the $\Delta^{\beta\gamma}$-lactone on distillation under ordinary pressure (Thiele, Tischbein, and Lossow, Annalen, 1901, 319, 180).

The γ-lactones which are derived from the hydroxydicarboxylic acids are, of course, no longer neutral substances, but contain a free carboxyl group; the following compounds are important members of this class: *Butyrolactone-α-carboxylic acid* 
$$\begin{array}{l}\mathrm{CH_2{-}CH_2{-}CH{\cdot}COOH}\\ |\qquad\qquad\quad |\\ \mathrm{O}\text{—————}\mathrm{CO}\end{array}$$

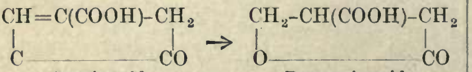
is formed from ethyl *cyclo*propane-1 : 1-dicarboxylate by the addition and subsequent elimination of hydrogen bromide (Fittig and Roder, Annalen, 1885, 227, 19):



$$\begin{array}{c}\mathrm{CH_2}\\ \mathrm{CH_2}\end{array}\!\!>\mathrm{C}<\!\!\begin{array}{c}\mathrm{COOC_2H_5}\\ \mathrm{COOC_2H_5}\end{array} \rightarrow \mathrm{CH_2Br{\cdot}CH_2{\cdot}CH}<\!\!\begin{array}{c}\mathrm{COOH}\\ \mathrm{COOH}\end{array} \rightarrow \begin{array}{l}\mathrm{CH_2{-}CH_2{-}CH{-}COOH}\\ |\qquad\qquad\quad |\\ \mathrm{O}\text{—————}\mathrm{CO}\end{array}$$

The lactonic acid forms a thick viscid liquid which is readily soluble in water, and when heated at 120° evolves carbon dioxide and passes into butyrolactone. *Butyrolactone-β-carboxylic acid, Paraconic acid* 
$$\begin{array}{l}\mathrm{CH_2{-}CH(COOH){-}CH_2}\\ |\qquad\qquad\qquad\ |\\ \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

is formed by the reduction of aconic acid by zinc-dust and acetic acid (Reitter, Ber. 1898, 31, 2722)

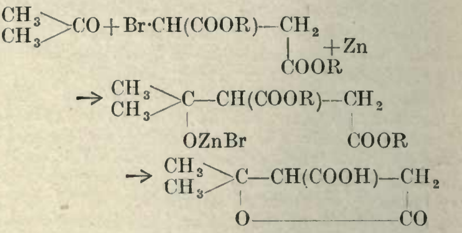


$$\begin{array}{l}\mathrm{CH{=}C(COOH){-}CH_2}\\ |\qquad\qquad\quad\ |\\ \mathrm{C}\text{—————}\mathrm{CO}\end{array} \rightarrow \begin{array}{l}\mathrm{CH_2{-}CH(COOH){-}CH_2}\\ |\qquad\qquad\qquad\ |\\ \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

Aconic acid. Paraconic acid.

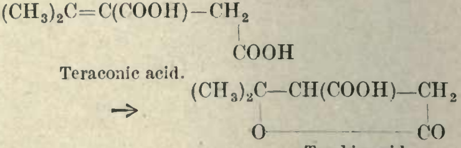
Terebic acid 
$$\begin{array}{l}\mathrm{(CH_3)_2{\cdot}C{-}CH(COOH){-}CH_2}\\ \quad |\qquad\qquad\qquad\quad |\\ \quad \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

is a product of the oxidation of oil of turpentine, and has been synthesised by several methods. Thus it is formed by the oxidation of *iso*propylsuccinic acid, as indicated by method (5), and is also produced when the ester, formed by the condensation of ethyl bromosuccinate with acetone in the presence of zinc (Reformatzky's method), is hydrolysed:



$$\begin{array}{c}\mathrm{CH_3}\\ \mathrm{CH_3}\end{array}\!\!>\mathrm{CO}+\begin{array}{l}\mathrm{Br{\cdot}CH(COOR){-}CH_2}\\ \qquad\qquad\qquad\ |\\ \qquad\qquad\quad\ \mathrm{COOR}\end{array}+\mathrm{Zn} \rightarrow \begin{array}{c}\mathrm{CH_3}\\ \mathrm{CH_3}\end{array}\!\!>\begin{array}{l}\mathrm{C{-}CH(COOR){-}CH_2}\\ |\qquad\qquad\qquad |\\ \mathrm{OZnBr}\qquad\quad \mathrm{COOR}\end{array} \rightarrow \begin{array}{c}\mathrm{CH_3}\\ \mathrm{CH_3}\end{array}\!\!>\begin{array}{l}\mathrm{C{-}CH(COOH){-}CH_2}\\ |\qquad\qquad\qquad |\\ \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

It is also obtained from teraconic acid by warming with sulphuric acid



$$\begin{array}{l}\mathrm{(CH_3)_2C{=}C(COOH){-}CH_2}\\ \qquad\qquad\qquad\qquad\ |\\ \qquad\qquad\qquad\quad \mathrm{COOH}\end{array} \rightarrow \begin{array}{l}\mathrm{(CH_3)_2C{-}CH(COOH){-}CH_2}\\ \quad |\qquad\qquad\qquad\quad |\\ \quad \mathrm{O}\text{——————}\mathrm{CO}\end{array}$$

Teraconic acid. Terebic acid.

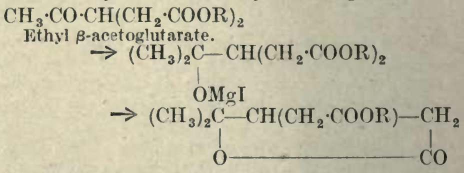
Terebic acid crystallises from water as needles which melt at 174°–175°.

Two other lactonic acids, which have played an important part in the elucidation of the chemistry of the terpenes, are terpenylic acid and homoterpenylic acid. *Terpenylic acid* 
$$\begin{array}{l}\mathrm{(CH_3)_2C{-}CH(CH_2{\cdot}COOH){-}CH_2,}\\ \quad |\qquad\qquad\qquad\qquad\quad |\\ \quad \mathrm{O}\text{———————}\mathrm{CO}\end{array}$$

which occurs frequently as a product of the degradation of the terpenes, was discovered by Hempel and investigated by Fittig and his pupils; its structure was determined by Wallach. The acid has been synthetically prepared by Lawrence (Chem. Soc. Trans. 1899, 75, 529) by the oxidation of β-*iso*propylglutaric acid

$$\mathrm{(CH_3)_2CH{\cdot}CH}<\!\!\begin{array}{c}\mathrm{CH_2{\cdot}COOH}\\ \mathrm{CH_2{\cdot}COOH}\end{array}$$

(compare method (5)), and by Simonsen (Chem. Soc. Trans. 1907, 91, 187) by the action of magnesium methyl iodide on ethyl β-acetoglutarate



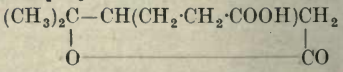
$$\mathrm{CH_3{\cdot}CO{\cdot}CH(CH_2{\cdot}COOR)_2}$$

Ethyl β-acetoglutarate.

$$\rightarrow \begin{array}{l}\mathrm{(CH_3)_2C{-}CH(CH_2{\cdot}COOR)_2}\\ \quad |\\ \quad \mathrm{OMgI}\end{array} \rightarrow \begin{array}{l}\mathrm{(CH_3)_2C{-}CH(CH_2{\cdot}COOR){-}CH_2}\\ \quad |\qquad\qquad\qquad\qquad\quad |\\ \quad \mathrm{O}\text{———————}\mathrm{CO}\end{array}$$

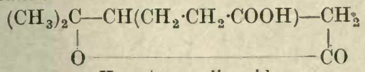
Terpenylic acid crystallises with 1 molecule of water as colourless prisms which melt at 56°. The water of crystallisation is removed by sulphuric acid and the anhydrous substance then melts at 89°.

Homoterpenylic acid



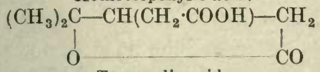
$$\begin{array}{l}\mathrm{(CH_3)_2C{-}CH(CH_2{\cdot}CH_2{\cdot}COOH)CH_2}\\ \quad |\qquad\qquad\qquad\qquad\qquad\quad |\\ \quad \mathrm{O}\text{————————}\mathrm{CO}\end{array}$$

was isolated by Baeyer during his researches on the constitution of pinene—the chief constituent of oil of turpentine: its relation to terpenylic acid and terebic acid is shown by the following formulæ :—



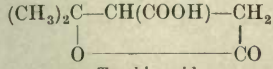
$$\underset{\underset{\displaystyle O}{|}}{(CH_3)_2C}\text{—}CH(CH_2\cdot CH_2\cdot COOH)\text{—}\underset{\underset{\displaystyle CO}{|}}{CH_2}$$

Homoterpenylic acid.



$$\underset{\underset{\displaystyle O}{|}}{(CH_3)_2C}\text{—}CH(CH_2\cdot COOH)\text{—}\underset{\underset{\displaystyle CO}{|}}{CH_2}$$

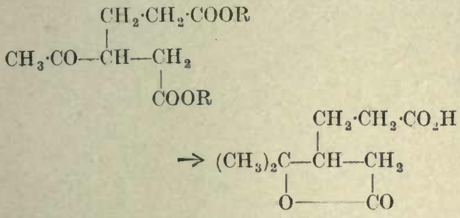
Terpenylic acid.



$$\underset{\underset{\displaystyle O}{|}}{(CH_3)_2C}\text{—}CH(COOH)\text{—}\underset{\underset{\displaystyle CO}{|}}{CH_2}$$

Terebic acid.

Homoterpenylic acid is, as a matter of fact, converted into terpenylic acid and some terebic acid by oxidation with nitric acid. Homoterpenylic acid has been synthesised by Simonsen (Chem. Soc. Trans. 1907, 91, 184) by treating ethyl β-acetoadipate with magnesium methyl iodide and hydrolysing the product.



$$CH_3\cdot CO\text{—}\overset{\overset{\displaystyle CH_2\cdot CH_2\cdot COOR}{|}}{CH}\text{—}\underset{\underset{\displaystyle COOR}{|}}{CH_2}$$

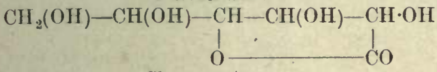
$$\rightarrow \underset{\underset{\displaystyle O}{|}}{(CH_3)_2C}\text{—}\overset{\overset{\displaystyle CH_2\cdot CH_2\cdot CO_2H}{|}}{CH}\text{—}\underset{\underset{\displaystyle CO}{|}}{CH_2}$$

The acid crystallises from water as glistening prisms which melt at 100°–102°.

The formation of γ-lactones from polyhydroxycarboxylic acids. Those polyhydroxy derivatives of the carboxylic acids which have a hydroxyl group in the γ-position yield γ-lactones (Fittig, Annalen, 1892, 268, 4, 34, 40, 62, 68). When hydroxyl groups are present in both the γ- and δ- positions, the γ-lactone is formed, since the five-membered γ-lactone ring is more easily closed than the six-membered δ-lactone ring, thus :

$CH_2(OH)\text{-}CH(OH)\text{-}CH(OH)\text{-}CH(OH)\text{-}CH(OH)\text{-}COOH$

Gluconic acid.



$$CH_2(OH)\text{—}CH(OH)\text{—}\underset{\underset{\displaystyle O}{|}}{CH}\text{—}CH(OH)\text{—}\underset{\underset{\displaystyle CO}{|}}{CH\cdot OH}$$

Gluconolactone.

The hydroxylactones, which are derived from the acids of the sugar group and which therefore contain several hydroxyl complexes, are characterised by showing a greater tendency to crystallise than the hydroxy acids themselves; their formation has therefore been of considerable service in elucidating the structure of the sugars. The remarkable property possessed by the acids of the sugar group of passing into the aldehyde, that is, the sugar itself, when reduced by nascent hydrogen, thus :

$$\underset{\text{Gluconic acid.}}{CH_2(OH)\text{—}(CH\cdot OH)_4\text{—}COOH} \rightarrow \underset{\text{Glucose.}}{CH_2(OH)(CH\cdot OH)_4CHO}$$

is entirely dependent on the formation of the lactone. That is to say, the acid itself is not reducible but only the lactone (E. Fischer, Ber. 1889, 22, 2204 ; 1890, 23, 930).

The following lactones are derived from the pentahydroxycarboxylic acids: *d-Mannonolactone* $C_6H_{10}O_6$ melts at 149°–153°, and has $[\alpha]_D = +53{\cdot}8°$; *l-Mannonolactone* melts at 140°–150°, and has $[\alpha]_D = -54{\cdot}8°$: *(d+l)-Mannonolactone* melts at 149°–155°. *d-Gluconolactone* $C_6H_{10}O_6$ melts at 130°–135° and yields grape sugar when reduced by sodium amalgam. *l-Gluconolactone* melts at 185° and gives *l*-xylose when oxidised by hydrogen peroxide. *d-Galactonolactone* melts at 91° in the anhydrous state, but with water yields a hydrate, containing one molecule of water of crystallisation, which melts at 64°. The *(d+l)-lactone* melts at 122°–125°. *α-Rhamnoselactone* melts at 162°–168° ; *β-Rhamnoselactone* melts at 134°–138°. The following lactones are derived from the hexahydroxycarboxylic acids: *d-Mannoselactone* (m.p. 149°); *l-Mannoselactone* (m.p. 154°); *α-d-Glucoselactone* (m.p. 140°–145°) ; *β-d-Glucoselactone* (m.p. 151°) ; *α-d-Galactoselactone* (m.p. 150°) ; *d-Fructoselactone* (m.p. 130°). These lactones are reduced by sodium amalgam to the corresponding heptoses.

The formation of γ-lactones from the acids of the sugar series has been used by Purdie and Irvine (Chem. Soc. Trans. 1903, 83, 1021) to supply direct evidence of the γ- linkage in glucosides. Thus α-methylglucoside when alkylated by the aid of silver oxide yields tetramethyl-α-methylglucoside which, on hydrolysis, is converted into tetramethylglucose (m.p. 81°–83°). When this substance is oxidised by bromine water it is converted into tetramethylgluconolactone

$$CH_2(OH)CH(OH)\text{—}\underbrace{CH\text{—}(CH\cdot OH)_2\text{—}CH}_{O}\cdot OCH_3$$

α-Methylglucoside.

$$\rightarrow CH_2(OCH_3)\text{-}CH(OCH_3)\cdot\underbrace{CH\text{-}(CH\cdot OCH_3)_2\text{-}CH}_{O}\cdot OCH_3.$$

Tetramethyl-α-methylglucoside.

$\rightarrow CH_2(OCH_3)\text{-}CH(OCH_3)\text{-}CH(OH)\text{-}(CH\cdot OCH_3)_2CHO$

Tetramethylglucose (m.p. 81°–83°).

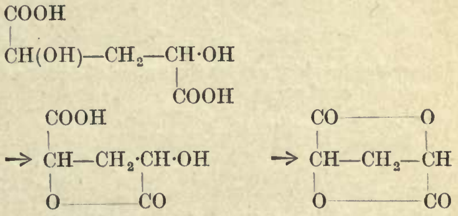
$CH_2(OCH_3)\text{-}CH(OCH_3)\text{-}CH(OH)\text{-}(CH\cdot OCH_3)_2\text{-}COOH$

Tetramethylgluconic acid.

$$\rightarrow CH_2(OCH_3)\text{-}CH(OCH_3)\text{-}\underbrace{CH\text{-}(CH\cdot OCH_3)_2\text{-}CO}_{O}$$

Tetramethylgluconolactone.

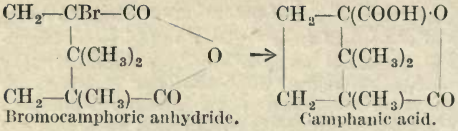
Polyhydroxy derivatives of the dicarboxylic acids yield γγ-dilactones, where possible. Thus αα′-dihydroxyglutaric acid yields in the first instance the hydroxylactonic acid melting at 167°–168°, and finally the dilactone (Fittig, Annalen, 1907, 353, 1)



$$\overset{\overset{\displaystyle COOH}{|}}{CH(OH)}\text{—}CH_2\text{—}\underset{\underset{\displaystyle COOH}{|}}{CH\cdot OH}$$

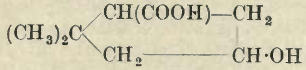
$$\rightarrow \overset{\overset{\displaystyle COOH}{|}}{\underset{\underset{\displaystyle O}{|}}{CH}}\text{—}CH_2\cdot\underset{\underset{\displaystyle CO}{|}}{CH\cdot OH} \quad \rightarrow \overset{\overset{\displaystyle CO}{|}}{\underset{\underset{\displaystyle O}{|}}{CH}}\text{—}CH_2\text{—}\overset{\overset{\displaystyle O}{|}}{\underset{\underset{\displaystyle CO}{|}}{CH}}$$

The formation of lactones from alicyclic compounds appears to proceed in much the same manner as with the open chain substances. In many cases, the formation of the lactone proceeds normally as, for example, when bromocamphoric anhydride is converted into camphanic acid by the action of boiling water (Wreden, Annalen, 1872, 163, 330) :



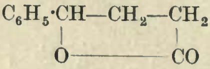
Bromocamphoric anhydride. Camphanic acid.

On the other hand, steric hindrance seems, in some cases, to prevent the formation of the lactone. Thus 1-1-dimethyl-4-hydroxy-*cyclo*pentane-2-carboxylic acid



shows no tendency to pass into the inner anhydride (Perkin, Thorpe, and Walker, Trans. 1901, 79, 783). It is, however, possible that in this instance the hydroxy acid may represent the *trans*-configuration of this substance, in which case the formation of the lactone would be prevented (*see* orthocoumaric acid).

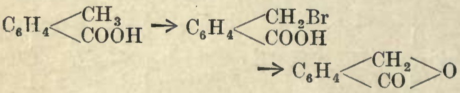
The γ-lactones of the aromatic series. The following lactones are important members of this series. (For methods of preparation see above.) *The lactone of o-hydroxyphenylacetic acid* $C_6H_4<\substack{CH_2\\O}>CO$, exists in two modifications, a labile form, melting at 28°, and a stable form, melting at 49°. It boils at 248°–252° and is slowly converted into the hydroxy acid on shaking with water. *Phenylbutyrolactone*



melts at 37°. It is volatile with steam and has a pleasant aromatic odour. *Phenylparaconic acid*  is formed by the condensation of benzaldehyde with sodium succinate in the presence of acetic anhydride. It crystallises with $\frac{1}{4}H_2O$ and melts at 99°. When dried at 90° it melts at 121° and after resolidifying melts at 106°. If the melted specimen is heated at 115° and seeded with a crystal melting at 121°, the modification of higher melting-point is produced (Fittig, Annalen, 1889, 255, 143). It is sparingly soluble in cold water. *Phthalide* $C_6H_4<\substack{CO\\CH_2}>O$ is formed by the reduction of phthalic anhydride and was first obtained by Kolbe and Wischin in 1866 by the reduction of phthalyl chloride

$$C_6H_4<\substack{CCl_2\\CO}>O.$$

It can also be obtained by the action of bromine on *o*-toluic acid at 140° :



$$C_6H_4<\substack{CH_3\\COOH} \rightarrow C_6H_4<\substack{CH_2Br\\COOH} \rightarrow C_6H_4<\substack{CH_2\\CO}>O$$

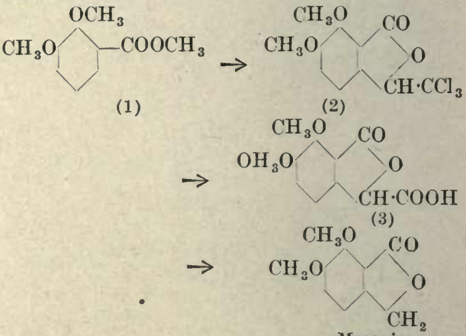
Phthalide.

Phthalide crystallises from hot water as rhombic plates which melt at 73° ; it boils at 290° without decomposition and is sparingly soluble in alcohol, ether and in cold water. The lactone is converted by alkalis into the salt of the corresponding hydroxy acid

$$C_6H_4(CH_2{\cdot}OH)COOH.$$

This acid is stable, but by long standing in aqueous solution, or by melting, is converted into phthalide.

Meconine  This substance, which was formerly named *opianyl*, was discovered independently in 1830 by Couerbe and by Dublanc in opium. It also occurs in the root of the *Hydrastis canadensis* (Linn.), and is, moreover, one of the products which are formed when narcotine is oxidised by nitric acid. It has been prepared synthetically by Fritsch in the following way (Annalen, 1898, 301, 352): Methyl 2:3-dimethoxybenzoate (1) is condensed with chloral, under the influence of concentrated sulphuric acid, to form 5:6-dimethoxytrichloromethylphthalide (2). This compound, when hydrolysed, is converted into the corresponding carboxylic acid (3) which is transformed into carbon dioxide and meconine when heated :



(1) (2) (3)

Meconine.

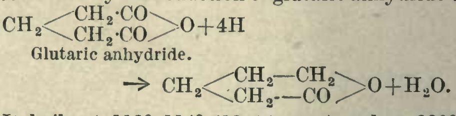
Meconine forms white crystals which melt at 101°–102°. It sublimes unchanged and dissolves in 700 parts of water at 15·5° and in 22 parts at 100°.

δ-Lactones. The remarks which have already been made respecting the ease of formation of the γ-lactones from the γ-hydroxy acids apply also to the production of the δ-lactones from the corresponding δ-hydroxy acids, excepting that the six-membered δ-lactone ring is not so readily formed as the five-membered ring of the γ-lactones and is consequently more easily broken.

Aliphatic δ-lactones. *δ-Valerolactone*

$$CH_2<\substack{CH_2-CH_2\\CH_2-CO}>O$$

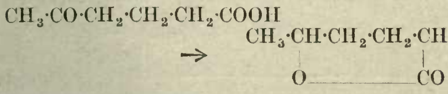
is formed by the reduction of glutaric anhydride :



$$CH_2<\substack{CH_2{\cdot}CO\\CH_2{\cdot}CO}>O+4H \rightarrow CH_2<\substack{CH_2-CH_2\\CH_2-CO}>O+H_2O.$$

Glutaric anhydride.

It boils at 113°–114° (13–14 mm.) and at 220° under ordinary atmospheric pressure, is sparingly soluble in water and is characterised by passing, on standing, into a crystalline polymeride melting at 47°–48°. When water is added to the lactone an acid reaction is at once obtained, showing that the lactone ring is readily broken. *δ-Caprolactone,*  was the first δ-lactone of the aliphatic series to be prepared and was obtained by Fittig and Wolff (Annalen, 1883, 216, 127) by the reduction of γ-acetobutyric acid:

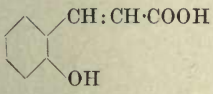


$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH \rightarrow \begin{array}{l}CH_3{\cdot}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2\\ \quad O\text{———————}CO\end{array}$$

It boils at 230°–231° and forms needles melting at 17°–19°. It is miscible with water and absorbs moisture from damp air passing into the hydroxy acid.

Aromatic δ-lactones. Several δ-lactones of the aromatic series are of considerable importance because they either occur free in nature or are obtained as the products of fission of certain natural glucosides. They are largely used industrially for the preparation of perfumes.

Coumarin  which is the δ-lactone of *o*-hydroxycinnamic acid

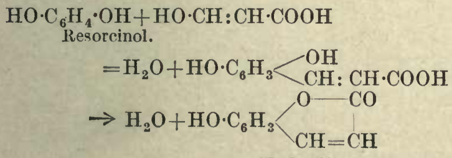


may be regarded as the prototype of this group to which the general name of 'the Coumarins' is applied, chiefly because the other members of the series are derivatives of coumarin in which hydroxyl or methoxyl groups are present in the benzene nucleus.

The coumarins may be prepared either by applying the Perkin method for the synthesis of coumarin (see below) to the necessary derivatives of salicylaldehyde, or by the v. Pechmann method, which is carried out by heating phenols with malic acid in the presence of concentrated sulphuric acid (v. Pechmann, Ber. 1884, 17, 929; v. Pechmann and Welsch, *ibid.* 1646). This reaction is explained by assuming that the strong sulphuric acid first decomposes malic acid into carbon monoxide, water, and hydroxyacrylic acid, thus:

$$\underset{\text{Malic acid.}}{COOH{\cdot}CH(OH)CH_2{\cdot}COOH} \rightarrow CO+H_2O+CH(OH){:}CH{\cdot}COOH$$

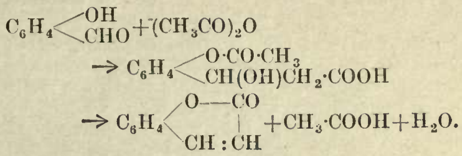
and that the hydroxyacrylic acid then condenses with the phenol to form the coumarin, thus:



$$\underset{\text{Resorcinol.}}{HO{\cdot}C_6H_4{\cdot}OH}+HO{\cdot}CH{:}CH{\cdot}COOH$$
$$=H_2O+HO{\cdot}C_6H_3{<}\begin{array}{l}OH\\ CH{:}\ CH{\cdot}COOH\end{array}$$
$$\rightarrow H_2O+HO{\cdot}C_6H_3{<}\begin{array}{l}O\text{——}CO\\ \quad|\\ CH{=}CH\end{array}$$

Umbelliferone.

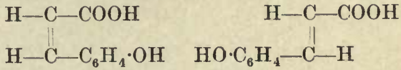
This reaction yields the best results with the *m*-substitutes phenols. *Coumarin* was first isolated in 1820 from Tonka beans, the seed of the *Dipteryx odorata* (Willd.), and was subsequently characterised by Guibort. It was first prepared synthetically by Perkin from salicylaldehyde by heating with sodium acetate and acetic anhydride:



$$C_6H_4{<}\begin{array}{l}OH\\ CHO\end{array}+(CH_3CO)_2O$$
$$\rightarrow C_6H_4{<}\begin{array}{l}O{\cdot}CO{\cdot}CH_3\\ CH(OH)CH_2{\cdot}COOH\end{array}$$
$$\rightarrow C_6H_4{<}\begin{array}{l}O\text{——}CO\\ \quad|\\ CH:CH\end{array}+CH_3{\cdot}COOH+H_2O.$$

This synthesis may, moreover, be applied to the formation of other coumarins since, by the method of Gattermann (Ber. 1899, 32, 278, 287), many hydroxyaromatic aldehydes can now be prepared from phenols by the action of hydrocyanic and hydrochloric acids in the presence of aluminium chloride.

Coumarin forms prismatic crystals which melt at 67° and boil at 290°–290·5°. It is sparingly soluble in cold water but readily dissolves on warming. The corresponding hydroxy acid, coumarinic acid, cannot be isolated in the free state, but when coumarin is boiled for some time with a solution of potassium hydroxide, an acid separates on acidification which decomposes above 200° with evolution of carbon dioxide but does not yield coumarin (Zwenger, Annalen Suppl. 1872, 8, 23). This acid, which is called orthocoumaric acid, is stereoisomeric with the unstable coumarinic acid (Clayton, Chem. Soc. Trans. 1910, 2102) the two acids being represented by the formulæ:

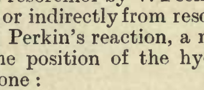


$$\begin{array}{l}H\text{—}C\text{—}COOH\\ \quad\ \|\\ H\text{—}C\text{—}C_6H_4{\cdot}OH\end{array}\qquad\begin{array}{r}H\text{—}C\text{—}COOH\\ \|\quad\quad\ \ \\ HO{\cdot}C_6H_4\text{—}C\text{—}H\end{array}$$

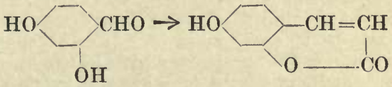
Coumarinic acid (cis-form) *o*-Coumaric acid (trans-form).

The ease of formation of coumarin from coumarinic acid is explained by the proximity of the hydroxyl and carboxyl groups in the cis-configuration (*cf.* Borsche, Ber. 1904, 37, 346).

Umbelliferone, Hydroxycoumarin



This substance, which is the δ-lactone of 2:4-dihydroxycinnamic acid, is found in the bark of the *Daphne Mesereum* (Linn.) and is also obtained by distilling various resins such as galbanum and asafœtida. Its synthesis may be effected directly from resorcinol by v. Pechmann's malic acid method, or indirectly from resorcylaldehyde by the aid of Perkin's reaction, a method which establishes the position of the hydroxyl group in umbelliferone:

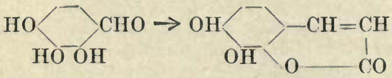


Resorcylaldehyde. Umbelliferone.

Umbelliferone crystallises from hot water in slender needles melting at 225°. It dissolves very sparingly in water, yielding a solution which shows a marked blue fluorescence.

Herniarin is the methoxyl derivative of umbelliferone  $CH_3O{\cdot}C_6H_3{<}\begin{array}{l}CH{=}CH\\ \quad|\\ O\text{——}CO\end{array}$, and occurs in *Herniaria hirsuta* (Linn.) (Barth and Herzig, Monatsh, 1889, 10, 161). It melts at 117°–118°.

Daphnetin  is obtained by the fission of the glucoside daphnin, either by acids or by ferments. It can be prepared synthetically either from pyrogallol by the malic acid method or from pyrogallolaldehyde by Perkin's reaction; the second method of preparation determines the positions of the hydroxyl groups in daphnetin:

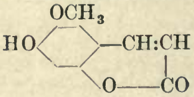


Pyrogallolaldehyde. Daphnetin.

Daphnetin crystallises as needles or prisms, melts at 256°, and develops a pleasant coumarin-like smell when heated. It dissolves in alkali, forming a reddish-yellow solution and gives in aqueous solution a green colouration with ferric chloride.

Æsculatin  is isomeric with daphnetin. It occurs in the bark of the horse chestnut, partly free and partly as the glucoside æsculin. It also occurs in the seed of the *Euphorbia Lathyris* (Linn.), and can be prepared synthetically from hydroxyhydroquinone by converting this substance into hydroxyhydroquinonealdehyde  by means of hydrocyanic and hydrochloric acids in the presence of zinc chloride (Gattermann's reaction), and then by subjecting the aldehyde to the Perkin reaction. Æsculetin crystallises from water as leaflets or needles, melts at 268° with decomposition, and is sparingly soluble in cold water, but readily dissolves in hot water and in alcohol. The aqueous solution, which has a faint blue fluorescence gives a green colouration with ferric chloride. The lactone dissolves in alkali, forming a yellowish-red solution.

Scopoletin (*Chrysatropic acid*)

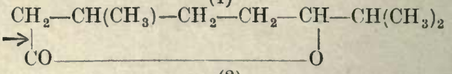


which is the methoxyl derivative of æsculetin, was isolated by Eykman (Rec. trav. chim. 1884, 3, 171) from the rhizome of *Scopolia japonica* (Maxim.). It also occurs in *Atropa belladonna* (Linn.), in *Gelsemium*, in the bark of the *Prunus serotina*, and in jalap. The lactone crystallises from ethyl acetate as needles which melt at 204°, and exhibits a fine blue fluorescence in aqueous solution, which is enhanced by the addition of alkali. The constitution of this substance as 4-hydroxy-5-methoxy-coumarin has been determined by Moore (Chem. Soc. Trans. 1911, 99, 1043).

ε-Lactones. The existence of ε-lactones has been shown to be possible by the researches of v. Baeyer and his collaborators. Thus when the hydroxy acid (1) is distilled, it is partially decomposed into water and the ε-lactone; β-methyl-ε-*iso*propyl-ε-caprolactone (2) (Baeyer and Öhler, Ber. 1896, 29, 29; Baeyer and Seuffert, *ibid.* 1899, 32, 3619):

$$COOH{\cdot}CH_2{\cdot}CH(CH_3)CH_2{\cdot}CH_2{\cdot}CH(OH)CH(CH_3)_2$$

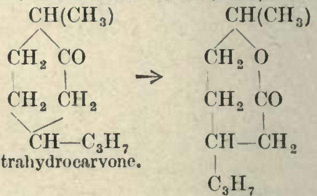
(1)



(2)

The hydroxy acid (1), which is derived from menthone by oxidation and subsequent reduction, exists in two forms, one of which is liquid, the other solid. There are, therefore, two lactones (both of which are feebly lævorotatory), one melting at 47° derived from the solid acid, and the other, a liquid boiling at 135° (12 mm.) derived from the liquid acid. Both modifications of the lactone are insoluble in cold alkali but dissolve on warming. The solid ε-lactone (m.p. 47°) is also formed when menthone is oxidised by Caro's acid (Baeyer and Villiger, Ber. 1899, 32, 3628; 1900, 33, 860).

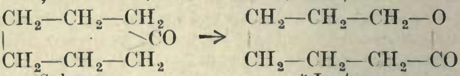
β-*iso*-**Propyl-ε-methyl-ε-caprolactone** is formed when tetrahydrocarvone is treated with Caro's acid (Baeyer and Villiger, Ber. 1899, 32, 3629; Wallach, Annalen, 1902, 323, 331):



Tetrahydrocarvone. ε-Lactone.

The lactone boils at 155·5°–156° (21 mm.).

ζ-Lactones. An unstable lactone of this series is formed when suberone is treated with Caro's acid (Baeyer and Villiger, Ber. 1900, 33, 862; v. Braun, *ibid.* 1906, 39, 4362):



Suberone. ζ-Lactone.

The lactone was not isolated but its existence in the crude product of oxidation was inferred from the fact that when treated with alcohol and sulphuric acid it was converted into the ethyl salt of ζ-hydroxyœnanthylic acid

$$OH(CH_2)_6COOR.$$

LACTOPHENIN *v.* Synthetic drugs.

LACTOPICRIN *v.* Lactucarium.

LACTOSE *v.* Carbohydrates.

LACTUCARIUM. *Lettuce opium.* The inspissated juice of *Lactuca virosa* (Linn.) and other species of *Lactuca* (*v.* Woodville, Med. Bot. 1, 31,; Bentl. a. Trim. 160, 161). Lactucarium is sometimes employed in medicine as a substitute for opium, and has often been examined chemically. A list of the earlier investigations, with a summary of the results, is given by Pereira (Mat. Med. 1853. 2, 1569).

Nearly half the weight of lactucarium consists of the tasteless inodorous compound *lactucerin* or *lactucon*, first obtained in a crystalline form by Lenoir (Annalen, 59, 83).

It was further studied by Franchimont and Wigman (Ber. 12, 10); Hesse (Annalen, 234, 243; 244, 268); Kassner (*ibid.* 238, 220), and others. Lactucarium is first washed with benzene and then extracted with hot alcohol. From the alcoholic solution crude lactucerin separates in crystals. These are purified by solution in ether, agitation of the ethereal solution with aqueous potash, the addition of alcohol until a precipitate begins to form, filtration, and finally the addition of water, when the lactucerin comes down in microscopic needles (Kassner). Franchimont and Wigman prepared a lactucerin or lactucon from lactucarium derived from *Lactuca altissima* (Bieb.), which gave the formula $C_{14}H_{22}O$. It melts at 296°, is insoluble in water, sparingly soluble in benzene and carbon disulphide, but dissolves in ether, light petroleum, and in fixed and volatile oils. By the action of phosphorus pentasulphide a *hydrocarbon* $C_{14}H_{22}$ was obtained, which boils at 247°–252°.

According to Hesse, lactucerin consists of a mixture of the acetates of two isomeric alcohols. Alcoholic potash decomposes the esters, and, on the addition of water, a precipitate of the two alcohols falls, which may be separated by taking advantage of their different solubility in alcohol. *α-Lactucerol* $C_{18}H_{30}O,H_2O$, the least soluble in alcohol, consists of silky needles which melt at 173°–181°. It is soluble in chloroform, ether, light petroleum, or hot alcohol. The *acetate* $C_{20}H_{32}O_2$ or $CH_3{\cdot}CO{\cdot}OC_{18}H_{29}$ which exists in lactucerin, may also be prepared from the alcohol. It is crystalline and melts at 202°–207°. It is slightly soluble in cold alcohol and glacial acetic acid, and easily in chloroform, ether, and light petroleum. The *diacetate* melts at 198°–200°, the *propionate* at 152°, and the *benzoate* at 156°. *β-Lactucerol* $C_{18}H_{30}O,H_2O$ may be obtained in long needles from ether or chloroform. It is more soluble in alcohol than α-lactucerol, and forms an *acetate* $C_{20}H_{32}O_2$ or $CH_3{\cdot}CO{\cdot}OC_{18}H_{29}$, the constituent of lactucerin, which is obtained in crystals from alcohol and melts at 230°. It is less soluble in alcohol and light petroleum than the α-acetate. Crude lactucerin, examined by Flückiger and Hanbury, melted at 232° (Flück. a. Hanb. 398).

After purifying crude lactucerin by sublimation in a current of carbon dioxide, Kassner found it to melt at 210°, and on analysis to give numbers agreeing better with the formula of Franchimont and Wigman, $C_{14}H_{22}O$ or $C_{28}H_{44}O_2$, than with that proposed by Hesse. Fusing lactucerin with potash, Kassner obtained a new compound, *lactucol* $C_{13}H_{20}O$ or $C_{13}H_{19}{\cdot}OH$, together with acetic acid and hydrogen. Lactucol consists of needles melting at 160°–162°. It forms an *acetate* which melts at 198°–200°.

Lactucin, lactucic acid, lactopicrin, and lactucerin, as constituents of the Canadian lettuce *Lactuca canadensis* (Linn.), have been investigated by Flowers (Pharm. J. [iii.] 10, 44).

From German lactucarium Sperling (Chem. Zentr. 1904, i. 1162) obtained *lactucon*, m.p. 184°, to which he gives the formula $C_{23}H_{36}O_2$. On hydrolysis it yields acetic acid and lactucol $C_{21}H_{33}OH$, the latter melting at 154°–155°.

The bitter taste, and probably the medicinal value of lactucarium, depends upon three other constituents, which occur in relatively minute quantities. The first of these, *lactucin* $C_{11}H_{12}O_3,H_2O$, was studied by Walz (Annalen, 32, 85; J. Pharm. 14, 25; Neu. J. Pharm. 15, 118); Aubergier (Compt. rend. 19, 923); Ludwig (Arch. Pharm. [ii.] 50, 1 and 129); Kromayer (*ibid.* [ii.] 105, 3); Ludwig and Kromayer (*ibid.* [ii.] 111. 1); and Buchner (Rep. Phar. 43, 1). It has a decidedly bitter taste and crystallises in white pearly scales. It is soluble in water, sparingly soluble in alcohol or acetic acid, and insoluble in ether. It reduces Fehling's solution. Of the remaining two constituents, *lactucic acid* is a light yellow mass, becoming crystalline on standing (Ludwig and Walz), and *lactopicrin*, an amorphous bitter mass, soluble in water and alcohol (Kromayer, Die Bitterstoffe, Erlangen, 1861, 79).

Lactucarium also contains a trace of volatile oil, sugar, gum, albumen, caoutchouc, resin, asparagin, oxalic, citric, and malic acids, and yields 8–10 p.c. of *ash* (*cf.* Kremel, Pharm. Zentralh. 1888, 512). A. S.

LACTUCERIN, LACTUCEROL, LACTUCIC ACID, LACTUCIN, LACTUCOL, and **LACTUCON** *v.* Lactucarium.

LAC VARNISH *v.* Varnish.

LÆVOBORNEOL *v.* Camphors.

LÆVOCAMPHOR *v.* Camphors.

LÆVULIC ACID *v.* Ketones

LÆVULOSE *v.* Carbohydrates.

LAKE ORE *v.* Limonite; Iron.

LAKES. The origin of their manufacture, as well as of the term 'lake' itself, is seen from the following brief historical sketch:—

According to Pliny, the dried scum collected by the dyers of Tyrian purple from their dye-liquors furnished a costly purple-coloured pigment employed by painters. The *indicum* of the Roman artists was probably obtained in the same manner from a woad or indigo vat. Caneparius, a Venetian writer on dyeing, in 1619, states that it was the custom of dyers to evaporate the waste lac dye-liquors in order to obtain an artificial lac used by artists.

Similar pigments were afterwards prepared or collected from the waste dye-liquors of kermes, brazilwood, &c. Such pigments were called by the Italians *laccæ*, and these were distinguished from each other by adding the name of the substance whence the colour was derived—*e.g. lacca di verzino* (Brazilwood), *lacca di grana* (kermes), *lacca di cremise*, &c.

As to the word 'lake' itself, the Indian 'lac' or 'lakh' means a hundred thousand, and refers to the immense numbers in which the lac insects (*Coccus laccæ*) appear at certain seasons on the branches of the trees infested with them.

At the present time true lakes are like those of the early days—namely, insoluble pigments obtained by precipitating solutions of organic colouring matters with metallic salts, &c. They are, indeed, the same coloured precipitates which it is the object of the dyer to produce and fix directly on the fibre, but they are no longer the waste products of the dye-bath, but are specially prepared for the use of artists and others.

The precipitating agent employed in their preparation varies according to the nature of the colouring matter; if the latter is of an acid or phenolic character the active constituent of the former is of a basic character, and *vice versâ*. The essential part of all such lakes consists of colouring matter chemically combined with the active constituent of the precipitating agent.

In some cases, no doubt, there may be colouring matter or precipitating agent mechanically mixed with the true lake, the amount varying according to the proportions and the method of preparation adopted; but these must be regarded as more or less adventitious and not essential to the composition of a lake.

Most of the vegetable colouring matters are of a phenolic character, and the metallic compounds of some are so insoluble that, to produce lakes from them, it suffices to add to a filtered solution of the colouring matter the solution of the metallic salt, for example, alum. In most cases, however, the acid character of the colouring matter is not sufficiently pronounced to enable it to displace the acid of the metallic salt; hence the further addition of an alkali (*e.g.* sodium carbonate) is necessary, in order to neutralise the strong acid of the salt and to liberate the base, with which the colouring matter then combines to form the lake.

If it is possible to employ an alkaline solution of the colouring matter, a lake may be at once obtained on adding to it a metallic salt solution.

Freshly precipitated metallic hydroxides are also capable, in many cases, of attracting and combining with phenolic colouring matters when agitated or heated with their solutions.

It is well to bear in mind that not unfrequently the normal compounds of a colouring matter with a single metallic hydroxide are comparatively soluble, and in these cases the addition of a second metallic salt (*e.g.* calcium salts) may be found necessary to bring about the formation of the lake, which then bears the character of a double salt. All the older lakes, derived from vegetable or animal colouring matters, were produced by one or other of the foregoing methods; and these same methods may be employed with all phenolic colouring matters produced from coal tar. A variety of pigments are now obtained by precipitating certain basic and acid coal tar colours from their solutions by making suitable additions, and although they are not always veritable lakes, they usually bear the name 'aniline lakes,' and are, therefore, most conveniently considered here.

In some cases, no doubt, certain elements of the precipitant combine with the colouring matter, and produce an insoluble pigment to which the term 'lake' may be legitimately extended. In those instances, however, where their production depends upon the property, possessed by many insoluble bodies, of attracting the colouring matters from their aqueous solutions by mere absorption, or in virtue of molecular surface attraction, &c., they cannot be regarded as true lakes. The same remarks apply to the modern pigments from insoluble azo colours (pigment colouring matters) and the developed or ice colours.

Such insoluble substances as are here referred to act as a base or substratum for the colouring matter; they are termed 'carriers,' and consist of kaolin, aluminium hydroxide, barytes, &c.

It is quite usual, however, to find such insoluble bodies mixed with all lakes, not as precipitants, but for the purpose of increasing the body or covering power of the pigment, or as diluents in order to obtain pale shades.

Good lakes should never dissolve in the vehicles by means of which they are applied as pigments, otherwise all their covering power will be lost, and what should be a paint becomes in this case merely a coloured varnish.

LAKES DERIVED FROM PHENOLIC COLOURING MATTERS.

Reds.

Madder-lake. In the preparation of madder-lake extraction of the madder with *boiling* water is avoided, in order not to dissolve those impurities which would cause the production of a less brilliant lake. It is well, first of all, to decompose the glucoside of the madder, and thus increase the actual colouring matter, by steeping in slightly tepid water and allowing the mixture to ferment for 24 hours, then wash with cold water and extract with alum solution at 60°–70°, employing about equal weights of madder and alum. The hot filtered alum solution of the colouring matter is precipitated as an alumina lake by adding sodium carbonate, and the precipitate is washed.

Another method is to precipitate impurities from a hot filtered decoction of madder by adding a small quantity of lead acetate, then filter, add a solution of alum, and precipitate with sodium carbonate.

Matters may be so arranged as to precipitate basic aluminium sulphate instead of aluminium hydroxide, namely, by adding an insufficiency of sodium carbonate to the cooled solution of alum and colouring matter, and then boiling the mixture.

Garancine is preferable to madder for preparing madder-lake, since it does not contain any of the colouring matter in the form of glucoside (ruberythric acid), and the soluble impurities have also been for the most part removed. Extract 1 kilo. garancine repeatedly for several hours with 20 litres of boiling water containing 0·25–0·5 kilo. alum, and filter hot through flannel. On cooling, the colouring matter separates from the filtrate as a flocculent precipitate. This is collected and dissolved in ammonia, and the filtered solution is precipitated with alum, or stannous chloride, or a mixture of both. The colour intensity of the lake varies with the proportions of ammonia and precipitant employed. A method similar to that described for madder may also be employed in preparing madder-lake from garancine.

Bright carmine-red lakes are obtained if, in the preparation of madder-lake, an ammoniacal solution of cochineal-carmine is employed for precipitating the alum solution, instead of the sodium carbonate. This method can be adopted to render the lower qualities of madder-lakes more attractive. Cheap qualities of madder-lakes are also prepared sometimes by extracting mixtures of madder and Brazilwood with sodium carbonate, and precipitating with alum or a solution of tin.

So-called 'crystallised-madder-lakes' are such as contain a certain quantity of potassium or sodium sulphate, &c., and are not to be recommended.

'Madder-pink-lake' is simply madder-lake diluted with about 7 parts of 'blanc fixe' (precipitated barium sulphate).

Madder-lake is entirely, or for the most part, soluble in caustic potash and soda. If chalk or other diluent is present, this may remain undissolved. Boiled with dilute sulphuric or hydrochloric acid, the lake is decomposed, alizarin being liberated in the form of a flocculent or crystalline precipitate. In dilute ammonia pure well-made madder-lake is not soluble (distinguishing test from cochineal-carmine).

References.—Colomb, Bull. Mülh. 12, 307; Dingl. poly. J. 73, 47; Persoz, Traité de l'Impression des Tissus, 1, 507; Merimé, *ibid.* 1, 505; Robiquet and Colin, *ibid.* 1, 505; Khittel, Polyt. Centr. 1859, 81.

Alizarin-red lake is the modern representative of the old madder-lake. It is made either with alizarin (20 p.c.) only, or with mixtures of alizarin and purpurin. Generally the alizarin-red lake contains, in addition to alizarin and aluminium hydroxide, calcium salts, sulphated oil (Turkey-red oil), and sodium phosphate; the exact function of these latter in the formation of the lake is not properly understood, but they exercise great influence on the brightness of the final product as well as in rendering it less sensitive to the action of dilute acids and alkalis.

The Turkey-red oil may be assumed to influence the brilliancy of the shade as in the production of Turkey red by the dyer; the part played by the sodium phosphate is more obscure, but it is always present in the finished lake, and without it there is a loss in brightness.

The absence of calcium salts is also detrimental; in most cases no satisfactory lake can then be obtained.

The general procedure is to dissolve the alizarin in a cold solution of soda, adding in succession the sodium phosphate and Turkey-red oil with thorough stirring to ensure complete admixture. The solution of aluminium sulphate is then run in at such a rate that the evolution of carbon dioxide never becomes very vigorous. When no more gas is given off the requisite amount of lime-water is included and the whole mass stirred for many hours; heat is applied very gradually, so that the boiling-point is reached in 4 or 5 hours, always stirring. After boiling for several hours the lake is allowed to cool, well washed by decantation, filtered, and dried at the temperature of the air.

A method given by Meister, Lucius, and Brüning for their brands of alizarin RR and 1B extra, is as follows:—

2 kilos. aluminium sulphate 18 p.c. are dissolved in 13 litres of water and precipitated hot by the addition of a solution of sodium carbonate (1 kilo. calcined soda in 7 litres of water), stirring continuously. The precipitated alumina is boiled for half an hour to remove the last traces of carbon dioxide, and after standing overnight, the supernatant liquor is decanted off.

To this cold substratum the solution of sodium phosphate (0·16 kilo. in 1·8 litres water) is next added, and subsequently calcium chloride (1·266 kilos. liquor, 24°Bé., diluted with 2 litres of water) in the same manner, stirring well during the additions, and taking care that the former has been thoroughly incorporated before proceeding with the latter.

2 kilos. of the colouring matter mixed with 2 litres of water and 0·6 kilo. of Turkey-red oil (50 p.c.) diluted with 0·8 litre of water are further run in with the same precautions and the whole heated gradually to boiling within 1 hour and boiled for 2½ hours, stirring throughout the whole time as before.

Modern improvements in the methods of manufacturing alizarin-red lakes have furnished results showing a much higher degree of intensity and brightness than was formerly possible. After-treatment of the lake by boiling (steaming) under pressure is said to yield brilliant shades and of great intensity.

Slight additions of tin salts are also added on occasion to brighten the shade.

In making alizarin-red lake it is very essential that the aluminium sulphate employed be free from iron if brilliant lakes are desired. Further, the solutions should be as dilute as possible, as this ensures fineness of structure and softness in the finished article.

Maroon and **claret-red lakes** are produced from alizarin with chromium salts, and **purple lakes** may be obtained by the aid of iron salts.

In connection with the production of alizarin-red lake, the following observations of Liechti and Suida (Mittheil. Gewerb. Museum, Wien, May, 1885) are of interest.

Pure aluminium hydroxide is incapable of directly forming a lake with alizarin—*e.g.* when boiled with an aqueous solution of the latter. The addition, however, of calcium salts at once effects the formation of a lake.

Aluminium-alizarin lakes of definite composition are best prepared by mixing solutions of aluminium salts with an alkaline solution of alizarin. Lakes are also produced if a solution of aluminium acetate mixed with alizarin is heated; or if aluminium hydroxide is heated with alizarin and ammonia, and the mixture is carefully neutralised with acetic acid; or if a mixture of aluminium hydroxide, alizarin, and concentrated sodium acetate solution is heated.

Normal aluminium alizarate $Al_2(C_{14}H_6O_4)_3$, produced by the double decomposition of solutions of aluminium sulphate and ammoniacal alizarin (1 mol. Al_2O_3 to 3 mols. alizarin), forms a purplish-red precipitate, which changes to purplish-black on drying. It is soluble in distilled water and alcohol with a red colour, and in alkalis, especially ammonia, with a fine purplish-red tint. Basic aluminium alizarates of definite composition are prepared by proportionately decreasing the amount of alizarin employed in the above-mentioned decomposition. $Al_4(C_{14}H_6O_4)_3(OH)_6$ is a bright-red precipitate changing to brownish-red on drying. It is soluble in ammonia with a bright-red colour. $Al_2(C_{14}H_6O_4)(OH)_4$ is also a bright-red precipitate, which gives a red powder on drying. In ammonia it is much less soluble than the foregoing. $Al_4(C_{14}H_6O_4)(OH)_6$ is a bright-red precipitate, which still remains a fiery-red powder on drying and is very sparingly soluble in ammonia. All the above basic aluminium alizarates are insoluble in water and in alcohol.

Alkaline solutions of normal aluminium alizarate and of the basic compound

$$Al_4(C_{14}H_6O_4)_3(OH)_6$$

may be mixed with solutions of sodium phosphate, sulphated oil, soap, &c., without undergoing decomposition, but, on neutralising these mixed solutions with acids, very brilliant red lakes are precipitated. Normal aluminium phosphate $Al_2(PO_4)_2$ obtained by precipitation and well washed, cannot be dyed with alizarin, The formation of a lake only occurs when a calcium salt, *e.g.* calcium acetate, is also added. Aluminium-calcium-alizarin lakes of varied composition may be prepared by boiling together definite proportions of pure aluminium hydroxide, calcium acetate solution, and alizarin. They form either dark or bright brownish-red precipitates. All are insoluble in water, and some are insoluble in ammonia. The amount of calcium entering into the composition of the lakes produced in this manner depends upon the amount of alizarin employed and *vice versâ*.

The probable formula of normal alizarin-red lake is given as $Al_2Ca(C_{14}H_6O_4)_3(OH)_2$ by the above-mentioned authors.

Cochineal-carmine. In the preparation of this brilliant scarlet lake, cochineal is extracted in tin-lined vessels with a large quantity of boiling water. Certain additions are made to the filtered decoction, and it is then allowed to stand for several weeks, or even months, in shallow vessels of tin or porcelain, during which period the carmine gradually separates in the form of a fine red powder. The additions referred to vary with different makers, and include the following: potassium binoxalate, acid potassium tartrate (cream of tartar), alum with or without cream of tartar, hydrochloric acid, &c. In all cases the presence of iron must be strictly avoided. The necessary ingredients may also be added to the water with which the cochineal is boiled, in which case the decoction must be filtered hot, since it rapidly becomes turbid on cooling. The addition of gypsum, calcium carbonate, zinc oxide, &c., so usual in other cases, must be avoided, since these would produce violet-coloured lakes.

The manufacture of cochineal-carmine is now very restricted, and the methods employed for producing the finest product have always been kept secret.

According to Alyon and Langlois 500 grams cochineal are boiled for 1½ hours in 30 litres water containing 25 grams sodium carbonate. The decanted solution is well stirred up with 25–35 grams powdered alum, and then allowed to settle about 20 minutes; the clear liquid is poured off, a dilute solution of isinglass or albumen is added, and the whole is heated until the carmine collects together in the form of a coagulum. After cooling and allowing to settle, the supernatant liquid is decanted off, the carmine is collected on a filter, washed, and dried at a low temperature. The deeply coloured filtrate serves for the production of carmine-lake.

Even alum alone could apparently be used as the precipitating agent, according to an old recipe, but it seems likely that in this case water possessing an alkaline reaction must of necessity have been employed. Boil 16 parts ground cochineal for 10 minutes with about 600 parts of water, then add 1 part ground alum, boil a few minutes longer, filter the hot solution and allow the filtrate to stand in shallow porcelain basins. In the course of a few days the carmine is said to separate in the form of a red slimy precipitate, which is collected and dried. The decanted liquor on standing yields a further quantity of carmine of a lower quality; its precipitation is facilitated by the addition of a small quantity of stannous chloride.

The residual cochineal which has thus been only partially exhausted serves for the preparation of carmine-lake.

In other similar recipes a mixture of alum and cream of tartar is used instead of alum only, but in that of Madame Cenette, at one time a celebrated maker of carmine, the statement that the effective precipitating agents are potassium nitrate and potassium binoxalate is difficult to understand.

Chinese carmine is said to be prepared by extracting cochineal with a boiling solution of alum, heating the filtered decoction with the addition of a solution of tin in nitric and hydrochloric acid (*aqua regia*), and finally leaving the liquid to stand till the carmine separates.

Cochineal-carmine is insoluble in water but soluble in alcohol. In ammonia solution it dissolves readily with a purplish crimson colour; from this solution tartaric acid precipitates the original carmine, for although when dried the precipitate has a brownish-red colour it becomes bright red when powdered. The following analysis of cochineal-carmine is given by C. Liebermann (Ber. 18, 1969):

Moisture	17 p.c.
Nitrogenous matter . .	20 ,,
Ash	7 ,,
Colouring matter . . .	56 ,,
Wax	traces

The ash consists of SnO_2 0·67 p.c., Al_2O_3 43·09, CaO 44·85, MgO 1·02, Na_2O 3·23, K_2O 3·56, P_2O_5 3·20. From these analyses Liebermann considers cochineal-carmine to be a peculiar aluminium-calcium-protein compound of the carmine colouring matter, somewhat analogous to the Turkey-red lake, in which alizarin is combined with aluminium and calcium. According to the experiments of the late J. Bedford of Leeds, cochineal-carmine can only be prepared if a calcareous water is employed, or calcium salts are not added during the reaction. Cochineal carmine can, indeed, be readily produced by adding to a cold extract of the dye prepared with a hard water potassium carbonate, alum, and subsequently cream of tartar (or potassium binoxalate) in definite proportion. The carmine precipitate separates very gradually during some days, and has an extremely brilliant character. If a small quantity of stannic chloride is also added to the mixture the precipitation is hastened and the product possesses a more scarlet tint (private communication).

Carmine-lake is simply an ordinary aluminium or tin lake of the colouring matter of cochineal, produced by adding sodium carbonate to a cochineal decoction containing alum or stannous chloride, or both. The latter may also be added to an alkaline solution of the colouring matter.

Florentine-lake is merely a special quality of carmine-lake, containing usually an excess of alumina, and sold in the form of 'drops'; and the so-called Venetian-lake, Hamburg-, Chinese-, Roman-, and scarlet-lakes, are all varieties of Florentine-lake.

Brazil Indian-lake or **lac-lake** is a dark purplish-red lake analogous to carmine-lake, and prepared in a similar manner from the Indian product 'lac.'

Brazilwood lake can be prepared by extracting Brazilwood or peachwood with boiling water, adding alum and tin solution to the filtered decoction, and finally precipitating with sodium carbonate, avoiding excess. Another method is to add precipitated and washed aluminium hydroxide to a filtered decoction of Brazilwood. Freshly prepared decoctions are never suitable for the manufacture of these lakes; they should always be oxidised, by exposure to air or otherwise, in order to change the principle brazilin into the necessary colouring matter brazileïn.

Vienna-lake is a species of Brazilwood lake, prepared in the following manner. A mixture of ground starch (30 kilos.), chalk (10 kilos.), and a little gypsum, is stirred up with a decoction of Brazilwood; then ground alum (1 kilo.) is added and the whole is well stirred for 12 hours and finally allowed to settle. After decanting the clear liquor, Brazilwood decoction is again added to the residual precipitate, together with a further quantity of alum (1 kilo.), and the stirring is continued as before. This process is repeated until the precipitate has taken up sufficient colouring matter and acquired the character of a lake. The decanted liquors are agitated with fresh starch, chalk, &c., in order to yield further quantities of lake.

In the foregoing process the alum is decomposed by the chalk, and the alumina precipitate thus produced combines with the colouring matter. At first the lakes appear violet through the presence of excess of chalk, but with the continued addition of alum they gradually acquire a crimson colour.

Fine dark carmine-red lakes are obtained by adding stannous chloride and cream-of-tartar to a concentrated old decoction of Brazilwood.

Yellows.

Persian-berry lake is prepared by extracting Persian-berries two or three times with boiling water, dissolving alum in the combined and filtered liquors, and then precipitating with sodium carbonate, taking care to avoid excess. The precipitate is collected on a filter, washed, and sold in the form of paste. This lake, containing much starch, and sold in the dry form, is said to be employed in the colouring of sweetmeats.

Persian-berry carmine is produced if stannous chloride is employed instead of alum in the above process. It is a bright orange lake employed by calico-printers.

Persian-berry lakes may also be made after the manner of Vienna-lake, *i.e.* with the use of chalk, alum, and starch.

It is essential to employ only freshly prepared decoctions if bright-coloured lakes are desired.

Quercitron-yellow lake, Flavin-lake, or **Dutch-pink** is made according to the method adopted in the case of Venetian-lake, by precipitating a decoction of quercitron-bark containing alum with chalk. The methods employed in making yellow lakes from Persian-berries may also be used. To ensure bright colours the decoction of quercitron bark is clarified by adding a little gelatin solution, thereby removing the tannic acid. Sometimes milk of lime is used instead, taking care to avoid excess.

It is said that these quercitron colours retain their intensity by gaslight better than all other vegetable yellows, and are hence useful for theatre decorations, &c.

The yellow natural colouring matters, especially flavine and Persian-berries, are still in some demand for the production of green lakes by combination with basic green artificial colouring matters.

The yellow lake is first prepared and a solution of the coal-tar colour precipitated upon it by tannin and tartar emetic. A partial precipitation of the basic colour is effected by the tannic acid in the vegetable colour, but must be completed by a further addition. These lakes are used for wall papers and for colouring toys.

Stil de grain is a low quality of Dutch-pink.

English- and **Italian-pinks** are other qualities of quercitron-bark yellow lakes.

The above lakes are sold in the dry condition in the form of pyramidal-shaped 'drops.' They never possess the brilliancy of those obtained from Persian-berries.

LAKES DERIVED FROM ARTIFICIAL COLOURING MATTERS.

The great increase in the number and variety of coal-tar colouring matters has given rise to a corresponding increase in the colour lakes made from them. Moreover, many of the lakes so formed are at least as fast as any obtainable from natural colouring matters. In consequence the latter have lost much of their former importance.

In the preparation of these lakes the 'base' or 'carrier' upon which the colouring matter is precipitated in a more or less insoluble form is a most important element, since it determines in great measure their brilliancy, covering power, and general qualities.

On the other hand, upon the character of the colouring principle depend other properties of the lake, *e.g.* fastness to light, to spirit, to alkalis and acids.

'Carriers' for lakes are usually very finely divided, insoluble, white (more rarely coloured) materials, such as starch, kaolin (China clay), gypsum, heavy spar (barytes), artificial barytes (blanc-fixe), lithopone, precipitated chalk, kieselguhr, zinc white, red lead, &c. They are intimately mixed with the colour solution, and attract the colouring matter either directly or when suitable precipitating agents are added to the mixture. More often, however, they are formed and precipitated along with the colouring matter, and may then consist of aluminium hydroxide, phosphate, or arsenate, or the first named along with barium sulphate.

The precipitating agent to be employed in any particular case varies according to the nature of the colouring matter—whether acid or basic, for example—and the purpose for which the lake is intended. For lakes employed in decorative painting finely ground barytes is considered to be the most serviceable 'carrier.' Gypsum and kaolin are also used. The chief base for lakes employed in printing wall-papers is blanc-fixe, since it excels all others in giving body and covering power; usually some quantity of alumina, starch, or China clay is admixed with it to render the resulting lake lighter and easier to work. Higher-class papers contain a proportionately greater amount of alumina.

For paper-staining, lithographic, and printing inks the lakes must possess fineness and covering power to a very high degree, and for these aluminium hydroxide, precipitated apart from the colouring matter, is highly esteemed. It is particularly valuable in producing lakes of a transparent nature for use in the three-colour process; some blanc-fixe is often precipitated together with the alumina. Starch, China clay, zinc white, and lithopone are also employed where transparency in the pigment is not of primary importance.

China clay is most largely used with the basic coal tar colours, since for these its attractive power is very marked. Barium sulphate and aluminium hydroxide precipitated during the process of forming the lake, are chiefly used with the azo colours and the acid colouring matters generally. Lead sulphate and red lead are important bases for the eosin lakes.

The proportions of the various materials employed in making the lakes vary considerably according to the desired intensity of the final product.

All lakes should be washed with water, preferably by decantation, till neutral and free from soluble salts. They are sold as pastes or powders, the latter being sometimes in the form of light porous blocks or 'drops' of suitable size.

In all cases the 'extra' brands of all colouring matters should be purchased. They contain the dyestuff in a more highly concentrated form, for ordinary brands are standardised for the use of the dyer by the addition of starch, common salt, or sodium sulphate, and these are useless, or even harmful, from the point of view of the lake manufacturer.

A. *From Basic Colouring Matters.*

The chief methods of precipitating basic colouring matters are—

(*a*) With tannic acid; (*b*) with soap or sulphonated oil; (*c*) with sodium phosphate or arsenate; (*d*) with resin soap; (*e*) with casein or albumen.

(*a*) Tannic acid is the most generally used of all precipitating agents for basic colouring matters, combining with them to form tannates insoluble in water. It is but rarely used alone, since the resulting lakes are dull and extremely fugitive; an addition of half the equivalent quantity of tartar emetic causes the complete fixation of the lake, and improves its properties as regards brightness, fastness to light, spirit, &c. Sodium acetate, or occasionally sodium carbonate, is employed to reduce the acidity of the solution.

The 'carrier' is well mixed with water, the solution of the colour added together with sufficient sodium acetate to combine with the mineral acid liberated by the colour base. The solution of tannic acid is next poured in whilst stirring well, and the precipitation completed with tartar emetic.

This method is most suitable for green and red colours, such as malachite green, brilliant green, magenta, rhodamine, and safranine.

(*b*) A method especially suitable for violet and blue basic colours is based on the precipitation of their colour bases as salts of oleic, palmitic, and stearic acids. A pure soap, containing no free alkali, or a sulphonated olive oil (*e.g.* Turkey-red oil) is employed. Aluminium sulphate, tannic acid, zinc or tin salts are also added on occasion.

(*c*) For basic colours of the methyl violet class a further method consists in the precipitation of aluminium phosphate, together with the added colour by means of aluminium sulphate and sodium phosphate to which sufficient sodium carbonate has been added to produce a perfectly neutral solution.

$$\mathrm{Al_2(SO_4)_3+2Na_2HPO_4+Na_2CO_3}$$
$$\mathrm{=Al_2(PO_4)_2+3Na_2(SO_4)+H_2O+CO_2}.$$

Similarly sodium arsenate, freshly prepared from white arsenic and sodium carbonate, is used in place of sodium phosphate—no addition of soda is then necessary, but care must be taken that the solution is neither strongly acid nor alkaline. As a rule, the precipitation is made in a very slightly acid solution obtained by using a slight excess of aluminium sulphate with addition of sodium acetate.

(*d*) All basic colouring matters form lakes of great brilliancy with resin soap, *i.e.* a solution of colophony in caustic or carbonated alkali. They are precipitated on the carrier along with a metallic salt of the resinate, usually zinc or aluminium.

Auramine, magenta, rhodamine, and patent blue furnish the most satisfactory lakes, and are much used for wall papers. They are of no value for oil or lithographic work, being very fugitive and readily soluble in alcohol and benzene.

It has been found possible to use the benzene solution of these 'resinate' colours for dyeing silk without injuring its finish, lustre, and general appearance. They are also used for preparing coloured varnishes employed in ornamenting metallic surfaces, wood, leather, glass, &c.

(*e*) According to Weber albumen can be employed as a precipitating agent for basic colouring matters with production of lakes of excellent brilliancy, notably fast to water and light. A cold aqueous solution of the dyestuff is mixed with the albumen (also in aqueous solution), stirred into the carrier, and the whole precipitated by raising the temperature to 90° with or without the final addition of a little acetic acid.

Casein may also be applied in a somewhat similar manner.

It is stated that this method is also applicable to the acid colouring matters, and is of special importance for producing non-poisonous eosin and rhodamine lakes.

Blue and violet lakes of great brilliancy may be obtained by mixing certain blue and red colour solutions with precipitated and washed Prussian-blue, which thus becomes dyed.

Potassium dichromate along with starch, &c., has been used as a precipitant with safranine, with which it produces a brownish-red lake changing to carmine-red on drying.

Basic colouring matters are especially remarkable for their ready absorption by inert materials, such as kaolin, starch, diatomaceous earth, green earth, &c., without the aid of any precipitating agent. A solution of the dyestuff is well mixed with the finely divided and well-washed base, and allowed to stand for some time with occasional stirring. A certain amount of colouring matter is attracted from the solution and the carrier becomes, as it were, dyed. Other carriers, *e.g.* gypsum, blanc-fixe, zinc oxide, &c., may be used, but their attractive power for the colouring matter is very small, and they serve chiefly as diluents. The lakes from the silicious earths are the more firmly fixed, and withstand the action even of strong alkalis. For this reason they find application in the manufacture of cheap lime washes.

Coloured powders, prepared according to these latter methods, can scarcely be regarded as true lakes, as they mostly give up their colouring matter on repeated washing.

B. *From Acid Colouring Matters.*

The great majority of the acid colouring matters referred to here are the sulphonic acid derivatives of certain colour bases and azo colouring matters derived from benzene, naphthalene, &c. With these barium chloride is almost exclusively employed as the precipitating agent; a further addition of aluminium sulphate is also often made, especially if the colouring matter exhibits mordant dyeing properties according to the law of Liebermann and Kostanecki.

More rarely, lead salts replace barium chloride.

Some of the phenolic colouring matters which possess special features may be included under this head, notably the eosins. Lead acetate or nitrate is especially suitable as a precipitating agent for colours of this class.

Other suitable materials are alum, aluminium acetate, calcium, magnesium, zinc, or stannic salts; as a rule, they are used in conjunction with caustic or carbonated alkali.

As in the case of the basic colour lakes, so here, the 'base' or 'carrier' upon which the lakes are precipitated is of great importance, and the reader is referred to what has been said already upon this point.

The standard method for the formation of lakes from acid colouring matters containing the sulphonic acid group is that with aluminium sulphate and barium chloride. The aluminium sulphate is precipitated as hydroxide in the first instance by soda, the colouring matter stirred in and then precipitated by the addition of barium chloride. In this way part of the 'carrier' is also produced, in the form of artificial barytes, at the moment of precipitation through the interaction of the barium chloride and the sodium sulphate resulting from the decomposition of the aluminium sulphate, and not only is the precipitation rendered more complete thereby, but also a very intimate admixture of the 'carrier' and precipitated colour is secured.

A proportion of inert 'carrier,' *e.g.* heavy spar, kaolin, lithopone, may also be added to the solution of aluminium sulphate before precipitation when lakes of greater opacity or less tinctorial power are desired; an extra addition of Glauber's salt before the final precipitation, will bring about the same result by increasing the amount of artificial barytes produced. Replacing the aluminium sulphate by alum yields lakes of a higher quality and valuable for printing purposes. They are, of course, more costly to manufacture.

A typical example of this method, published by the Farbwerke vormals Meister Lucius and Brüning, Hoechst am Main, is the following:—

30	parts	aluminium sulphate	1/100 solution
12	,,	calcined soda .	1/100 ,,
12	,,	colouring matter .	1/50 ,,
42	,,	barium chloride .	1/100 ,,

Precipitate at 50°–60°C. This method is stated to be suitable for the various brands of azo scarlets.

Reds. These are chiefly derived from the azo colouring matters. A great variety are now on the market, furnishing shades from a very bright scarlet to a dark bluish-red. Such are Ponceau 2G, G, GR, R, 2R, 3R, &c., Fast red, Bordeaux red, Crocein scarlet, &c.

Red lakes, in nearly all cases, are shaded by admixture with other colours, especially the various brands of oranges (*see* below under *Combined Lakes*). In such cases it is of considerable importance whether the colours are dissolved separately or together, the latter method often producing brighter lakes than the former.

Generally speaking, complete precipitation is obtained by the use of barium chloride upon a 'base' of alumina with or without the admixture of an inert diluent, blanc-fixe being produced simultaneously with the precipitation; certain colours are more difficult to throw down completely, but this may be obviated by suitable variations of quantities, temperature, dilution, &c. The addition of a little Turkey-red oil frequently has a favourable influence.

Another method in the case of some red azo colouring matters consists in treating a solution of aluminium sulphate with milk of lime, forming a 'base' of alumina and calcium sulphate. The colour is thrown down upon this by the addition of barium chloride, and at the same time the calcium sulphate is replaced more or less completely by blanc-fixe. The resulting lakes are said to be very soft and light.

The milk of lime may be replaced by levigated chalk with advantage.

Eosins. These colouring matters give scarlet and crimson lakes of great brilliancy, some of which (the so-called 'vermilionettes') are employed as substitutes for vermilion. They are mostly very fugitive. For yellowish-reds a yellow shade of eosin is employed; for reds, gradually increasing in blueness, erythrosine, phloxine, cyanosine, and rose bengal may be used. The usual precipitants are lead salts, 1 part pure eosin being precipitated by 1 part lead acetate, or 0·75 lead nitrate. Aluminium, tin, and zinc salts are also used.

The nature of the precipitating agent influences the shade of the resulting lake; thus lead acetate gives more yellowish products than lead nitrate from the same colouring matter. Lead salts give blue, tin and aluminium salts yellow shades.

For 'vermilionettes' red lead is a suitable base, with or without the addition of small quantities of lead sulphate or barytes. Better class varieties are made with chromate-of-lead-orange and alumina, in order to lessen their high specific gravity. Due allowance must be made for the variation in shade caused by the presence of a coloured 'carrier.' Their production is very simple; the solution of colouring matter is mixed with the base, complete precipitation being obtained on the addition of a lead salt.

Printing and lithographic colours (known as *geranium* lakes) are largely produced from the eosin colouring matters. They may be transparent or opaque, according to the special use for which they are intended; they all possess great covering power. Alumina and blanc-fixe—either alone or in conjunction—and lead sulphate are chiefly used as the 'carriers'; or, occasionally, starch, kaolin, or red lead. The colour is precipitated upon them by a lead salt. Aluminium (as alum, &c.) does not produce so complete a precipitation.

If desired the lake may be shaded up by the addition of rhodamine B, which unites with, and is precipitated along with the eosin.

Combined lake pigments are also made with the various brands of azo scarlets and orange II.

Oranges. The methods applicable to the red colouring matters are also suitable for making orange lakes.

Orange II. furnishes a bright lake of good fastness to light, and is in considerable demand on account of its cheapness. Other brands are orange R, O, and fast orange O. For better-class lakes used in printing and lithography brilliant orange G and R are employed.

As stated above, orange colouring matters find frequent application in shading the scarlet azo colours.

Yellows. The number of yellow lakes is comparatively small owing to the superior properties of the various chrome yellows (*see* PIGMENTS). They are employed, however, to shade green lakes in a manner similar to that of the oranges for azo scarlets.

The most important colours used are naphthol yellow S, quinoline yellow S, Victoria yellow, &c.

Greens. The colouring matters mostly employed for these lakes are sulphonic acids of the triphenylmethane series, *e.g.* the various acid greens, but are among the most difficult of all the acid colouring matters to precipitate.

Naphthol green belongs to a different class.

They are only partially precipitated by barium chloride, employing the usual aluminium sulphate and soda method, and special modifications must be resorted to, such as after-precipitation with further quantities of aluminium sulphate or barium chloride, or both at once, reversing the order of precipitation and so on.

The lakes from acid greens (the so-called viridine greens) possess a bluish-green shade. Lakes from naphthol green are particularly fast to light. Better results and a greater range of shades are obtained by admixture with naphthol yellow or quinoline yellow. Combination apparently takes place with the basic amino groups of the acid green with the formation of a less soluble combined colour.

Blues. With the exception of the red acid colouring matters the blues furnish the greatest number of colours for lake-making. A large number of shades are obtainable, but, unlike the scarlets, a separate brand is used for each particular shade, and mixtures are rarely found necessary. Alkali blues (opal blue, water blue, &c.), patent blue, and erioglaucine are chiefly in demand. They are readily precipitated by barium chloride upon a mixed alumina and blanc-fixe or other suitable base. The patent blues and erioglaucines are exceptions; for the former the addition of a little barium hydroxide has been found effective, for the latter some zinc sulphate is added, and this is precipitated by sodium carbonate as mixed hydroxide and carbonate.

For printing purposes alkali blue can be precipitated by Turkey-red oil or soap, and subsequent addition of a lead or aluminium salt, with a suitable carrier. The latter, again, may be dispensed with, and in such cases the lakes often exhibit a magnificent lustre.

Violets. Very few violet lakes are manufactured from acid violet dyestuffs, although they are very much faster than the corresponding lakes from basic colours. Fast acid violet is principally employed. They are all expensive to make, and only find application for special purposes.

A very blue violet is formyl violet S4B; it furnishes lakes suitable for the manufacture of printing inks.

All these colours are precipitated by barium chloride upon a suitable 'carrier.'

C. *From Mordant Colouring Matters.*

Besides the very important alizarin-red lakes already described, a certain number of other adjective colouring matters are used for lake making. They are mostly closely related to alizarin itself, *e.g.* alizarin orange, brown, bordeaux, yellow, green, black, blue; acid alizarin blue, and galloflavin, cœrulein, and gallein are also employed. They furnish lakes very fast to light, although they cannot compare in brilliancy of shade with other, but much more fugitive lakes from basic and acid colours.

Lake formation is brought about in the same manner as with alizarin red, the general principle involved being the precipitation of an alkaline solution of the colour by aluminium hydroxide.

Colours which do not dissolve in soda require a modification or reversal of the usual method; they are stirred up with the solution of aluminium sulphate (or alum), and combination is effected by addition of soda, sodium phosphate, and Turkey-red oil.

The Badische Anilin und Soda Fabrik publish a special method for cœrulein:

22 lbs. colouring matter in 27½ gallons of water with 44 lbs. sodium bisulphite (40°Bé.) are well mixed and allowed to stand for 12 hours; then heated to 70°C. with a further 27½ gallons of water, filtered, and the filtrate diluted with 110 gallons water. The whole is then raised to boiling, and 44 lbs. potassium alum added. After half an hour's boiling a final addition of 33 lbs. sodium bisulphite is made, the boiling again continued for half an hour, and the lake filtered, washed, and dried at the ordinary temperature.

D. *From Insoluble Colouring Matters.*

A series of azo colours insoluble in water are now made by the principal German colour-works and sold in paste form for working up into lakes, according to specially adapted methods. The range of shades varies from yellow to bluish-red. The series of 'pigment' colours (Meister Lucius and Brüning) may be mentioned, *e.g.* pigment chlorine GG, pigment orange R, pigment red G and B, pigment purple A, and lake red C and D.

Also the autol orange and red and lithol red of the Badische Co., together with the helio purpurin and helio fast red of Bayer & Co. and the 'red for lakes' of the Berlin Aniline Co.

They are mixed with suitable 'carriers' such as heavy spar, lithopone, orange lead, magnesium oxide, and chalk. Frequently the mixture is simply ground together in the cold; another method is to heat to boiling and add barium chloride. Salts of magnesium, copper sulphate, and ferrous sulphate with Turkey-red oil are also used. The dry lakes are subjected to prolonged grinding with zinc white, orange lead, &c., this process greatly increasing their intensity. They are employed for lithographic and printing inks, as well as for oil and varnish colours and possess good brilliancy, whereas many of them are exceptionally fast to light as well as to alkalis and spirit.

E. *From Developed Azo Colours.*

The application of the 'ice colours' to carriers for the production of lake pigments was a natural outcome of their successful use upon textile fibres.

At the present time the method is in very general use as the lakes made after this manner are distinguished by their fastness to light and other valuable properties. Practically all shades are obtainable except a green.

The pigments are all produced by the diazotisation of an amino followed by coupling with a phenol or another amine in a solution which contains the 'base' or 'carrier' in suspension.

The chief amines used in diazotising are: *m*- and *p*-nitraniline, the nitro-toluidines, anisidine, nitrophenetidine, benzidine, tolidine, α- and β-naphthylamines. Bluer shades, but less fast to light, are obtained from aminoazobenzene and -toluene.

The diazo compounds are coupled with various phenols and amines, especially β-naphthol which produces very bright lakes fast to water (the *insoluble azo-colours*). Other phenols used are phenol itself, resorcinol, α-naphthol, and its disulphonic acid, and β-naphtholdisulphonic acid.

The principal amines are diphenylamine and *m*-phenylenediamine.

Certain precautions are necessary to produce lakes of maximum brightness, *e.g.* care must be taken to regulate the proportions of acid and alkali so that a neutral liquor is present when the formation of the lake is complete. In practice a little sodium acetate is added, acetic acid having a less harmful action than free hydrochloric acid. An alkaline liquor renders the lake dull and dirty in shade.

The following recipes (published by Chem. Fabrik Griesheim-Elektron) will best illustrate the manufacture of these lakes.

A base (A) is prepared from solutions of
1330 grams aluminium sulphate
650 ,, calcined soda,
490 ,, barium chloride.

The precipitate is washed thoroughly and well mixed with the alkaline solution of β-naphthol (B) prepared from
300 grams β-naphthol dissolved in
300 c.c. caustic lye (34°Bé.) and 2 litres boiling water.

Add 300 grams calcined soda in 3 litres cold water,
180 grams Turkey-red oil,
300 grams sodium acetate, making the whole up to 10 litres.

Into this is run the diazo solution (C) from
280 grams *p*-nitraniline dissolved in
600 c.c. hydrochloric acid (21°Bé.) and 2 litres boiling water.

The temperature of this liquid is then reduced to 10°C. by addition of 2 litres cold water and ice and then diazotised with a solution of 144 grams of sodium nitrite.

The precipitated lake is washed thoroughly and dried. The above recipe is said to yield a deep-red shade.

The azophor reds of M.L.B. may be used in place of the diazotised bases.

F. *From Sulphide Colouring Matters and Indigo.*

Within recent years a number of processes have been patented for the manufacture of lake-pigments from the vat dyestuffs, especially the sulphide colours. They are brought into solution as in dyeing cloth and precipitated upon a base by various means.

According to one such patent, taken out by Cassella & Co., the dyestuff (25 p.c. paste) is dissolved in 1 p.c. sodium sulphide and precipitated upon barytes or other suitable 'carrier' by the addition of sodium carbonate and barium chloride.

In another method, patented by the Berlin Aniline Co., the dyestuff is dissolved in sodium sulphide, a solution of barium chloride added, and oxidation brought about by blowing air through or adding manganese dioxide.

For instance, 20 parts sulphur black T extra are dissolved in a solution of 15 parts sodium sulphide, a solution of 25 parts barium chloride run in and air blown through the mixture.

Lakes may also be obtained from indigo. They are said to be exceptionally fast and especially suitable for producing very bright combined lakes.

COMBINED LAKE PIGMENTS.

As already mentioned a lake is frequently produced by the precipitation of more than one colouring matter, either separately or in conjunction, upon the 'carrier.' The colours may be of similar chemical nature, but varying shade, or they may differ absolutely in both these respects. To the first class belong, for example, the numerous scarlet lakes obtained by combining orange and scarlet colouring matters of various shades.

Lakes belonging to the second class differ materially both in shade and properties from any member of the combination used to produce the pigment, *e.g.* the maroon lakes made from scarlets combined with magenta or safranine.

For the latter lakes and others of the same class the initial colour is always either red, orange, or yellow, and from these all possible shades from bluish-red to yellowish-green are obtained by the addition of other colours such as magenta, safranine, methylene blue, malachite green, acid green, and even diamond black.

The methods available for manufacturing these combined lakes are obviously too numerous for detailing here, but a few general outlines and precautions may be indicated. Thus due consideration must always be given to the acid or basic character of the colours used and suitable means of precipitation arranged. Acid and basic colours should never be dissolved together, since combination takes place often with the production of a dark resinous precipitate. The same applies to colours such as the acid greens, which contain groups capable of combining with the acid or basic groups of the second colour.

The first colour may be made into a pigment (termed the 'initial lake'), upon which a second colour is then precipitated by suitable reagents. When, as most frequently happens, the initial lake is prepared from a soluble azo colour by means of barium chloride, and a basic colour is thrown down upon it, care must be taken that the precipitating agent used in the latter case does not affect the pigment first formed. For this reason materials such as Turkey-red oil and resin soap must be excluded, and the tannic acid and tartar emetic method is the only one really suitable for this purpose.

Analysis of Lake Pigments.

The analysis of the colouring matters in a lake is often a matter of great difficulty, and the subject remains largely in an empirical state. The composition of the 'base' or 'carrier,' on the other hand, presents no serious difficulties; a portion of the lake is incinerated and the residue examined by the usual processes of qualitative analysis. In this way the presence of mineral pigments to which coal-tar colours have been added may also be detected. Valuable indications may often be given by the presence of the precipitating agent in the mineral residue, *e.g.* a red lake which is found to contain lead is most likely to have been produced from a colouring matter of the eosin series, &c.

Other properties, chemical and physical, also furnish important evidence, the colour, fastness to light, to acids, alkalis, spirit, &c. Further, the selling price of a lake will often be a deciding factor where two colours are under consideration, of similar shade but different in price.

The class of colouring matter from which any given sample of a lake may have been derived can generally be settled with considerable precision by employing the schemes drawn up by various authors for the analysis of dyestuffs, both on the fibre and in the solid state, making allowance for the alterations in properties brought about by the presence of the carrier and precipitating agent. The identification may be carried further by noting the behaviour of the sample towards such reagents as sulphuric acid, caustic soda, hydrochloric acid, alcohol, &c.; but where more than one colouring matter is present the only satisfactory method of determining the shading colours is by trials in the laboratory or by comparison with a series of standards. Modern pigments, as previously stated, are mostly examples of 'combined' lakes, and in such cases, though the principal constituent may be identified, it is frequently all but impossible to detect the small quantity of the secondary colours present by any process of direct analysis. In this case it is best to ascertain their nature indirectly by a comparison with lakes specially prepared for the purpose.

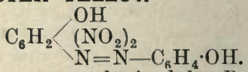
For the analysis of lake pigments.—Tests for Coal-tar Colours in Aniline Lakes, Geo. Zerr, translated by Mayer. A. G. P.

LAMPBLACK is the soot or finely divided carbon produced by the imperfect combustion of various substances of a fatty or resinous nature, such as vegetable and animal oils, pinewood, and dead oil; and it may be taken that whatever the combustible material which, on full exposure to the oxygen of the air, produces the best illumination, that material will, if partially deprived of air, produce the greatest amount of sooty deposit. The German mode of manufacturing lampblack consists in collecting it on a woollen cloth exposed to the smoke emitted from resinous woods burning in a close furnace. The cloth being shaken from time to time, the particles are detached and collected. Lampblack is employed in the manufacture of printing-inks and pigments (*v.* Indian ink; Carbon).

LANCASTER YELLOW



$$C_6H_2\left<\begin{array}{l}OH\\(NO_2)_2\\N=N-C_6H_4\cdot OH.\end{array}\right.$$

A colouring matter obtained by P. Greiss, in 1875, by the action of picramic (*iso*purpuric) acid on phenol. Sparingly soluble in water; soluble in sulphuric acid, with reddish-yellow colour. Dyes silk and wool in an acid bath brownish-yellow. No longer used.

LANOLIN *v.* Cholesterol.

LANTHANUM. Sym. La. At.wt. 139·0. Crude lanthana was obtained from the cerite earths in 1839 by Mosander, who afterwards separated this material by fractional crystallisation of the sulphates into lanthana and 'didymia' (neo- and praseo-dymia).

Sources.—The minerals containing the cerite metals, *e.g.* cerite, orthite, monazite, and lanthanite (native lanthanum carbonate containing didymium).

Separation. If the material employed as the source of lanthanum contains considerable quantities of yttrium earths a preliminary separation of the two main groups may be effected with sodium sulphate.

Methods of Isolation depending on Differences in Basic Strength.

The separation of lanthana from 'didymia' is quickly effected, although with some loss of material, by adding magnesia to a boiling solution of the mixed salts until the liquid ceases to give the characteristic absorption bands of neodymium and praseodymium, the less basic oxides of these elements being precipitated, whilst the more basic lanthana remains dissolved (Muthmann and Rölig, Ber. 1898, 31, 1718; R. J. Meyer and Marckwald, *ibid.* 1900, 33, 3009). Fractional precipitation with ammonia or caustic soda is hardly to be recommended for experiments on a large scale, because of the difficulty of collecting and washing the hydroxides. Moreover, ammonium salts are decomposed by lanthana and 'didymia' so that these bases are not effectively removed from solution by ammonia.

An interesting modification of the basic method consists in utilising the ignited mixed oxides of the rare earth metals to precipitate fractionally an equivalent proportion of these metals from the neutral solution of their nitrates. A solution of the neutral nitrates is divided into two parts, one portion precipitated with oxalic acid, the oxalates ignited, and the resulting oxides added to the remaining portion of the nitrates in 12 p.c. aqueous solution. A vigorous action occurs, the mixture is diluted, heated on the water-bath, and the clear liquid decanted from the precipitate. The fractionation is repeated on both the soluble and insoluble portions. By this process the lanthanum accumulates in the solutions, whilst the praseodymium and neodymium are concentrated in the precipitates (Hermann, J. pr. Chem. 1861, 82, 385; Auer von Welsbach, Monatsh. 1883, 4, 630; *ibid.* 1884, 5, 508; Schottländer, Ber. 1892, 25, 378).

Boiling the rare earth oxides with ammonium salts leads to a fractionation, since the more basic constituents displace ammonia and pass into solution (Drossbach, Ber. 1902, 35, 2826).

The fractional decomposition of the nitrates is another method depending on differences in basic strength (Bettendorff, Annalen, 1890, 256, 159; Urbain, Ann. Chim. Phys. 1900, [vii.] 19, 184).

The mixed nitrates of lanthanum, praseodymium, neodymium, and samarium melt at about 400°–500° to a clear liquid, in which are gradually formed small crystals of basic nitrate. The solution obtained by boiling the product of fusion with 10 parts of water deposits the basic salt. The fusion is then repeated on the normal nitrates from both the insoluble and soluble portions. The lanthanum accumulates in the undecomposed nitrate, while praseodymium, neodymium, samarium, together with terbium and yttrium metals are found in the basic nitrate fractions.

Methods of Isolation by Crystallisation.

By a systematic fractional crystallisation of the double ammonium nitrates

$$R(NO_3)_3,2NH_4NO_3,4H_2O$$

in nitric acid solution, Auer von Welsbach succeeded in separating lanthanum from the other cerite metals, and also in dividing 'didymium' into its components, praseodymium, and neodymium. In this fractionation lanthanum accumulates in the least soluble portions, and is followed successively by praseodymium and neodymium, whilst the most soluble fractions contain samarium and the terbium and yttrium metals (Monatsh. 1885, 6, 477). In operating on large quantities of cerite earths it is more convenient to work in neutral solutions rather than in nitric acid, but in the absence of acid the number of fractions is considerably increased (Wien Sitzungsber. 1903, 11A, 112).

Other modifications of von Welsbach's method have been devised, having for their object the more rapid separation of praseodymium and neodymium (*cf.* Schéele, Ber. 1899, 32, 409; Dennis and Chamot, J. Amer. Chem. Soc. 1897, 19, 799; Demarçay, Compt. rend. 1900, 139, 1019, 1185; Drossbach, Ber. 1902, 38, 2826; Lacombe, Bull. Soc. chim. 1904, [iii.] 31, 570).

By each of these processes lanthanum can be readily separated in a highly purified condition, because it yields the least soluble double nitrates. Last traces of praseodymium are removed by fractional crystallisation of the double carbonates $K_2R_2(CO_3)_4$, $12H_2O$, where R=La, Ce, Pr or Nd, the metals being arranged in ascending order of solubility (R. J. Meyer, Zeitsch. anorg. Chem. 1904, 41, 94).

The classical 'sulphate' method may also be employed in separating lanthanum from the other cerite metals (Holtzmann, J. pr. Chem. 1858, 75, 321).

Metallic lanthanum, m.p. 810°, sp.gr. 6·1545–6·193, sp. heat 0·04637, is best prepared by the electrolysis of the fused chloride, a current of 50 amperes and 10–15 volts being required; it is the most active of the rare earth metals, tarnishing in dry air, and in presence of moisture becoming coated with white hydroxide (Muthmann, Kraft and Weiss, Annalen, 1903, 325, 261; 1904, 331, 1).

When heated in air lanthanum furnishes a mixture of oxide and nitride, and in hydrogen it yields the hydride. With aluminium, lanthanum forms the alloy $LaAl_4$, a crystalline white substance (sp.gr. 3·923), stable in air, and insoluble in nitric acid (*cf.* Muthmann and Beck, Annalen, 1904, 331, 46).

Lanthana (*Lanthanum oxide*) is a snow-white powder produced by heating the hydroxide or oxalate; its sp.gr. is 5·94, or 6·53 after raising to white heat. The amorphous oxide readily absorbs water or carbon dioxide, but the crystalline modification (sp.gr. 5·296) obtained in rhombic prisms by heating lanthanum carbonate in fused borax can no longer be directly hydrated.

The oxide has been reduced to the metal by magnesium but not by aluminium.

Lanthanum hydroxide $La(OH)_3$, a white amorphous precipitate produced by adding excess of ammonia or caustic alkali to the solution of a lanthanum salt, is the strongest base of the rare earth series; it turns red litmus blue, absorbs carbon dioxide from the atmosphere, and displaces ammonia from ammonium salts. In the presence of hydrogen peroxide, the hydroxide gives a hydrated lanthanum peroxide.

Lanthanum hydride LaH_3 or LaH_2 (Winkler, Ber. 1891, 24, 873; Muthmann and Kraft, Annalen, 1903, 325, 279), formed by direct union of its components at 240°, is a black substance more stable in air than the corresponding cerium compound

Lanthanum carbide LaC_2, sp.gr. 5·02, is prepared by heating in a carbon tube, with an electric current of 350 amperes and 500 volts, 100 parts of lanthana and 80 parts of sugar carbon. When decomposed with water the carbide yields 70–71 p.c. of acetylene, 27–28 p.c. of methane, and 2·0 p.c. of ethylene (Moissan, Compt. rend. 1896, 123, 148).

Lanthanum nitride LaN, a black powder prepared from lanthanum and nitrogen at red heat, is decomposed by moisture yielding ammonia and lanthanum hydroxide (Annalen, 1903, 325, 261). A basic lanthanum azide $La(N_3)_2{\cdot}OH,1\frac{1}{2}H_2O$ having explosive properties, is obtained by dissolving lanthana in aqueous hydrazoic acid, and precipitating with ether-alcohol (J. pr. Chem. 1900, [ii.] 61, 408).

Lanthanum sulphide La_2S_3. A yellow powder, sp.gr. 4·9108, obtained by heating the anhydrous sulphate in hydrogen sulphide, is stable in air but decomposed by boiling water. A higher sulphide La_2S_4 has been produced by the further action of hydrogen sulphide on the sesquisulphide at 600° (Biltz, Ber. 1908, 41, 3341).

Lanthanum nitrate $La(NO_3)_3,6H_2O$ crystallises from water in transparent colourless prisms; it loses $5H_2O$ over strong sulphuric acid, and is readily soluble in alcohol. A strong solution of the commercial nitrate is used as a stamping fluid for marking the maker's name or brand on incandescent mantles, so that when these are burnt the design appears in brown on the white thoria skeleton.

Lanthanum ammonium nitrate

$$La(NO_3)_3,2NH_4NO_3,4H_2O$$

monoclinic crystals, is isomorphous with the corresponding double salts of the other cerite metals (Kraus, Zeitsch. Krist. 1901, 34, 307).

Lanthanum magnesium nitrate

$$2La(NO_3)_3,3Mg(NO_3)_2,24H_2O$$

separates in lustrous colourless rhombohedral prisms belonging to the hexagonal system. Lanthanum also forms well-defined double nitrates with pyridine, quinoline, and other organic bases.

Lanthanum sulphate $La_2(SO_4)_3,9H_2O$ is the most stable of three hydrates, and the least soluble sulphate of the rare earth series, its solubility diminishing with rise of temperature; it separates in hexagonal prisms, isomorphous with the cerous salt $Ce_2(SO_4)_3,9H_2O$. The anhydrous sulphate is produced by heating the hydrate with strong sulphuric acid, when the acid sulphate $La(SO_4H)_3$ first produced is afterwards decomposed above 280°. The double sulphates $La_2(SO_4)_3,3K_2SO_4$ and

$$La_2(SO_4)_3,Na_2SO_4,2H_2O$$

are sparingly soluble, particularly in the presence of excess of alkali sulphate.

Lanthanum fluoride LaF_3 prepared in the anhydrous state by burning lanthanum carbide in fluorine (*cf.* Moissan, *l.c.*) and as a gelatinous precipitate $2LaF_3,H_2O$ by the interaction of hydrofluoric acid and lanthanum acetate; the sulphate yields the acid fluoride $2LaF_3,3HF$.

Lanthanum chloride $LaCl_3$, m.p. 907°, sp.gr. 3·947, is prepared by the general methods for preparing anhydrous chlorides (*cf.* CERIUM; and Matignon and Bourrion, Compt. rend. 1904, 138, 627; 1905, 140, 1181; Ann. Chim. Phys. [viii.] 5, 127); it is a colourless compound dissolving in water or alcohol with considerable generation of heat. In aqueous solution this salt shows very little hydrolytic dissociation; its hydrate $2LaCl_3,15H_2O$ or $LaCl_3,7H_2O$ forms triclinic crystals, the alcoholate is $LaCl_3.2C_2H_5{\cdot}OH$ (Zschiesche, J. pr. Chem. 1868, 104, 174; Cleve. Bull. Soc. chim. 1874, [ii.] 21, 196). The following double chlorides $2LaCl,3PtCl_4,24H_2O$; $LaCl_3,PtCl_4,13H_2O$; and $LaCl_3,AuCl_3,10H_2O$ have been described.

Lanthanum platinocyanide

$$2La(CN)_3,3Pt(CN)_2,18H_2O$$

forms yellow fluorescent prisms with a blue reflex.

Lanthanum acetate $La(C_2H_3O_2)_3,1\frac{1}{2}H_2O$, thin prisms, furnishes in the cold with ammonia a gelatinous precipitate of basic acetate, which, when mixed with solid iodine, becomes blue like starch iodide. This reaction, which does not occur with the nitrate or with the precipitate from boiling solutions of the normal acetate, depends on the colloidal nature of the basic salt, the colour being due to an adsorption compound. Although this colouration is used as a test for lanthanum it is uncertain so long as other elements are present (Biltz, Ber. 1904, 37, 719).

Lanthanum oxalate $La_2(C_2O_4)_3$, 9, 10, or $11H_2O$, a white curdy precipitate becoming crystalline, is more soluble in acid or in aqueous ammonium oxalate than the oxalates of other rare earth metals (*cf.* Cleve, Bull. Soc. chim. 1874, [ii.] 21, 196; Power and Sheddon, J. Soc. Chem. Ind. 1900, 19, 636; Brauner and Pavlíček, Chem. Soc. Trans. 1902, 81, 1243).

Lanthanum acetylacetonate $La(C_5H_7O_2)_3$, colourless needles, m.p. 185°, crystallises from water with $3H_2O$ (Annalen, 1902, 323, 26; 1904, 331, 334).

Spectra of lanthanum.—Spark and Arc Spectra, *v.* Exner and Haschek, Die Wellenlängen der Bogenspektra, I. and II. 1904; Rowland, A Preliminary Table of Solar Spectrum Wave Lengths, 1896.

Unless rendered impure by the presence of traces of other rare earths, lanthana and lanthanum salts do not become luminiscent *in vacuô* under the influence of cathode rays.

G. T. M.

LAPIS-LAZULI (Ger. *Lasurstein*; Fr. *Outremer*). An opaque precious stone valued for its rich deep blue colour. It takes a good polish, and is much used for small ornaments and for inlaying. Formerly it was the only source of the then valuable pigment ultramarine, which is now manufactured on a considerable scale.

Rather than being a simple mineral, it is a mixture of minerals, amongst which the members of the sodalite group predominate, together with calcite, pyroxene, amphibole, mica, scapolite, felspar, iron-pyrites, &c. The material is really an impregnation of various secondary minerals in a crystalline limestone, and has been formed by the contact-metamorphism of calcareous rocks at their junction with granite. The minerals of the sodalite group have been investigated by Brögger and Bäckström, and for the predominant blue constituent of lapis-lazuli they proposed the name *lazurite* (Zeitsch. Kryst. Min. 1890, 16, 231). This is a sodium aluminium silicate and sulphide, and is essentially the same in composition as artificial ultramine. The formulæ they give for the members of the sodalite group are:

Sodalite $Na_4(AlCl)Al_2(SiO_4)_3$
Haüynite $(Na_2,Ca)_2(NaSO_4{\cdot}Al)Al_2(SiO_4)_3$
Noselite $Na_4(NaSO_4{\cdot}Al)Al_2(SiO_4)_3$
Lazurite $Na_4(NaS_3{\cdot}Al)Al_2(SiO_4)_3$.

An analysis by Brögger and Bäckström of lapis-lazuli from Central Asia gave:

SiO_2	Al_2O_3	CaO	Na_2O	K_2O	SO_3	S	Cl	Total.
32·52	27·61	6·47	19·45	0·28	10·46	2·71	0·47	99·97

Here, as in all other analyses, sulphate and chloride are present in addition to sulphide, and, in fact, the haüynite molecule actually predominates in this case.

Lazurite is decomposed and decolorised by hydrochloric acid, with the separation of gelatinous silica and evolution of hydrogen sulphide. It is occasionally found as deep-blue crystals with the form of the rhombic-dodecahedron; sp.gr. 2·38–2·42; hardness 5½.

The best quality of lapis-lazuli comes from Badakshan in Afghanistan; the mines here were visited by Marco Polo in the year 1271. Another occurrence of importance is at the western end of Lake Baikal in Siberia; here the material varies in colour from deep-blue to light-blue, violet, and green. Large blocks of pale-blue lapis-lazuli are also found in the Chilean Andes, and small crystals in the ejected limestone blocks of Monte Somma, Vesuvius.

L. J. S.

LARCH TURPENTINE *v.* OLEO-RESINS.

LARD. The term 'lard' was originally used to denote the fat rendered from the leaf of the pig, *i.e.* the fat from the kidneys and the bowels. The increased consumption of lard during the latter half of the last century (which has seen the rise of large American packing houses manufacturing lard on an enormous scale) has chiefly contributed to the extension of the above definition of lard, so that at present 'lard' denotes the fat from any and every part of the hog.

Leaf lard is still being sold on a small scale as 'butcher's lard' and 'home-rendered lard,' but the amount is insignificant in comparison with the enormous quantities produced in the slaughter-houses of the United States and Canada. The term 'bladder lard,' so named from the package, used to be leaf lard rendered in small establishments. At present this term is still used to denote the best quality of home rendered, as also of American lard of the quality (*c*) (*v. infra*). The commercial quality 'keg lard' contains, besides leaf lard, the fat taken from other parts of the animal. This extension of the term 'lard,' viz. that it denotes the fat taken from any and every part of the hog, has been implicitly acknowledged by the Adulteration Laws of the United States, according to which lard is defined as the 'rendered fat from slaughtered, healthy hogs, free from rancidity and containing no more than 1 p.c. of substances other than hog fat.'

The production of, and trade in, lard at present may be considered as being completely dominated by the processes and trade usages in vogue in the United States, especially in the large packing houses of Chicago.

The rules of the Chicago Board of Trade define the following brands of edible lard: (*a*) Neutral lard No. 1; (*b*) Neutral lard No. 2 ('Imitation neutral lard'); (*c*) Leaf lard; (*d*) Choice lard, choice kettle-rendered lard; (*e*) Prime steam lard. These brands will be described here in the order in which they are produced in the factory, so as to give, at the same time, a concise account of the manufacturing processes involved in the production of edible lard.

(*a*) **Neutral lard** is prepared from the leaf, which is taken out of the animal immediately after it has been slaughtered, freed from the flesh and skin, and chopped up in a fat-cutting machine into small lumps, which are thoroughly washed with iced water. The comminuted mass is then delivered into jacketed rendering vessels, in which it is heated up to a temperature of 40°–50°. The lard so obtained is practically neutral, and is used almost exclusively in the manufacture of margarine (termed in America 'oleomargarine').

(*b*) **Neutral lard No. 2** ('Imitation neutral lard') is the fat taken from the back, and rendered in a similar manner.

As the Neutral lard No. 1 and Neutral lard No. 2 are not 'cooked' (*i.e.* not rendered at a higher temperature than 50°), these lards do not keep well, and cannot, therefore, be used, like 'leaf lard' and 'steam lard,' for domestic purposes.

(*c*) **Leaf lard ('Flare lard,' 'Flair lard').** When the residue from (*a*) is subjected to steam heat under pressure in a digester, the leaf lard of commerce is obtained. Formerly this was the only kind of lard recognised by the Chicago Board of Trade, and was prepared from the whole leaf, and thus embraced the three qualities described under (*a*), (*b*), and (*c*). This lard is not exported, but is consumed at home. The Adulteration Laws of the United States now define leaf lard as 'the lard made from the internal fat of the abdomen, excluding that adhering to the intestines, and having the iodine number 60.'

The portions of the leaf remaining after the rendering of Neutral lard No. 1, are put together with the residues obtained in the preparation of Neutral lard, and 'rendered' by steam heat in open steam-jacketed kettles or in autoclaves (digesters).

Thus (*d*) '**Choice lard**' or '**Choice kettle-rendered lard**' is obtained. The latter term is due to this fat being rendered in steam-jacketed kettles, which represent the survival of the old-fashioned open kettles, in which butchers used to render the lard over free fire. Such lard has the peculiar, pleasant flavour of fried fat, and therefore the name 'Kettle-rendered lard' has been retained, even after the rendering over free fire had given way to heating by means of steam. In large establishments the rendering is carried out under pressure in digesters. The regulations of the Chicago Board of Trade define 'Choice lard' as lard made from leaf and trimmings only, either steam or kettle rendered. The manner of rendering is branded on each tierce. Its flavour is much superior to that of 'Prime steam lard.'

(*e*) **Prime steam lard,** also termed 'Standard prime steam lard,' is obtained from any trimmings not used up in the production of lard (*d*), and all other parts of the hog that will yield lard, with the exception of the liver, lungs, the intestines proper, and that part of the heart which is free from fat. This quality is rendered in digesters in a similar manner to lard (*d*). Such lard is passed solely on inspection, and as the inspector has no authority which enables him to supervise rendering establishments, in order to secure a proper control, we may take it that prime steam lard consists of the fat from any part of the hog, either from the whole animal, or from portions of it (head, foot, &c.).

The foregoing qualities represent the commercial qualities of *edible* fat.

All those parts of the hog which have not been used for the production of the above qualities are worked up in autoclaves, in order to obtain the last portion of the fat they contain. The fat so recovered is termed 'Yellow grease.' With this yellow grease are mixed all the refuse fats resulting in the course of rendering the edible qualities. 'Yellow grease' is also obtained from the fat rendered from all the animals that have died in the 'stock-yards.' If in the working up of animals which have died in transit, the intestines, &c., have been removed, a whiter quality of fat is obtained. This is sold as 'white grease' for manufacturing purposes. A lower kind of grease than the 'Yellow grease' is 'Pig's foot grease,' a by-product obtained in the glue department of the rendering houses. This 'Pig's foot grease' finds an outlet in the manufacture of low class lard oil and of soap.

The two qualities of 'Neutral lard' hardly require refining. After the clear melted lard has settled in the jacketed vessel, it is run off into a receiving tank, in which the last traces of water and any fibres are precipitated by sprinkling salt over the fat. In fact, this part of the manufacture simulates exactly the processes employed in the preparation of 'Premier Jus.' The settled lard is then immediately ready for use in the manufacture of margarine—which is mostly produced in the same works,—or is run into tierces for shipment.

The next qualities of edible lard usually undergo a somewhat more complicated process of refining, consisting in treating the melted fat in a refining vessel with fuller's earth, and blowing it at the same time with air. The fat is thereby also deodorised. It is next pumped through a filter press, from which the clear, bleached lard is run over horizontal cylinders cooled by brine. The warm lard is thus quickly chilled on the cooled surface of the lard cooler, and forms a continuous sheet of solidified fat. Before the cylinder dips again into the warm lard on the other side, the solidified mass is removed by a scraper ('doctor'), and falls into a trough. In this trough a rotating screw conveyer breaks up the sheet of fat and carries it forward into a mixer, in which the lard is agitated by a mechanical arrangement. Here 'lard stearine' is added to 'stiffen' the lard, in case it be too soft.

The lard stearin is obtained by subjecting cooled lard in hydraulic presses to a moderate pressure, when the softer portion—lard oil—exudes. The lard stearin either serves in the manufacture of butter substitutes (margarine, 'oleomargarine'), or is used, as described above, for 'stiffening' soft lard. In this country, where the addition of beef fat for 'stiffening' lard is now forbidden, considerable quantities of lard stearin are used.

Leaf lard is the hardest; the lards from the back, &c., are softer. The consistence of the lard is not only conditioned by the part of the animal from which it has been taken, but depends also, and chiefly, on the food which has been given to the animal. Hogs fed exclusively on acorns or on 'tankage' yield a harder lard than hogs fed on maize.

Leaf lard has a granular texture and a salve-like consistence, and should be of pure white colour. The lards which represent mixtures from all parts of the body, especially those manufactured in large slaughter-houses, have no longer a crystalline texture, as the object of the last operation in the manufacture is to destroy such texture and give to the product a smooth appearance.

The lard rendered from the leaf, as also from the back, has an agreeable taste. The lower qualities have an insipid taste; this disappears, however, on standing. Some of the steam lards have an 'animal flavour,' which may be judged by an inexperienced person to indicate admixture with tallow or 'beef stearine.' This flavour also disappears on standing or on warming.

Lard consists of the glycerides of lauric, myristic, palmitic, stearic, and oleic acids, and small quantities of linolic acid (and perhaps also of linolenic acid). The proportion of stearic acid determined in a number of commercial lards, varied from 6 to 24·91 p.c.

The analytical differences between lards from different parts of the hog are best expressed by their iodine values. Since important differences exist between North American and European lards, chiefly and almost solely owing to the mode of fattening, it is important to note that American lards have considerably higher iodine values than lards obtained in Europe. The iodine values of the latter range, as a rule, between 46 and 60. The iodine value of American lard reaches, however, higher figures than 60, and may even exceed 70.

Lard (like butter and olive oil) used to be adulterated on the largest scale. Beef fat, beef stearin, cotton seed oil, cotton seed stearin, and other vegetable oils, amongst which during the last few years cocoanut oil and palm kernel oil predominate, are the adulterants most frequently employed. Such admixtures had been for a long time an openly acknowledged practice in the United States of America, and such expressions as 'refined lard,' 'compound lard,' and 'lard compound' were used to designate a mixture of lard with vegetable oil, chiefly cotton seed oil, and cotton seed stearin. At present, however, the restrictions imposed by law have become much more stringent, and lard exported from the United States under official supervision, may be accepted as guaranteed pure, that is, free from admixture with another animal or with a vegetable fat.

The detection of adulterants in lard plays a most important part in the practice of the public analyst. It is impossible here to follow the various practices of the adulterators of lard and follow up such adulterations through their several stages. The reader must, therefore, be referred to Lewkowitsch, Chemical Technology, ii. 577–615. It may, however, be pointed out that the chief characteristics which the analyst must determine are: specific gravity, melting-point, iodine value of the fat, iodine value of the liquid fatty acids, and amount of unsaponifiable matter. The proportion of the latter is important, inasmuch as admixture of paraffin wax with lard (which had been practised to a considerable extent in former years, and had then been abandoned) appears to have been resumed during the last few years. Modern methods of chemical analysis have rendered the detection of vegetable oils and fats added fraudulently to lard, a somewhat easy process, as the phytosteryl acetate test permits the detection of even as little as 1 p.c. of admixed vegetable oil or fat, and the endeavours of the adulterator to circumvent this test by the addition of a very small quantity of soft paraffin wax have been frustrated by more refined methods of chemical analysis. The detection of cocoanut oil and palm kernel oil is rendered (in addition to the phytosteryl acetate test) somewhat easy by the determination of the volatile fatty acids. In this connection, however, a note or warning must be sounded, as it has been shown recently that hogs fed on copra (as is done in the Philippine Islands) furnish a lard which exhibits the characteristics of lard adulterated with cocoanut or palm nut oil (the cocoanut oil having been pushed forward into the body fat, much as feeding cows with oil cake leads to the pushing forward of the vegetable oil into the milk fat). Detection of added beef fat or beef stearin to lard is more difficult, and the (formerly relied upon) Belfield test, which was supposed to rest on the detection of (beef) stearin, has been shown to be entirely nugatory. The so-called Stock-Belfield test, which aimed at a quantitative determination of added 'beef stearin,' has been shown to be utterly fallacious, inasmuch as the crystals, on the isolation of which reliance was placed, are given by the lard stearin itself. A method proposed by Polenske, viz. to determine the so-called 'difference' between solidifying- and melting-points has been shown to be unreliable.

A considerable amount of lard is consumed in the manufacture of lard substitutes.

J. L.

LARDERELLITE (*Ammonium borate*). A mineral found in the lagoons of Tuscany. It occurs in small crystalline rhomboidal plates.

B_2O_3	72·06

H_2O	18·11
	100·00

(D'Achiardi, Chem. Soc. Abstr. 1900, ii. 600).

LARD SUBSTITUTES consist chiefly of a mixture of lard, or lard stearin with 'beef stearin' ('oleostearin'), cotton seed stearin, cotton seed oil, maize oil, arachis oil, sesame oil, cocoanut oil, and palm kernel oil. In the infancy of this industry these artificial products were sold under such names as 'refined lard,' 'commercial lard.' Other products (*e.g.* 'lard compound') contained no lard whatever, being judiciously prepared mixtures of beef stearin and cotton seed oil. At present, however, all lard substitutes proper contain some lard, or at least 'lard stearin,' as a basis. The manufacture consists simply in mixing the various fats, in the melted state, and oils in a mixing machine, and cooling the mixture rapidly by running it over cooling cylinders, so as to destroy any tendency to crystallisation.

In order to impart to the finished mixture a pure white colour, it is usual to stir air into the fat until it acquires a salve-like consistence. The stirring with air must not, however, be carried too far, as otherwise the lard substitute not only becomes more liable to rancidity, but easily acquires a foamy consistence. J. L.

LASERPITINE $C_{15}H_{22}O_4$. An alkaloid obtained by Kütz (Arch. Pharm. 1883, 221, 161) by extraction with light petroleum of the roots of the white *Laserpitium latifolium* (Linn.). Forms large colourless well-formed crystals belonging to the monoclinic system. Melts at 118°; is insoluble in water and dilute acids. Easily soluble in chloroform and ether, slightly soluble in alcohol and light petroleum.

LASURSTEIN *v.* LAPIS-LAZULI and PIGMENTS.

LAUDANUM. Laudanum is understood in this country at the present day to be the simplest liquid preparation of opium available for medical purposes. The word is an old one, and has undergone considerable change of meaning, but its precise origin has never been ascertained with certainty.

According to some authorities, the term is borrowed from *labdanum* or *ladanum*, an oleoresin of Greek origin, which is collected from various species of *Cistus* (*v.* OLEO-RESINS); while others derive the word from the Latin *laus*, praise, which is supposed to indicate the high esteem in which the medicine has always been held. In a discussion of this question (Pharm. J. [iii.] 17, 404, 424, 503, 584, 644), it is pointed out by Eagle that according to Mathiolus (Comment. Dioscoridis Mat. Med. Lugduni, 1563) certain Italians applied the term laudanum to labdanum, and thus Littré and Robin (Dict. Méd. Paris, 1877) and others give the Italian equivalents of the two words as synonymous. This statement of Mathiolus would appear to have been the source of the view that laudanum is derived from labdanum which has been adopted by several lexicographers and writers on materia medica. Hooper (Lex. Med. London, 1848) and Dunglison (Dict. Med. Sc. Philadelphia, 1868) are, however, on the side of the *laus* derivation, and the remarks of such writers as Crollius (Basilica Chymica, Francofurti, 1611), Bruno (Lex. Castello-Brun. Norimbergæ, 1688), Lemery (Pharm. Universelle, 1716), and others are so decidedly in its favour that the weight of evidence at present appears to be with this hypothesis.

But be this as it may, the term laudanum was applied in the 17th century to indicate solid or semi-solid mixtures which generally, though not always, contained opium (*cf.* Lond. Dispensatory, 1678). These were gradually replaced by liquid preparations, of which the most celebrated was that of the physician Sydenham, 1644–1689, whose life was written by Dr. Johnson. This was the *Laudanum liquidum Sydenhami* of the London Pharmacopœia of 1720, and is represented by the *vinum opii* of recent medicine. A *tinctura opii* of simpler composition has, however, long taken the lead among galenical preparations of opium. This is a liquid extract made with proof spirit, and represents in all important respects the physiological activity of the crude drug. To this tincture the term 'laudanum' is now applied, both in this country and in the United States, not only by writers such as Pereira (Mat. Med. 1853, 2135) and Stillé and Maisch (Nat. Dispensatory, 1886, 1537), but more especially in the practice of pharmacy. The editors of the British Pharmacopœia for 1898 have also added the term laudanum as a synonym for tincture of opium (*cf.* OPIUM). A. S.

LAUREL CAMPHOR *v.* CAMPHOR.

LAUREL OIL, Bayberry oil, is obtained from the berries of the laurel tree, *Laurus nobilis* (Linn.), either by pressing the pounded berries or by boiling them with water. The berries contain from 24 to 30 p.c. of fat. Laurel oil has a green colour; at the ordinary temperature it has a buttery consistence; its taste and aromatic odour are characteristic.

Laurel oil is completely soluble in boiling alcohol; on cooling, crystals of trilaurin separate. Judging from its high iodine value, viz. 66 to 96, laurel oil must contain considerable quantities of olein and perhaps also of less saturated glycerides. From the characteristic numbers which laurel oil gives in analysis, the conclusion must be drawn that the proportion of laurin cannot be very high. The presence of laurin is, however, definitively proved by the fact that on distilling laurel oil *in vacuô*, trilaurin is obtained in the distillate. In the unsaponifiable matter of laurel oil, Matthes and Sander identified melissyl alcohol (myricyl alcohol), phytosterol, and laurane, $C_{20}H_{42}$.

Laurel oil is only used in veterinary practice. It is stated to be adulterated with other fats (lard), coloured green with copper salts. J. L.

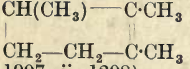
LAUREL WAX. *Myrtle berry wax* (*v.* WAXES).

LAURIC ACID *v.* DODECATOIC ACIDS; and OILS, FIXED, AND FATS.

LAURIN *v.* LAURUS NOBILIS (Linn.).

LAUROLENE and *iso*-**LAUROLENE,** hydrocarbons of the formula C_8H_{14}, first obtained by the distillation of various camphor acids or their salts. (*See* Wreden, Annalen, 1877, 187, 171; Reyher, Inaug-Dissert. Leipzig, 1891, 51; Aschan, Annalen, 1896, 290, 185; Noyes, Amer. Chem. J. 1895, 17, 432; Koenigs and Meyer, Ber. 1894, 27, 3470; Damsky, Ber. 1887, 20, 2959; Moitessier, J. 1866; Walker and Henderson, Chem. Soc. Trans. 1896, 753.)

Laurolene, Δ'-1 : 2 : 3-*trimethyl-cyclo-pentene,*

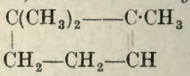


(Eijkmann, Chem. Zentr. 1907, ii. 1208).

Preparation.—(1) By slowly distilling camphanic acid in an atmosphere of CO_2 (Aschan, *l.c.*); (2) by heating sulphocamphylic acid at 170°–180° with aqueous H_3PO_4 (Koenigs and Meyer, *l.c.*); (3) by treating amino-lauronic acid with HNO_3 (K. and M.). Synthesised from αδ-dimethyladipic acid *via* 1 : 2 : 3-trimethyl-*cyclo*-pentanol (Noyes and Kyriakides, J. Amer. Chem. Soc. 1910, 32, 1064).

Properties.—Colourless liquid; b.p. 120°–122°; sp.gr. 0·8097 at 4°/4°, 0·8048 at 10°/10°, 0·8010 at 15°/15°, 0·7974 at 20°/20°, 0·7939 at 25°/25°; mol. mag. rot. 8·987; mol. refraction 61·114 (Crossley and Renouf, Chem. Soc. Trans. 1906, 26); has a sweet odour resembling camphor and turpentine. Rotation very irregular, varies from 0° to +23° and −29°. Combines with 2 mols. Br in chloroform solution; oxidised by HNO_3 to oxalic acid (Crossley and Renouf); oxidised by dilute alkaline $KMnO_4$ to a diketone, b.p. 204° at 750 mm. (corr.), which yields a disemicarbazone, m.p. 194° (corr.) (Noyes and Derick, J. Amer. Chem. Soc. 1910, 32, 1061). With fuming HI on the water-bath yields *laurolene hydriodide*, a greenish-brown, unstable liquid which, heated with zinc dust in 90 p.c. alcohol, yields *dihydrolaurolene*, 1 : 2 : 3-trimethyl-*cyclo* pentane, as a colourless liquid, b.p. 111·5°–114° at 760 mm.; unacted on by Br or $KMnO_4$. It has sp.gr. 0·7718 at 4°/4°; 0·7670 at 10°/10°; 0·7633 at 15°/15°; 0·7596 at 20°/20°; 0·7567 at 25°/25°; mol. mag. rot. 8·332; mol. refraction 61·138.

iso-**Laurolene,** Δ^2-1:1:2-*trimethyl-cyclo-pentene*



(Blanc, Bull. Soc. chim. 1898, 19, 699; Compt. rend. 1906, 142, 1084). Formed by dry distillation of campholytic acid, sulphocamphylic acid, *iso*-campholytic acid, &c. (Walker and Henderson, Chem. Soc. Trans. 1896, 753). Prepared from *iso*-lauranolic acid by heating in sealed tubes for 4 hours at 300° (Blanc, Bull. Soc. chim. 1898, 19, 699); or by distilling with 1½ times its weight of pure anthracene (Crossley and Renouf, Chem. Soc. Trans. 1906, 41). Blanc synthesised it from αα-dimethyladipic acid *via* dimethyl-*cyclo*-pentanone (Compt. rend. 142, 1084).

It is a colourless, mobile liquid, with sweet camphoraceous odour; b.p. 108°–108·2° at 742 mm.; sp.gr. 0·7953 at 4°/4°; 0·7907 at 10°/10°; 0·7867 at 15°/15°; 0·7830 at 20°/20; 0·7795 at 25°/25°; mol. mag. rot. 8·749; mol. refraction 60·565 (Crossley and Renouf). Oxidised by HNO_3 to oxalic acid; oxidised by dilute $KMnO_4$ to dimethyl hexanonoic acid

$$CO(CH_3)C(CH_3)_2CH_2{\cdot}CH_2{\cdot}COOH,$$

with $HgCl_2$ solution gives a sticky amorphous precipitate. Combines with 2 atoms Br, forming 2 : 3-dibromo-1 : 1 : 3-trimethyl-*cyclo*-pentane, m.p. 80°–85°. Heated at 125° with fuming HI yields the *hydriodide*, which, on reduction with zinc-dust in 90 p.c. alcohol, yields *dihydro-iso-laurolene* (1 : 1 : 2-trimethyl-*cyclo*-pentane).

Dihydro-*iso*-laurolene can also be obtained by heating *iso*-laurolene with HI at 200° or with conc. H_2SO_4 (Zelinsky and Lepeschkin, J. Russ. Phys. Chem. Soc. 1901, 33, 549; also 1899, 31, 407). It is a colourless liquid, having a sweet camphoraceous odour, b.p. 113°–113·5° at 750 mm.; sp.gr. 0·7847 at 4°/4°; 0·7800 at 10°/10°; 0·7762 at 15°/15°; 0·7727 at 20°/20°; 0·7694 at 25°/25°; mol. mag. rot. 8·249; mol. refraction 61·078 (Crossley and Renouf).

LAURUS NOBILIS (Linn.). *Bay, Sweet Bay* (*Laurier commun*, Fr.; *Lorbeer*, Ger.).

The classic or noble laurel or bay tree is indigenous to the Levant and is found all along the shores of the Mediterranean. The leaves are used as a flavouring agent, and both the leaves and fruit were formerly employed in medicine.

The fruit, or so-called bay berries, was analysed by Bonastre (J. Pharm. Chim. [ii.] 10, 30) and by Grosourdi (J. 1851, 562). Besides water, a large proportion of starch, lignin, sugar, and small quantities of resin, pectin, albumen, and colouring matter, bay berries contain *solid and liquid fat, volatile oil*, and a *peculiar camphor.*

From the fat, Marsson (Annalen, 41, 330) isolated *lauric acid* $C_{12}H_{24}O_2$, being one of the twelfth members of the $C_nH_{2n}O_2$ or formic acid series of fatty acids. It was subsequently found in numerous other fats (*cf.* Heintz, J. pr. Chem. [i.] 66, 1). Glycerin trilaurate or *trilaurin*

$$C_3H_5(C_{12}H_{23}O_2)_3$$

is associated in the fat with the glycerides of oleic, linoleic, palmitic, myristic, and stearic acids (Staub, Nat. Disp. 1886, 874).

The analytical constants of the expressed oil after being freed from the volatile oil are given by Matthes and Sander (Arch. Pharm. 246, 165), who have also investigated the resinous unsaponifiable matter which is present in the fatty oil. This was found to contain myricyl alcohol; a *phytosterol*, $C_{27}H_{44}O,H_2O$, colourless needles, m.p. 132°–133°; a hydrocarbon, *laurane* $C_{20}H_{42}$, which crystallises from alcohol in slender needles, melting at 69°; and an aromatic unsaturated oily substance.

Bonastre (J. Pharm. Chim. [ii.] 10, 36; 11, 3) was the first to distil a volatile oil from bay berries. It has been studied by Forcke (Arch. Pharm. [ii.] 17, 177); Brandes (*ibid.* [ii.] 22, 160); Bley (Rep. Pharm. 48, 96); Gladstone (Chem. Soc. Trans. 17, 3; 25, 1); Blas (Annalen, 134, 1); Wallach (*ibid.* 252, 94); and Brühl and Müller (Ber. 25, 547). The specimen examined by the last-mentioned investigators distilled between 175° and 275° under ordinary pressure and left a viscid residue. The distillate contained lauric acid, and after treatment with potash and digestion with sodium, yielded a liquid, b.p. 167°–171°. This liquid was found to consist of cineol, pinene, and other hydrocarbons, and is probably the substance described as laurene by the earlier observers. The crude oil also contains large proportions of alcoholic or ketonic compounds which, like menthol or camphor, combine with sodium, the salts so formed being decomposed by water.

Bay camphor or *laurin* $C_{22}H_{30}O_3$ was isolated by Bonastre (J. Pharm. Chim. [ii.] 10, 32) and further investigated by Delffs (J. pr. Chem. [i.] 58, 434) and Marsson (Annalen, 41, 329). The yield is about 1 p.c. It consists of prismatic crystals without taste or smell. It is insoluble in water, but soluble in alcohol and ether, and is chemically neutral and indifferent.

The leaves of *Laurus nobilis* also contain a volatile oil. Examined by Thoms and Molle (Arch. Pharm. 242, 161), free acetic, *iso*butyric, and (*iso* ?) valeric acids were found to be present, also about 1·7 p.c. of free eugenol and about 0·4 p.c. of eugenolic esters. The acid obtained by hydrolysing the oil by alcoholic potassium hydroxide consisted mainly of acetic acid; the other volatile acids present were probably valeric and hexoic. A monobasic acid $C_{10}H_{14}O_2$, m.p. 146°–147°, was also obtained. On fractionating the oil, after the removal of the free acids, phenols, and esters, cineol was obtained. The yield of cineol was equal to 50 p.c. of the original oil. From fractions between 212° and 230°, geraniol was isolated. The fractions of a still higher boiling-point contain oxygenated compounds, probably a sesquiterpene alcohol associated with a sesquiterpene. These fractions, and also the original oil, give an intense blue colouration when dissolved in glacial acetic acid and bromine vapour is blown over the surface of the solution.

The volatile oil of the leaves of the allied Californian laurel, *Umbellularia Californica* (Nutt.), contains the following substances in approximately the percentages given: eugenol, 1·7; *l*-pinene, 6·0; cineol, 20·0; umbellulone, 60·0; safrole, a very small proportion; eugenol methyl ether, 10·0; and traces of fatty acids. *Umbellulone* $C_{10}H_{14}O$ is a colourless oil, boiling at 219°–220° (749 mm.), $[\alpha]_D - 37°$, and has an odour somewhat resembling mint. It is a ketone, and forms compounds with semicarbazide and hydroxylamine (Power and Lees, Chem. Soc. Trans. 85, 629).

The volatile oils obtained from *Laurus nobilis* must not be confused with others bearing similar names, such as commercial bay oil or bayberry leaf oil, distilled from the leaves of the West Indian tree *Pimenta acris* (Kostel.), and which is the flavouring agent in the toilet preparation known as bay rum (Markoe, Pharm. J. [iii.] 8, 1005; Ruse, *ibid.* [iii.] 13, 39); laurel oil of Guiana, natural oil of laurel, or ocotea oil, derived from a tree of Spanish Guiana (Stenhouse, Chem. Soc. Mem. 1, 43; 2, 121); or oil of common or cherry laurel, *Prunus Lauro cerasus* (Linn.) which is similar to volatile oil of bitter almonds. A. S.

LAUTH'S VIOLET *v.* AMINES; METHYLENE BLUE.

LAVA. The term lava is properly applied to those products which issue from volcanic orifices in an incandescent and often in a molten condition, presenting, when cooled, the appearance of slag or clinker, and consisting of rock more or less perfectly fused. It differs from other volcanic substances such as the ashes, sand, and scoriæ, not in chemical composition but in the conditions under which it is ejected from the crater. Thus the analyses by Silvestri of lava, scoriæ, sand, and ashes thrown out by Etna in the eruption of 1865 showed the practical identity of constituents in each form of product:

——	Ashes	Sand	Scoriæ	Compact lava
Silica	50·00	49·80	50·00	49·95
Alumina	19·08	18·20	19·00	18·75
Ferrous oxide	12·16	12·42	11·70	11·21
Manganous oxide	0·40	0·45	0·50	0·49
Lime	9·98	11·00	10·28	11·10
Magnesia	4·12	4·00	4·20	4·05
Soda	3·72	3·60	3·40	3·71
Potash	0·60	0·49	0·69	0·70
Water	0·36	0·29	0·33	0·23
Phosphoric acid Titanic acid Vanadic acid Ferric oxide	traces	traces	traces	traces

Of the whole number of chemical elements, ten, viz. oxygen, silicon, aluminium, iron, magnesium, calcium, sodium, potassium, hydrogen, and titanium, are of common occurrence in lavas; although traces of practically all other elements are found somewhere or other amongst volcanic products.

Among the ten elements commonly existing in lava, oxygen makes up nearly one-half of the weight, silicon one-fourth, and aluminium one-tenth. The other seven elements vary in their proportions relatively to each other. Silica is present in proportions of from one-half to four-fifths of all lava, and, with the bases, viz. oxides of aluminium, calcium, iron, magnesium, potassium, and sodium, forms the silicates. In proportion as the acid constituent silica exists in greater or smaller relative quantity, lavas have been distinguished as 'acid lavas' and 'basic lavas': to this classification Judd (Volcanoes, 1888, 48) suggests the additional term of 'intermediate lavas.' Under this arrangement, 'acid lavas are those which contain from 66 to 80 p.c. of silica; they are poor in lime, magnesia, and oxide of iron, but rich in potash and soda. The basic lavas contain from 45 to 55 p.c. of silica; they are rich in lime, magnesia, and oxide of iron, but poor in soda and potash. In the intermediate lavas the proportion of silica varies from 55 to 66 p.c.' It may be taken, further, that these three distinctive names correspond with the nomenclature of former writers, viz. trachytes, greystones, and basalt. Since basic or basaltic lavas contain a larger proportion of heavy oxides than the acid or trachytic lavas, it follows that the former possess a higher sp.gr. and may usually be classified according to their weight.

In colour fresh lava ranges from nearly white in the acid to nearly black in the basic. After a time, all lavas become reddened on account of the iron present in them being affected by exposure to the weather.

A fourth but much smaller class of lava is one resembling the stony portion of meteorites. Judd suggests for this class the name of ultra-basic lava. This lava contains a very low percentage of silica and a high proportion of iron and magnesia. It has a sp.gr. usually exceeding 3; and it is interesting as being composed of those minerals which occur in meteorites, viz. olivine, enstatite, augite, anorthite, magnetite, and chromite.

Under the microscope, thin slices of lava exhibit two kinds of materials, a glassy base and crystals of various minerals distributed through it in irregular order and proportion; apparently this variation is to be explained by the rate of cooling to which various portions of the molten mass have been subjected. This, however, does not affect the ultimate chemical composition.

Geologists adopt the following names of lavas, in five main classes, Rhyolites, Trachytes, Andesites, Phonolites, and Basalts; and the glassy and the perfectly crystalline forms are distinguished as follows:

Crystalline forms.	*Lavas.*	*Glassy forms.*
Granite	Rhyolite	Obsidian
Syenite	Trachyte	
Diorite	Andesite	
Miascite	Phonolite	
Gabbro	Basalt	Tachylyte

As examples of the extremes in composition of lavas, the following analyses may be quoted: I. rhyolite from Co. Antrim (J. H. Player); II. limburgite from Haddingtonshire (J. H. Player):

	SiO_2	TiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	Na_2O	K_2O	H_2O
I.	76·4	—	14·2	1·6	—	0·6	—	1·8	4·2	1·5
II.	40·2	2·9	12·8	4·0	10·4	10·4	11·9	2·7	0·8	3·4

Confining this article to the chemical aspects of lava, it may be said generally that the material ejected from the same volcano at wide intervals of time displays a similar chemical composition. Thus analyses of Vesuvius lava of (*a*) 1631, (*b*) 1767, and (*c*) 1868, show practical identity:—

——	(*a*) Eruption of 1631	(*b*) Eruption of 1767	(*c*) Eruption of 1868
SiO_2	48·12	48·20	46·58
TiO_2	0·22	0·27	0·27
Al_2O_3	17·16	17·92	20·00
Fe_2O_3	5·69	5·48	3·20
FeO	5·13	4·75	5·69
MnO	1·20	1·33	1·07
CaO	9·84	8·97	9·09
MgO	3·99	3·51	3·16
Na_2O	2·77	2·61	2·74
K_2O	7·24	7·70	7·35
H_2O	0·08	0·16	0·32

When we come to study the internal structure of ancient volcanos, however, we are impressed by the fact that lavas of very different chemical composition must have issued from the same vent at successive periods. As a general rule, to which there are not wanting notable exceptions, the first lavas to make their appearance have been of intermediate type; while acid and basic lavas have been ejected at a later period in the history of the volcano. Occasionally we find evidence that lavas of very different chemical composition have flowed from the same vent in frequent alternations.

Lavas are at times used as building stones and for paving; whilst those of Niedermendig on the Rhine (here a leucite-nepheline-tephrite) and of Hungary are used for millstones. Pumice (*q.v.*) is a lava full of steam-cavities. Puzzolana is a volcanic dust or ash extensively used for making concrete.

Much detailed petrographical study and numerous chemical analyses have been made of lavas and other rocks of igneous origin, and many names have been introduced for special varieties. See the German treatises on petrography by H. Rosenbusch and by F. Zirkel, and the text-books in English by A. Harker, F. H. Hatch, and J. P. Iddings (Igneous Rocks, 1909). For tabulated chemical analyses, see H. S. Washington, Prof. Papers, United States Geol. Survey, Nos. 14 and 28, 1903, 1904.

L. J. S.

LAVENDER, OIL OF, *v.* OILS, ESSENTIAL.

LAZULITE. A comparatively rare mineral occurring as sky-blue monoclinic crystals of pyramidal habit. It is a basic phosphate of aluminium, magnesium, and ferrous iron, $Al_2(Fe,Mg)(OH)_2P_2O_8$. This name is easily confused with the name lazurite (*v.* LAPIS-LAZULI).

L. J. S.

LAZURITE *v.* LAPIS-LAZULI.

LEAD. Syns. *Blei*; *Plomb*; *Plumbum*. Sym. Pb. At.wt. 207·1.

Occurrence.—Native lead is said to have been found at Grassington and Alston Moor, in certain mines in the province of Guanaxuato in Mexico; and according to Koksharow (J. Min. 1875, 873) in the Kirghis Steppe, where it occurs in hornstone associated with heavy spar and cerussite; also in the gold washings of Katharinenburg, in which it occurs in grains together with gold, magnetic and specular iron ores; also in India (Geol. Survey, India, List of Minerals). Some instances of the occurrence of native lead are given by Liversedge, in his Minerals of New South Wales.

A large number of lead compounds are found in nature, but only a comparatively small number can be considered as ores.

The principal ores of lead in the order of their importance are *galena, cerussite, anglesite.* Other less important naturally occurring compounds of lead are *pyromorphite, mimetisite, matlockite, mendipite, phosgenite, lead ochre, minium.* These are dealt with under their special titles.

Distribution of Lead Ores.

Lead ores are abundantly distributed through the rocks of the different geological formations, from the granite to the triassic formation; but most abundantly in rocks of the Silurian age and in those of the mountain limestone. Whilst many of these deposits are in the form of true veins, some there are which cannot be regarded as true veins. Veins of lead ore which are rich in one formation become suddenly impoverished in passing into another and different rocky stratum. In England three different kinds of deposits of lead ores are distinguished by the miners—viz. (1) rake veins, which are true veins in the geological sense of the word; (2) pipe veins, which are narrow masses, frequently oblong in shape and lying parallel to the rocky strata; (3) flat veins, which are small beds of ore lying in the middle of these strata. Galena generally contains some silver; but lead ores are not always argentiferous, those, however, which occur in crystalline metamorphic rocks are usually so. Further, the lead ores of the older rocks are generally argentiferous, but are not so productive of lead as those of the limestone districts, yet are more persistent in depth.

In England, lead ores are worked in veins and ‘flats’ in the mountain or carboniferous limestone in the neighbourhood of Alston Moor, where the counties of Northumberland, Cumberland, and Durham meet, and elsewhere in those counties. The lead-yielding districts of Derbyshire, Yorkshire, and the Mendip Hills are in the same formation. The Cornish and Devonshire mines are workings in true veins occurring in the Devonian formation—‘Killas’ of Cornwall and Devonshire. The lead workings of the Shelve district in Shropshire, of Cardiganshire, of Montgomeryshire, of Leadhills and Wanlockhead in Scotland, and those of the Isle of Man, are in rocks of the Silurian formation; whilst in Ireland, in Wicklow, and Newtownards in the County Down, lead ores are found in granite.

In Germany lead mines are worked in the valleys of the Lahn and Sieg, and these lead-bearing veins occur in Devonian strata. Those of the Hartz district are also in Devonian slates; they yield a highly argentiferous galena and silver ores proper. In the Hartz district there are three centres—viz. (1) that in the neighbourhood of Clausthal; (2) the mines in the vicinity of Andreasberg; and (3) those at Rammelsberg, near Goslar. The Freiberg mines are in gneiss and yield a highly argentiferous galena. The Silesian lead ores are found in irregular deposits in the muschelkalk, and are associated with ores of zinc and iron. A remarkable stratified deposit of lead ore of triassic age is that of Mechernich in the Eifel, where a bed of sandstone is filled in places with nodules formed of sand grains cemented together by galena.

The mines of Bleiberg and Raibel in Carinthia are among the most important lead mines in Austria. Here the ore is a very pure galena associated with molybdate of lead, and is found in limestones of the triassic formation. At Pzibram, in Bohemia, the veins are in Silurian strata, and yield a galena very rich in silver. The mines are from three to four thousand feet deep.

Whilst lead is found in almost every province in Spain, the chief workings are those of the provinces Jaen, Murcia, and Almeria. In the province of Jaen in the neighbourhood of Linares, two distinct systems of veins occur traversing the triassic sandstone and the granite upon which the former reposes. In the district round Carthagena in Murcia, the lead ores occur in veins in stratified and irregular deposits in Silurian rocks and trachytes. In the province of Almeria lead is found in veins in the mica schists and clay slates of the Sierra Almagrera. Some of the ore of this district is highly argentiferous.

The chief Italian sources of lead are the mines of Sardinia, which may be divided into three types—(1) Ore masses interstratified in Silurian rocks, as in the mine of Monteponi; (2) veins traversing Silurian clay slates, as in the Montevecchio mine, one of the most important lead mines in Europe; and (3) lodes traversing Silurian limestones, *e.g.* Malacalzetta. The ore of the Montevecchio mine consists of galena mixed with blende, iron pyrites, heavy spar, siderite, and copper pyrites. It is poor in silver, whilst that at Malacalzetta carries about 40 oz. of silver to the ton. In Sardinia, the ore is, in all cases, galena. There are numerous deposits of lead ore (galena) on the mainland. In the Brusmipiano mine, in the district of Milan, galena is found associated with cerussite, iron pyrites, jamesonite, copper pyrites, and malachite. At the Morso Alto mine and at the Boltino mine in the mining district of Florence, the galena worked is rich in silver, and at the latter mine is associated with fahlerz, bournonite, and native antimony ore.

The deposits of lead ores of Portugal are very similar to those of Spain. The most important district is that of Mutola, near the Guadiana. The galena contains about 24 oz. of silver to the ton, whereas the cerussite and anglesite associated with it are frequently much richer.

In Greece, ores of lead, silver, and zinc occur constantly associated with one another. They occur in mica schists, limestones, granites, and trachytes, sometimes in irregular masses and sometimes in the form of lodes. The chief mining district is that of Laurium, at the southern extremity of Attica.

In Sweden argentiferous lead ores occur in veins in granular limestones belonging to the crystalline slates. The chief mines are those of Sala, of Lofas in Dalacarlia, and of Guldmenshytta in Westmanland.

In France galena containing silver and associated with blende and iron pyrites occurs at Poullaouen in lodes traversing clay slates of Silurian age. The lodes at Huelgoët yield, in addition to argentiferous galena, cerussite, pyromorphite, and also native silver and horn silver. Whilst galena is found and worked in several localities in France, the most important mines are those of Pontgibaud in the Puy-de-Dôme, where lead lodes are worked which traverse rocks consisting of granite, gneiss, and schists, broken through by dykes of porphyry, and covered by sheets of basalt, beds of cinder, or by flows of lava. The galena is always argentiferous, and is accompanied by blende or iron pyrites, and occasionally by patches of fahlerz.

In Belgium, galena is found in numerous places, but the deposits are seldom of sufficient importance to pay the expenses of working. It is frequently associated with cerussite and pyromorphite. A productive lead mine exists at Bleiberg, near Moresnet, where a vein is worked which traverses the carboniferous limestone and the coal measures.

Lead ores are found in various parts of Russia; galena and several other lead minerals occur in a lode at Ekaterinenburg in the Urals. In the Caucasus deposits of galena exist. In Poland are deposits of galena in the dolomites of the muschelkalk, which have been worked for centuries. The most remarkable mines are those near Olkusk and Boleslaw. Lodes of lead ores occur near Chasing and Kielcé in rocks of Devonian age. Galena associated with fahlerz, molybdenite, iron pyrites, copper pyrites, and blende occurs in deposits in the mining district of Nertschinsk in Eastern Siberia.

Lead ores are found in various provinces of the Indian empire; they occur in beds or pockets, but seldom in veins. Many of these deposits have been worked by natives, but only on a small scale; there are practically no workings carried on at the present time.

Rich ores of silver and lead occur in the northern Shan States of Burma, which were formerly worked by the Chinese for the sake of the silver, and interest in this source of lead and silver has been revived.

Galena is found in many provinces in Japan, but the deposits of this mineral are not particularly valuable. In addition to this mineral, several lead antimony ores are found in Japan.

Australasia.—In Victoria, galena occurs in several localities; that at St. Arnaud is argentiferous. In New South Wales this ore is widely distributed over the colony, but no lead mines are known to be working. In South Australia, the mines of argentiferous galena are situated in the southern part of the colony, near Cape Jervis. In the Champion Bay district of Western Australia both lead and copper ores have been found in gneissic rocks, associated with granite and greenstone. In Tasmania argentiferous galena has been found; at the Penguin, and in the neighbourhood of Mounts Roland and Claude. Galena containing silver is occasionally found in the gold-bearing reefs of Coromandel and Thames, New Zealand.

Africa.—Argentiferous lead and copper ores are found in some mines in Algeria, and lead ores are known to exist in different parts of South Africa; these ores are found chiefly in the limestone formation extending from the junction of the Vaal with the Orange River in a northerly and then in an easterly direction to Rustenburg, in the north-west of the Transvaal. There is evidence of these ores having at one time been worked by the natives.

America.—In the United States of America, argentiferous galena, associated with blende, iron, and copper pyrites, occurs in the Atlantic States in the form of true veins; in the Azoic slates of New York and in the New England States in veins running parallel to the formation; in the State of New York it occurs in irregular deposits in the unaltered Lower Silurian rocks. The chief lead districts are, however, those of the Upper Mississippi Valley and the Missouri. The Upper Mississippi lead district is comprised within the States of Wisconsin, Illinois, and Iowa, the chief lead-producing district being that of the first-named State. The deposits of lead ore are found in the 'galena' or magnesian limestone of the Trenton period of the Lower Silurian formation, and cover an area of about 140 geographical square miles. These deposits assume a variety of forms, *e.g.* the *sheet*, a solid mass of ore filling a vertical fissure; this is the most characteristic mode of occurrence, in addition to which other forms are distinguished, such as an *opening, a crevice with pocket openings, cave openings, flat sheets,* and *vertical openings,* in all of which masses of lead ore occur in variously formed fissures in the limestone. The principal ore is a very pure galena, poor in silver, crystallising in cubes; it is accompanied by blende and zinc carbonate and a brown iron ore. The chief deposits of the Missouri district are situated in the counties of Washington, Franklin, and Jefferson. The ore occurs as 'float mineral,' a term applied to describe the mode in which galena is found imbedded in the superficial soil overlying the limestones of Lower Silurian age, in which the ore is found in deposits very similar to those in which it occurs in the Mississippi district. The galena is usually associated with iron and copper pyrites, and at the famous Lamotte mine, nickel and cobalt ores are found with it. In Utah and the Western States, large and irregular deposits of highly argentiferous lead ore occur.

In Canada galena is found in several localities around Lake Superior, a remarkable vein occurring at Silver Lake, some six miles northward from Thunder Bay, and at 500 feet above Lake Superior. A finely crystallised variety of galena has been found on the East Main coast of Hudson's Bay, in strata similar to those in which it occurs in the Mississippi district.

In Mexico lead ores are found in the mines at Guanaxuato and La Concepcion mine, and lodes containing argentiferous galena, quartz and calc spar occur in the mining district of Tatatila and Zomelahuacan.

For methods of assaying lead ores, *v.* art. ASSAYING.

SMELTING IN REVERBERATORY FURNACES.

The smelting of lead ores, of which galena is the principal one, is carried out either in reverberatory furnaces, blast furnaces, or shallow hearths. The ore is received from the mines dressed and freed as far as possible by mechanical means from the various minerals and gangue material with which it is found associated.

The following are the methods by which the extraction of lead is effected :—

I. *Method of Double Decomposition*, or method by reactions or roast reactions process (Röst reactions Arbeit), or air-reduction process. As the last name implies air aids in the reduction, and it does so in the following manner.

When galena is roasted at a moderate heat, it is partially converted into the oxide, and a portion is also oxidised to the sulphate ; if, after this roasting the temperature be raised, the unaltered galena reacts on the lead oxide and sulphate formed in the previous stage, and metallic lead is produced, sulphur dioxide being evolved.

These reactions are represented by the following equations :

$$(a)\left\{\begin{array}{l}2PbS+3O_2=2PbO+2SO_2.\\PbS+2O_2=PbSO_4.\end{array}\right.$$

$$(b)\left\{\begin{array}{l}PbS+2PbO=3Pb+SO_2.\\PbS+PbSO_4=2Pb+2SO_2.\end{array}\right.$$

II. Method of roasting and subsequent reduction of the oxidised compounds by means of carbonaceous matter (Röstreductions Arbeit).

III. The precipitation process (Niederschlags Arbeit) or method of affinity, in which iron is used to effect the removal of sulphur.

The treatment of a lead ore frequently requires the use of two if not all the above processes.

Smelting in reverberatory furnaces.—The Flintshire process is an example of the method by double decomposition carried out in reverberatory furnaces, which vary somewhat in construction and dimensions.

The following is a description given by Phillips of a *Flintshire furnace*.

The length of the hearth is usually about 11 feet, and its width 9 feet, and under this is an arched vault, extending the whole length of the bed to the fire-bridge. The hearth is made of slag, moulded into the proper form when in a plastic and semi-fluid state. Towards the centre of the hearth is a depression in which the fused metal accumulates, and at the bottom of this is situated the tap-hole. The fireplace is at one end, and before reaching the cavity of the furnace the flame has to pass over a fire-bridge about 2 feet in width, and from 12 to 14 inches below the arch. At the opposite extremity of the hearth are openings communicating with the flue in connection with a lofty chimney. The fuel is supplied through a door at one end of the fireplace, in addition to which the furnace is furnished with six working doors, about 9 inches by 12, protected by heavy cast-iron frames built into the brickwork and closed by iron plates, which can be easily removed when required. The bottom of this furnace is made nearly level with the doors on one of the sides, but is inclined towards the other in such a way as to be from 18 to 20 inches below the middle door, where it communicates with the tap-hole, beneath which a cast-iron tapping pot is set in the ground. In the top of the furnace is a hopper, from which a fresh charge of ore is let down as soon as that which is being worked is withdrawn.

In working this process, the charge (consisting of 21 cwt. in N. Wales, and from 12-14 cwt. in the north of England) is let down into the furnace, which is still hot from a previous working, and is spread evenly over the surface of the bed of the furnace, care being taken to prevent it dropping into the depression in the furnace-bed or well. During the first hour and a half, the charge is frequently stirred, and the supply of air carefully regulated by opening the various doors, the temperature being kept sufficiently high to ensure the oxidation of a portion of the galena, but at the same time not high enough to cause the charge to melt. It is during this period of calcination that the lead sulphide is in part converted into lead oxide and lead sulphate. At the end of this period the doors are closed, the fire is made up, then the temperature is raised to bright redness, and maintained at this point for about 25 minutes. This rise in temperature causes the charge to become plastic, and a reaction takes place between the unaltered galena and the oxy compounds of lead, by which lead is produced, and the metal runs down into the well in the bed of the furnace. At the end of this period, the doors are opened to cool the furnace and the charge, which, when it has become as pasty as ordinary mortar, is pushed back from the well and spread over the higher part of the bed. The doors are again closed and the temperature raised by addition of fresh fuel ; in this way the charge is rapidly run down into the depression in the furnace, and when this is accomplished, some slaked lime is thrown on to the surface and, by means of a rake, thoroughly mixed up with the charge. Thus the slags and unreduced ore are cooled and rendered sufficiently pasty to allow of their again being removed and spread over the higher portions of the furnace bed, where they are again calcined as in the first operation. This calcination lasts about half an hour. At the end of this stage, the temperature is again raised, and the whole charge is melted down into the well. During this stage it is not infrequent to throw a little coal slack on to the charge. When the charge has in this way collected in the well, some slaked lime is thrown on to it, and the slags pushed back on to the sloping side of the furnace and allowed to drain. The lead which has collected in the well is now tapped, and the slags, technically known as *grey* slags, are withdrawn in pasty lumps through the doors at the back of the furnace. The surface of the metal in the tapping pot is covered by slags and mattes, which retain mechanically a considerable proportion of metallic lead, the separation of which is effected by stirring with a paddle and throwing on to the surface some coal slack, which is well worked up with the molten metal. A considerable evolution of gas takes place ; this is ignited, and the heat produced suffices to melt and liberate the metal confined in the slag. The slag is then skimmed off, thrown into the furnace, and the lead ladled out into cast-iron moulds.

Before introducing another charge, the tap-hole is opened to allow the lead produced from the slag and skimmings to run into the metal pot, where it remains until the next charge is run off. The tap-hole is again closed, and another charge of ore dropped into the furnace from the hopper.

This process may, therefore, be summarised as follows:—

(1) Calcination of the ore at a low heat, whereby a certain amount of lead sulphide is converted into lead oxide and lead sulphate.

(2) Melting down of the charge, during which the unaltered lead sulphide reacts upon the oxidised products and a separation of lead occurs.

(3) The admixture of lime with the molten charge and the 'setting up' of the slags, a further separation of lead from the interaction of the sulphide and the oxy compounds of lead, and the production of an excess of lead oxide and lead sulphate over the lead sulphide present.

(4) The tapping of the metal which has accumulated during the operation, and the drawing of the slags in a pasty condition.

In Flintshire, the ores smelted by this method yield 75–80 p.c. of lead by the dry assay, and of this, 90 p.c. is obtained by smelting in reverberatory furnaces, the remaining 10 p.c. being obtained by subsequent treatment of the slags (of which about 4 cwt. per charge is produced) and fume. The time required for the working of the charge is from 5 to 6 hours.

In some cases, in Flintshire, another process of extraction is used, similar to that employed at one time in Cornwall. The mode of treatment consists of two operations:

(1) Calcination of the ore,
(2) Melting down of the calcined ore.

Each operation is effected in a distinct furnace. The method is a combination of all the different processes for the extraction of lead, utilising

(1) The air-reduction process,
(2) The desulphurisation of galena by iron,
(3) The reduction of oxidised lead compounds by carbonaceous fuel.

The ore treated in Cornwall consisted principally of galena associated with blende and sulphurised copper ores, and also a silicious gangue. Furthermore, it contained a considerable amount of silver. These ores yielded on an average 60 to 70 p.c. of lead containing about 35 ounces of silver to the ton.

The first operation, or calcination, was performed in a reverberatory furnace having three working doors, one on either side of the furnace, and the third on the side opposite the fire-bridge, and smaller than the others. Below the bed of the furnace was an arched chamber, into which the calcined ore was raked through holes in the bed opposite each of the lateral working doors. The furnace was built of ordinary rubble-work, lined internally with 9 inches of fire-brick. The doors were hung in a cast-iron framework, or had the sides protected by slabs of granite. The charge was introduced through a hole in the roof merely closed by a slab. The charge varied from 25 cwt. to 3 tons, but usually consisted of about 1 ton 18 cwt. to 2 tons, and was spread over the furnace bed and calcined at a high temperature, regulated so as to prevent clotting. The operation lasted from 15 to 18 hours, the charge being raked over every hour, and at the end was raked through the holes in the furnace bed into the vault below, whence it is conveyed into the flowing or melting furnace, which is very similar to the Flintshire furnace.

This furnace had five working doors, a pair on either side, and the fifth on the side opposite the fire-bridge, as in the calcining process. Near one of the lateral working doors, the hearth sloped to the one near the bridge, where the tap-hole was situated, from which the metal, &c., ran into an iron pot placed outside the furnace, near to which was a small pit to receive the regulus or slurry. The metal pot was also provided with a channel to convey away the slag.

The charge for such a furnace consisted of two tons of calcined ore, and was brought into the furnace through the back working doors. The charge was first spread over the sloping hearth, the doors closed, and the temperature raised until the charge was melted down, requiring some 2 or 3 hours.

In some cases, as with pure ores, the lead produced in this stage was tapped off, but more usually the charge was mixed with lime and culm (anthracite coal) and set up on the higher part of the furnace bed.

In some cases fluorspar was used as a flux, and 1 or 2 cwt. of scrap iron was added to assist in the decomposition of the lead sulphide.

The doors were again closed and luted, and the charge melted down. The furnace was then tapped, and the molten metal flowed into the metal pot, followed by the regulus or slurry, consisting chiefly of iron sulphide and containing the principal proportion of the copper. The regulus ran over from the metal pot into the pit below, and after a time the slag began to make its appearance; the lip of the pot was then stopped with ashes, and the flow of the slag directed along the channel by which it was conveyed out of the building.

The whole operation of melting, from the time of introducing the charge to the tapping of the metal, took about 8 hours. The slag was generally sufficiently free from lead not to require subsequent treatment. The regulus was treated for the lead and silver it contained, and then when sufficiently rich in copper sold to the copper smelter.

In calcination, 6 cwt. of coal were required for every ton of ore, the melting down requiring about 8 or 9 cwt. The lead obtained was usually hard, and required softening at a high temperature to remove the antimony which it contained.

A modification of the Flintshire process is used in France, the following description of which, as practised at Couëron, is taken from Phillips's account given in his Elements of Metallurgy:—

The construction of the furnaces at Couëron Loire Inférieure, France, will be readily understood by reference to the accompanying woodcuts.

Fig. 1 is a longitudinal section.

Fig. 2 is a horizontal section on the line CD.

Fig. 3 is a transverse section through the tapping-hole.

The fireplace A is of the usual dimensions, and the hearth B, instead of being on an arch, as is commonly the case in North Wales, is supported on iron bars, on which is laid a course of flat tiles. On these is placed a course of fire-bricks on edge, on which is arranged the usual slag bottom. The furnace has the ordinary number of working doors, *a*, with a fire-door *b*, and a tapping-hole *c*; there is a small fireplace below the pot *d*, to prevent the too rapid chilling of the lead during the process of ladling into moulds.

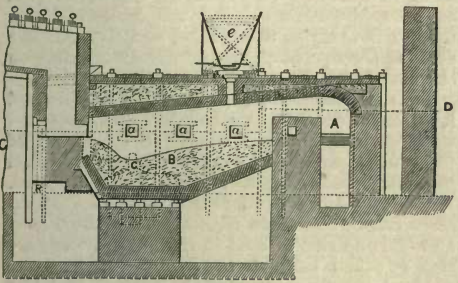


Fig. 1.

Although similar in form and dimensions to the ordinary Welsh furnace, it differs from it in one important particular, namely, in having the tapping-pot placed near the flue end instead of under the middle door.

This arrangement gives a larger surface to the hearth for roasting the charge, and permits of the lead being collected in the coolest part of the furnace, where it is least exposed to loss from volatilisation.

The mode of working varies with the nature and composition of the ores treated. This variation depends principally on the length of time required for roasting the ores before subjecting them to the higher temperature of reactions. Pure ores, especially those containing a notable proportion of lead carbonate or sulphate, require very little previous roasting, whilst those containing blende, pyrites, &c., must be calcined for a considerable time before smelting.

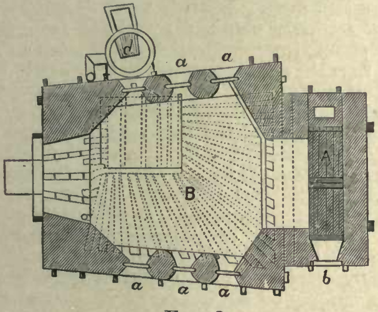

Fig. 2.

In general, the ores treated are derived from Sardinia, and contain on an average about 81 p.c. of lead, and but little silver. They are tolerably free from impurities, being composed of galena associated with lead carbonate and sulphate, and a calcareous gangue, in which are found small quantities of blende, calamine, ferric oxide, and silica. The cobbed ores, before delivery to the furnace, are ground between rollers and passed through sieves of eight holes to the linear inch. A charge of ore weighs 27 cwt.

Two men are employed at each furnace, one of whom, the chief, works on the fore-side and takes the leading part in the work.

In the treatment of rich ores, the ordinary method of working consists in roasting them in such a manner that more than one-half of the lead sulphide present in the ore is converted into a mixture of oxide and sulphate. On raising the heat of the furnace to bright redness the oxide and sulphate formed in roasting react on the undecomposed sulphide in the charge, producing metallic lead, sulphur dioxide, and a residue of slag.

The process is thus divisible into two well-marked and distinct operations:

I. Calcination or oxidation.

II. Smelting or reduction.

I. *Calcination.*—Supposing a charge to have been just worked off and the residual slags withdrawn, the furnace will be empty and at a red heat. The damper having been lowered, the charge of ore in the hopper, *e*, is let down through the opening in the arch, and spread evenly over the furnace bottom by means of rabbles. This done, the working-doors are closed, but the fire-door is left open and the fire damped with cinders, in order so to moderate the heat that the charge may become red-hot without clotting. The charge is thus left undisturbed for some time. During the first hour it is once or twice lightly rabbled; at the expiration of that time, after being well turned with the paddle, it will be found to be red-hot throughout. The damper is then lowered so as to leave just sufficient draught for the free escape of the gaseous products of calcination. The working-doors are now left partially open to admit the air necessary for the oxidation of the galena, and under its oxidising action the charge soon acquires a high temperature. Care must, however, be taken to prevent the heat from increasing so much as to cause softening of the ore. When the heat is properly controlled a white crust, consisting of a mixture of lead oxide and sulphate, in which the former predominates, is rapidly formed on the surface of the charge, and no fumes are visible.

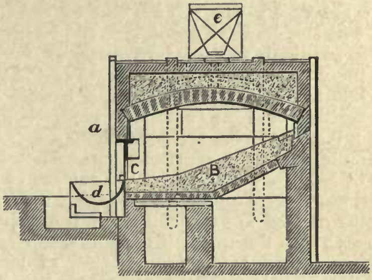

Fig. 3.

The surface is renewed from time to time, about every quarter of an hour, either by rabbling or by paddling. The requisite heat is maintained in the furnace during this process by firing with cinders only, which are preferable to coal for that purpose, not merely on account of their lower value, but also because they give a steadier heat and do not yield gaseous hydrocarbons to interfere with the oxidation.

The alternate raking and paddling of the charge is continued at regular intervals, until on examination, it is thought to be sufficiently desulphurised, which is generally the case at the end of from four to four and a half hours.

The grate is then freed from clinker, coal is thrown on the fire, the damper is opened, and a brisk fire is got up; thus in a few minutes the heat in the furnace is so raised as to lead to a *commencement of the reaction period.*

II. *Smelting.*—As soon as the firing has commenced, the ore lying at the back and extreme end of the furnace is raked towards the bridge. With the increase of temperature which now takes place, the roasted ore soon begins to soften and to give off white fumes, thus showing that the reactions which result in the liberation of metallic lead have commenced. Great care and attention on the part of the smelter are, however, necessary, in order to prevent too great a loss of lead by volatilisation during the heating up of the charge. The ore must on no account be allowed to liquefy, and as often as it shows a tendency to fuse, some slaked lime in powder is thrown on the charge and well worked into it with a rake. By this means, and by carefully regulating the draught, the charge can be heated to the required temperature without fusion. Lime must be frequently added during the process, but in small quantities at a time. The consumption of lime amounts altogether to about 2 p.c. of the ore treated.

Shortly after the reactions commence, globules of lead may be seen on the surface of the charge, and before an hour has elapsed a certain quantity of lead has drained down the slope of the hearth into the well. The charge, having in due time attained the temperature of bright redness, must not be fired too hard, therefore both the draught and the firing are so regulated that the heat is kept at the requisite degree without going beyond it.

The reactions are much aided by frequently rabbling and turning the ore; but as the working doors must remain open for this purpose it follows that a large quantity of air enters the furnace, thus oxidising the sulphide in the ore, and so cooling the charge that the flow of lead becomes interrupted. When the cooling is judged to have been carried sufficiently far, the charge is rabbled, the doors closed, and the fire so urged as to fill the furnace with flame during several minutes; then, on re-opening the doors and paddling, the flow of lead recommences as before.

At the expiration of from two and a half to three hours from the commencement of the reactions, a considerable amount of lead will have accumulated in the well. A first tapping is then made, the lead being received in the tapping-pot, under which a small fire has been previously lighted in order to warm it, and to retain the lead in a molten condition; the tap-hole is stopped with a plug of stiff clay.

The thick dross which rises to the surface of the lead, and which contains a certain quantity of sulphide removed from the charge by the hot lead and again separated on cooling, is skimmed off with a shovel and put back into the furnace. A little fine coal, together with some burning cinders and lime, is now thrown on the lead, which is vigorously agitated with a small paddle and stirred until it is clean. It is then skimmed, the skimmings being put on one side and the clean lead ladled into moulds.

The firing, paddling, and cooling of the charge are repeated several times, until at last the residue becomes dry and gives but little lead. Thereupon the heat in the furnace is considerably increased, but not sufficiently to fuse or flow down the charge, and towards the close of the operation the material remaining on the hearth consist to a great extent of oxides.

The pot skimmings, composed of cinders and lead matte, are now thrown into the furnace and well paddled with the charge, the reaction of the lead sulphide and cinders on the oxide and sulphate producing a further yield of lead. When this has ceased and it is seen that no more can be extracted without a very high heat and the addition of coal to the charge, the grey slag is raked through the middle door at the back of the furnace, and the second and last tapping is made.

The whole period of reactions occupies from 5 to 5½ hours. After the withdrawal of the slags, the bottom is examined, and if it is corroded into holes, or in any way injured, is repaired by putting into the cavities a mixture of grey slag and lime and beating it smooth with the paddle. It is of great importance to maintain the bottom perfectly smooth and with a good slope on all sides towards the tap-hole. A little lime is now spread over the bottom, and a fresh charge is at once let down into the furnace, the damper having previously been lowered to prevent loss of fine ore by the draught. The weight of coal consumed is equal to 40 p.c. of the ore smelted. The produce of lead per charge of 1350 kilos. of ore (at 81 p.c. of lead) is 15 pigs weighing 901 kilos. and 290 kilos. of slags containing 50 p.c. of lead. Hence the total loss of lead in the reverberatory furnace is 3·52 p.c. by volatilisation; out of this a certain proportion is recovered from the fume collected in the condensers and flues. A larger percentage of lead in pigs might be obtained by adding more coal to the charge towards the end of the process and firing hard, to reduce part of the lead left in the slags. It is, however, considered more economical to limit the production in the reverberatory to about 80 p.c. of the lead contained, and to carry the richer slags to the blast furnace. This is especially the case when the blast furnace is connected with good condensers and long flues.

It will be seen from the foregoing description that the process of reverberatory smelting adopted at Couëron differs principally from that generally employed in England in there being (1) no melting or flowing down of the charge; (2) the long preliminary calcination of the ore before commencing the reactions.

The position of the tap-hole near the flue end of the furnace gives a longer slope to the hearth, and allows of heavier charges being worked; at the same time the lead produced is collected in the well at a greater distance from the fire.

Spanish furnace or boliche.

In the south of Spain, the smelting of lead ores has been carried on for many centuries in a form of furnace known as the *boliche*. It consists of two chambers, separated from one another by a fire-bridge. One of these only is used for the reduction of the ore, and the second, which is situated between the first and the chimney, serves apparently to moderate the draught.

The fireplace projects from one side of the hearth, and is without a grate; the fuel, consisting of wood, is supplied through a door at the end of the fireplace.

The smelting hearth inclines towards the working door, situated at the end of the longer axis, immediately within which is a receptacle in the floor for the collection of the metal.

The boliche is constructed of rubble work, cemented together by clay and strengthened by buttresses built at the angles.

The interior is lined with firebrick, the lining for the hearth consisting of a species of clay resulting from the decomposition of talcose schists, known as 'laja' or 'laguena,' or of a mixture of this clay with broken galena.

The English firms smelting lead ores in the Linares district use a boliche constructed of sandstone and without any special lining, the sandstone being bound together by means of iron braces.

The method of smelting is in principle similar to the Flintshire process, and the process is divided into three operations:

1. *Caldeo,* or calcination, occupying from 1 to 1½ hours.
2. *Blandeo,* or sweating, lasting from 4 to 4½ hours.
3. *Corrida,* or running down, occupying the remainder of the shift, *i.e.* from 2 to 3 hours.

The ore thrown into the furnace through the working door is first spread evenly over the surface of the hearth and then calcined. When the calcination is completed, the temperature is raised and the running down of the charge begun. The slags are dried up after the completion of the melting down by throwing into the furnace the ash and breeze from the ashpit. The metal is tapped into a vessel, in which it is stirred with dry leaves, and finally ladled into moulds.

The yield of the boliche is about 80 p.c. of the lead of the ore as given by the dry assay. The grey slags contain from 45 to 50 p.c. of lead and represent 15 to 17 p.c. of the charge. These slags are subsequently treated in a blast furnace. The charge of a boliche consists of 60 arrobas, or 13 cwt. 1 qr. 16 lbs., and requires for its reduction 1550 to 1750 lbs. of brushwood. It is stated that the lead obtained by using the boliche is softer than that produced in the Flintshire furnace, but Phillips states that the difference in quality is not very marked. The difference is supposed to be due to the fact that in the boliche the smelting is effected at a much lower temperature. At Linares boliches have been built so as to burn a mineral fuel, but the result of working has in no way shown this form of furnace to be superior to the English reverberatory furnace.

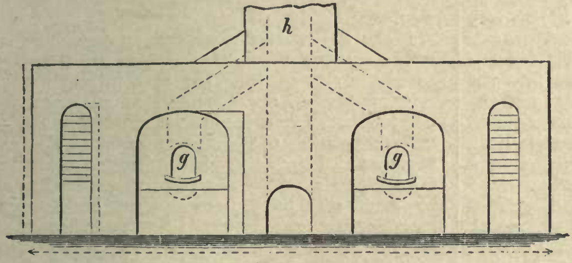

Fig. 4.

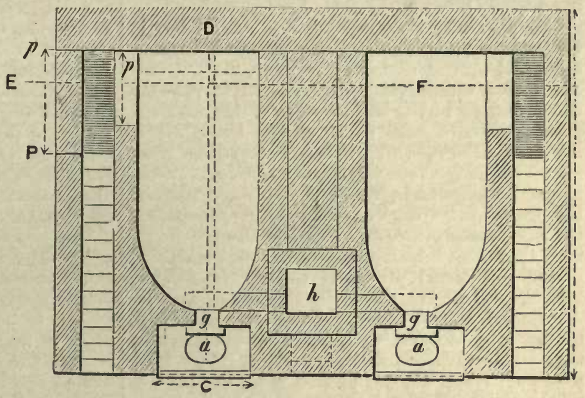

Fig. 5.

Bleiberg process.—At Bleiberg in Carinthia, reverberatory furnaces of a special construction are used, two being usually built side by side and arranged to work into one chimney.

Fig. 4 represents a front elevation, and Fig. 5 a horizontal section. The hearth is about 10 feet long, and at the back near the fire is about 4 feet 10 inches wide. This width is maintained for about half the length of the furnace, when it is gradually reduced, until at the working door it is about a foot wide. The hearth is sloped from the back and also from the two longer sides, thus forming a depression in which the metal may collect and flow into the metal pot, *a*, in front of the working door, *g*.

The hearth is formed of a lower layer of beaten clay and an upper one of fused slags, having a united thickness of about 6 inches. The fireplaces are built parallel to the longer axis of the furnace, and separated from the latter by a fire-bridge. The products of combustion pass into the chimney, *h*, by a flue above the working door. The grate is of stone, having a greater inclination than the hearth, and is traversed by openings for the admission of air.

The fuel employed is wood, but in some cases brown coal is used, and then the stone grate is replaced by one with iron bars.

The galena smelted at Bleiberg is associated with cerussite, anglesite, and lead molybdate, also with zinc blende, calamine, and willemite. The zinc ores are separated mechanically and treated for zinc. The lead ores are delivered to the smelter either in the rough state or in the form of slimes. In the former state on assaying they yield from 65–70 p.c. of lead, in the latter from 60–65 p.c.

In smelting, a charge of 375 lbs. of ore is thrown into the furnace through the working door and spread over the hearth. This is calcined at a temperature low enough to prevent the softening of the charge—the calcination occupying 3 to 4 hours—the charge being raked over at intervals. The temperature is next raised to bring about the usual reaction between the oxy compounds and the unaltered galena, the charge being carefully rabbled to promote a thorough admixture, and thus aid the reactions. This operation lasts from three to four and a half hours, the metal produced constantly flowing into the depression, and thence to the metal pot. At the end of this operation the slags are dried up by the addition of ashes and breeze, and then withdrawn from the furnace. The lead produced from the ore in this way, amounting from 125 to 150 lbs., is supposed to be specially pure, and is known as '*Jungfernblei*,' or 'virgin lead.' After the withdrawal of the slags a second charge of ore is treated, the slags produced being left in the furnace, and to them the slags from the previous smelting are added. These slags are free from sulphide and contain lead in an oxidised state only. The temperature is raised and charcoal added, the whole being intimately mixed with the rabble. The oxidised lead compounds are in this way reduced in from 7 to 8 hours, about 150 lbs. of lead being produced.

The complete working of the two charges will occupy from 21 to 23 hours, the yield of lead being usually about 2½ p.c. below that obtained in the dry assay.

Smelting galena with iron in reverberatory furnaces.—A method depending on the 'process of affinity' was at one time used in France in the reduction of a silicious Spanish galena. The furnace used was constructed with a hearth sloping from the fire-bridge to the working door. In front of the furnace, below the working door, is the tap-hole, in front of which is the metal pot for receiving the metal. Above the working door is a flue communicating with a chimney for the removal of the products of combustion, &c., the fireplace being at the end of the furnace opposite the door. The method of working consisted in introducing a charge of some 800 lbs. of galena, to which was added some 200 lbs. of scrap iron; the mixture was then heated and stirred from time to time, the galena in this way being reduced by the iron, when lead and iron sulphide are produced. The contents of the furnace are, at the end of the operation, run into the tapping-pot, in which the lead collects, and the matte and slag are allowed to flow over on to the floor. Both the matte and slag contain lead, for which they are subsequently treated in a blast furnace.

Galena containing 80 p.c. of lead yielded by this method from 67–70 p.c. of metal, the matte contained from 5–12 p.c. of lead, and from 4–5 p.c. are found in the slag, whilst 4 p.c. would be volatilised. This method of reduction of raw galena with iron in reverberatory furnaces is stated to be wasteful and expensive.

Smelting in Cupolas or Blast Furnaces.

Cupolas or blast furnaces are employed not only for the reduction of slags obtained in the smelting conducted in reverberatory furnaces, and of the various drosses produced in the purification and desilverising of lead, but also for the smelting of ores which by reason of the minerals associated with them and their poverty in lead are unsuited for treatment in reverberatory furnaces. This reduction is effected either by a treatment of the raw ore in the blast furnace, or by submitting the ore to a preliminary roasting and subsequently smelting it in a blast furnace.

In the treatment of raw ores the reducing agent is iron, which is added to the charge either in the form of metallic iron, as was at one time practised at Clausthal; or the iron is replaced by the basic iron silicates, obtained as slags in refining and puddling of iron, or from copper smelting. In some cases the iron required is added in the form of iron ores. The fuel usually employed is coke. This mode of smelting of raw ores is dependent on the decomposition of lead sulphide by metallic iron yielding metallic lead and iron sulphide. When basic iron silicates or other iron compounds are used, the iron required for the reduction is obtained by the reduction of these compounds by the carbon of the fuel or the carbon monoxide produced by its combustion. The iron sulphide formed unites with some lead sulphide and the sulphides of other metals, such as copper and silver, present in the ores, forming a fusible matte or regulus, which being lighter than lead collects above the metal in the hearth of the furnace, and is tapped out with the metal, from which it is easily separated. Some of the copper sulphide in the ore is reduced to metallic copper, and this alloys with the lead, as also does the silver which may have been reduced by iron and lead.

Antimony and arsenic sulphides, if present, are reduced by the metallic iron, the metals combining with the lead, or being in part volatilised and thus occasioning a loss of lead. As will be seen, these sulphides must also lead to an increased consumption of iron, and also a greater yield of matte. In addition to lead and matte, a fusible slag is formed, which consists chiefly of an iron silicate and contains lead, which is recovered from it by re-smelting in the blast furnace with another charge of ore. This is repeated until the amount of lead present is reduced sufficiently to allow of its being thrown away.

From the mattes produced as described, a further amount of lead is obtained by roasting the matte and smelting the roasted matte in a small cupola, an operation which produces, in addition to lead, a second matte and slag. A similar treatment of the second matte may, as at Clausthal and Freiberg, yield a further quantity of lead, and a matte in which, where lead ores associated with copper are smelted, the copper is sufficiently concentrated to serve for the extraction of the copper. The reduction of lead ores in blast furnaces is more usually preceded by a roasting of the ore, conducted as a rule in reverberatory furnaces, and in this manner the whole of the galena is converted into oxide and some sulphate, and finally the roasted ore is heated to a temperature sufficiently high to effect a partial fusion or render the mass of roasted material pasty. In this latter stage, a portion of the lead oxide reacts with the silica associated with the ore, producing a lead silicate. The roasted ore is next passed on to the blast furnace, where it is smelted with coke and suitable fluxes into the composition of which iron, either as metallic iron or as a basic silicate, enters. In some instances, the iron compounds required for the decomposition in the blast furnace are supplied by the iron ores associated in the first instance with the lead ores. This is the case in the smelting as conducted at Freiberg. In the melting down in the blast furnace, the oxy compounds of lead are reduced in part by the carbonaceous fuel, but chiefly by the iron, which in presence of carbonaceous matter is able to decompose the lead silicates. The product of this smelting should consist of lead, containing the greater portion of the silver present in the ore, and a slag consisting essentially of silicates of iron, lime, alumina, and magnesia and not more than 3 p.c. of lead. Highly silicious lead ores are smelted at Pontgibaud in this manner, the roasted ore being treated with a mixture of scrap iron, limestone, and lead slags in a blast furnace. At Couëron, the silicious ores are roasted and smelted in a blast furnace together with the grey slags produced in the smelting richer ores in reverberatory furnaces in the manner already described, to which are added agglomerated fume and iron slags. When the calcination of the ore is complete and the sulphur entirely removed by oxidation, the products of the subsequent smelting in the blast furnace consist of lead and slag only, but otherwise a matte or regulus is formed in addition, as at Freiberg. The mattes produced are treated in a manner similar to that already mentioned, being first roasted and subsequently smelted in a special cupola, or are returned, after roasting, to the blast furnace and smelted with a fresh charge of ore.

Various forms of blast furnaces have been employed in different lead-smelting districts for the reduction of lead ores. The older forms of furnace, such as those used at Clausthal and Freiberg, and the Castilian furnace for the smelting of Spanish slags and introduced into this country for the treatment of slags, have been replaced in late years by furnaces of newer construction; such as the Raschette furnace, the horizontal section of which is rectangular, with two long sides and two shorter. In each of the longer sides are placed three or more twyers, and there is a single twyer in each of the two shorter sides; the hearth is provided with a tap-hole on each of the narrow sides. The hearth bottom slopes downwards toward each narrow end. Water twyers similar to those employed in iron-smelting are also used. Another of the improved forms is the Pilz furnace, which is cylindrical in form, wider at the top than the bottom, with a circular or octagonal section inside and supplied with from 5 to 8 twyers. These furnaces are charged from the top, the gases being drawn off either by a vertical pipe leading to condensing flues, or by a lateral one. These furnaces have been further improved by replacing the brickwork in the hottest part of the furnaces by an annular cylinder of iron, provided with apertures for the twyers and an opening through which the slag flows. The sides of the cylinder are kept cool by a constant stream of water circulating through it. Blast furnaces provided with water-jackets are in use at Freiberg, at Couëron, and Pontgibaud (*v.* Phillips, Elements of Metallurgy), and at Leadville the Raschette furnaces there are provided with this arrangement. Water-jacketed furnaces for smelting lead ores, also for smelting slags, have been erected in this country.

The Raschette type of furnace, built with water-jackets, appears to be most favoured in American and Australian practice; the developments appear to be mainly in the increase in the dimensions of the hearth, and consequently increased number of twyers. Attempts have been made to adapt some of the devices which have proved serviceable in iron-smelting practice, *e.g.* closing the furnace and feeding by a bell and cone arrangement, also increasing the height of the furnace. Experience has shown that such adaptations are altogether unsuited for the working of lead, owing to its volatility. Hixon, in Notes on Lead and Copper Smelting (New York and London Scientific Publishing Co.), relates an experience in the working of a blast furnace at Aquas Calientes, which convincingly shows how little suited to lead smelting are high-shaft furnaces with top feed. The more usual arrangement of feeding the furnace from an open top, the gases being drawn off by a down-take below the feeding floor, is the more satisfactory.

Smelting of lead ores at Clausthal.—As an example of the practice of the 'iron precipitation' process, the treatment adopted at Clausthal may be cited, for a more detailed account of which the reader is referred to a series of papers by J. Clark Jefferson, A.R.S.M., in Engineering, vols. 24 and 25, from which the following account is taken.

The ores smelted at Clausthal consist of an argentiferous galena, associated with copper pyrites, fahlore, bournonite, zinc blende, spathic iron ore, iron pyrites, brown spar, quartz, calc spar, heavy spar, clay-slate, and greywacke. The minerals are first submitted to mechanical treatment and supplied to the smelter in the form of *schlieg*, of which the following may be regarded as representing the average composition:—

Lead	50·7	to 73·6 p.c.[1]
Silver	0·555	,, 0·185 ,,
Copper . . .	0·02	,, 0·6 ,,
Zinc	0·3	,, 4·1 ,,
Antimony . . .	0·02	,, 0·3 ,,
Iron	0·4	,, 3·7 ,,
Sulphur . . .	8·5	,, 14·2 ,,
Alumina . . .	0·07	,, 1·5 ,,
Lime	0·2	,, 1·4 ,,
Insoluble residue . .	5·9	,, 32·4 ,,

The old method of smelting practised at Clausthal consisted in reducing the *schlieg* by fusion with metallic iron and coke in a blast furnace 20 to 25 feet high and 3 feet square in the widest part. The form of furnace has gradually been altered, as also the method of treating the ores; the chief change in this latter has been the replacement of the iron by the iron silicates obtained from the copper works in

---

[1] Kerl Grundriss der Metallhüttenkunde, p. 60.

the Lower Harz, and also the use of the iron residues left by the extraction of copper from burnt pyrites by the wet method. In respect to furnace development it will be sufficient to describe the later model of furnace used, which is the third form in use at Clausthal; its construction will be understood from the accompanying diagram.

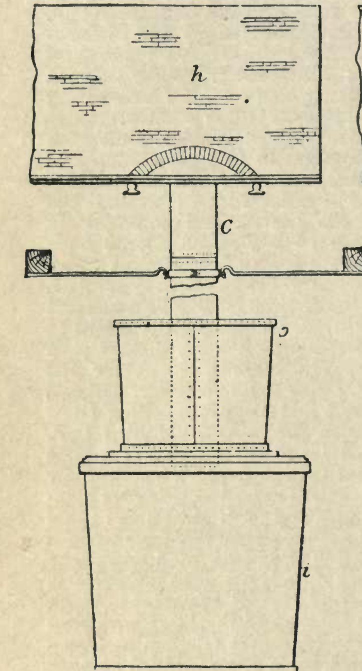

Fig. 6.

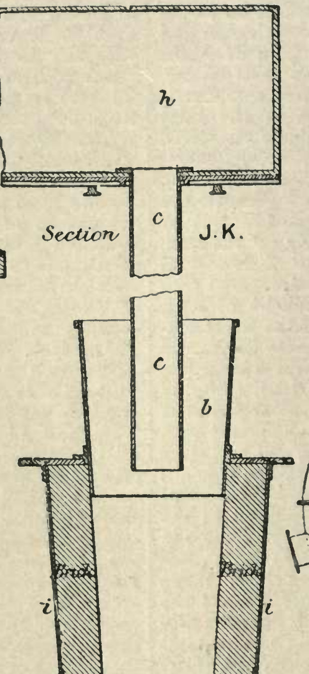

Fig. 7.

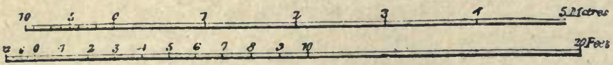

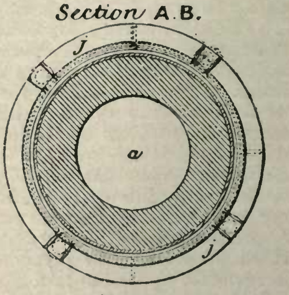

Fig. 8.

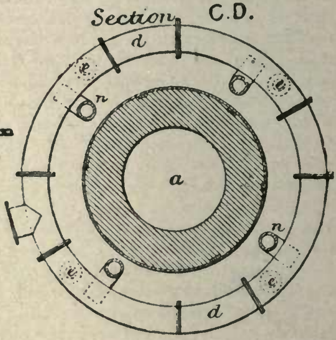

Fig. 9.

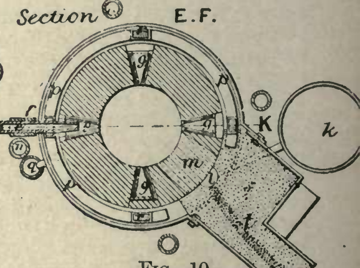

Fig. 10.

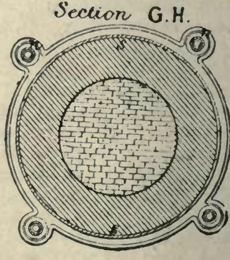

Fig. 11.

Fig. 6 is a front elevation; Fig. 7, sectional elevation; and Figs. 8, 9, 10, and 11, horizontal sections. *a*, is the shaft of the furnace; *b*, iron charging funnel; *c*, waste gas pipe; *d*, blast main; *e*, four vertical blast pipes; *f*, socket blast pipes; *g*, four water twyers; *h*, flue to condensing chamber; *i*, sheet-iron casing; *j*, bearers carrying sheet iron casing; *k*, iron tapping hearth; *l*, fore hearth; *m*, breast stone; *n*, iron column for supporting the bearers; *o*, copper piping to convey water to the twyers; *p*, outlet water pipe from the twyers; *q*, cast-iron cistern for water from the twyers; *r*, perforated sheet boxes to prevent a stopping up of the pipe *p*; *s*, cast-iron foundation cylinder; and *t*, slag gutter.

The furnace is built on a cast-iron foundation plate 1·5 inches thick; on this rests the main wall, which is 4 feet high, 4 feet 2 inches inside, and 7 feet 2 inches outside diameter. The space inside this brick wall is filled to a height of about 2 feet 3 inches with slag bricks, on the top of which is a layer of clay 1 foot in thickness, and this again covered flush with the top of the main wall with brick. In the centre and forming the bottom of the hearth is a slab of fire sandstone 16 inches thick. The shaft of the furnace built on this foundation is for a height of 7 feet built of fire-brick, and the remainder, 10 feet, is built of ordinary brick, the thickness being that of two bricks throughout the whole height. As will be seen, the section of the furnace gradually enlarges; its diameter at the hearth is 3 feet, and 5 feet at the extreme upper end. The height of the furnace is about 25 feet to the charging opening, and 21 feet 6 inches to the top of the boshes. The furnace bottom is made of clay and coal dust, resting on the slab of sandstone, and hollowed out as shown in Fig. 7. The four twyers are symmetrically arranged some 30 inches from centre to centre; the diameter of the circular blast main is 60 inches.

The materials smelted in these furnaces consist of ore in the form of *schlieg*, lime, roasted lead matte, slags obtained in smelting ore, as also a proportion of slags obtained from the smelting of regulus, together with slags obtained in smelting copper pyrites at Oker, known as Oker slags, or the residue left in the wet extraction of these copper ores. These two last-named materials supply the iron required for the reduction of the lead ore, the former in the form of iron silicate, and the latter containing iron in the form of the sesquioxide.

The materials composing the charge are prepared on the charging floor and thrown into the furnace with the fuel, the mineral and flux being disposed in layers alternating with layers of coke. The following is an example of the composition of the charge:

	Cwt.
Ore	100·00
Lead fume	1·01
Lead scrapings from the smelting house .	0·63
Roasted lead regulus	47·51
Schlieg scrapings from the charging floors	1·21
Oker slags	60·00
Slags from the same process	3·70
Regulus slags	42·00
Slags from schlieg smelting . . .	54·00
	310·06

The products obtained are work-lead (*Werkblei*), lead regulus (*Bleistein*), and a slag containing more or less lead. The lead, as is shown by the following analyses, contains many metallic impurities, a portion of which are derived from the minerals associated with the galena and some from the materials used in the reduction:

Lead . .	98·8378	98·9648
Copper . .	0·1862	0·2838
Antimony .	0·5743	0·7685
Arsenic . .	0·0009	0·0074
Bismuth . .	0·0039	0·0082
Iron . .	0·0035	0·0028
Zinc . .	0·0025	0·0028
Nickel . .	0·0023	0·0028
Cobalt . .	0·0016	0·0003
Cadmium . .	trace	trace
	99·6130	100·0414

The lead is refined at Lautenthal, or, if it contains sufficient silver, is desilverised by Parkes' process.

The following analysis gives the composition of the lead regulus:

Sulphur . . .	26·877
Iron	53·112
Lead	10·655
Copper	4·620
Silver	0·030
Antimony . . .	0·267
Arsenic . . .	—
Zinc . . .	2·110
Manganese . . .	0·385
Cobalt and nickel . .	0·306
Lime	0·383
Magnesia . . .	0·054
Silica	0·510
	99·309

The lead regulus is roasted in heaps, wood being employed as fuel, and in some cases coal, the roasting process occupying altogether some two months. The heaps are constructed as follows: first a layer of about 3 inches of powdered slag is spread on the ground, on this is placed a layer of pine wood, 100 cwt. of regulus requiring 110 cub. feet of wood for complete roasting. The regulus to be roasted is spread over the wood in a pyramidal heap, 14–20 feet broad, 20–30 feet long, and 5–6 feet high, and containing some 2000–3000 cwt. of regulus. The ignition is effected by setting fire to shavings placed under the wood. The first firing lasts from 8 to 10 weeks. After the heap has burnt out, it is broken up, and the portion insufficiently roasted separated, to be again submitted to a similar roasting. When by this roasting the sulphur has been sufficiently reduced, but not completely burnt away, the regulus is then smelted in the ore furnace, and this mode of treatment is adopted so long as the copper in the regulus does not amount to more than from 6 to 7 p.c., in which case the roasted regulus is smelted in a low blast furnace with slags from ore smelting and coke. This operation yields a work-lead amounting to 7–9 p.c. of the roasted regulus treated, and a regulus in amount varying from 24 to 42 p.c. of the roasted regulus. The amount of lead obtained is 75 p.c. of that contained in the regulus, the remainder being lost by volatilisation. This lead contains antimony and from 0·4 to 1·5 p.c. of silver. The regulus produced in this operation is again roasted and smelted, and thus a regulus produced which now contains some 20 p.c. of copper and is next treated for copper.

Lead-smelting at Freiberg.—The treatment of the great variety of minerals smelted at Freiberg for lead consists essentially of two sets of operations; first, the roasting of the ore to desulphurise it as completely as possible; secondly, the smelting of the roasted ore in blast furnaces and thus producing a work-lead, a matte or regulus, and a slag. The matte produced is submitted to repeated roasting and smelting operations, pretty much as practised at Clausthal.

The mines of Saxony, from which the ores smelted at Freiberg are chiefly derived, supply a great number of different mineral species which are classified as follows: (1) Lead ores, (2) copper ores, (3) arsenical ores, (4) zinc ores, (5) sulphur ores, (6) silver ores. The first class represent all minerals which contain above 15 p.c. of lead, and these are again subdivided into two groups: (1) '*Bleiische Erze*,' plumbiferous ores, containing from 15–30 p.c. of lead; (2) lead glances, in which the amount of lead in some cases is as much as 80 p.c. The mean lead content of the ores may be stated as 40 p.c., and this is associated with 150 grams of silver per 100 kilograms. The following represents the average composition of the '*bleiische Erze*':

Lead . . .	15–20 p.c.
Sulphur . . .	30 "
Zinc . . .	10 "
Arsenic . . .	7–15 "
Silver . . .	60 grams per 100 kilograms.

The copper minerals known as '*kiesblendige Erze*' are constituted of three species, viz. iron pyrites, copper pyrites, and zinc blende; the copper varies in amount from 1 to 3 p.c. Arsenical minerals are constituted of arsenical pyrites containing about 10 p.c. of arsenic, and the zinc minerals consist essentially of blende containing from 30 to 40 p.c. of zinc. All these various minerals are more or less argentiferous. Those minerals containing above 20 p.c. of sulphur are classed as sulphur minerals.

For the purpose of calcination the ores are divided into two classes; those containing at least 20 p.c. of sulphur and not more than 25 p.c. lead are submitted to a preliminary roasting in kilns so arranged that the sulphur dioxide produced may be utilised in the manufacture of sulphuric acid. In this operation a portion only of the sulphur is removed, the greater portion being reduced by roasting the partially desulphurised ore with raw ores which from their composition are unsuited for roasting in kilns. This second and final calcination is performed in reverberatory furnaces known as the 'Sinter röstöfen,' consisting of two beds, one above the other, the lower bed having the grate at one end, at the opposite end is a passage communicating with the upper part along which the heated gases pass and are finally conveyed from the furnace by a flue which communicates with condensing chambers.

This form of calcining furnace with two beds has been replaced by a furnace with a single bed, and with working doors upon both sides, in which the ore is charged at one end from a hopper placed above, viz. at the end furthest from the fire. The ore is spread in a layer over this portion of the furnace bed, and after remaining in this part for a given time it is moved on to the next portion of the bed, and its position filled by a fresh charge. In this way the charge is gradually moved along the furnace to the fire-bridge, and at this point it is subjected to a heat sufficiently intense to effect a partial fusion or agglomeration and is then withdrawn. In this manner the ore is continually submitted to a gradually increasing temperature, whereby the sulphur of the sulphides is burnt away and oxides produced, which in the final heating react with the silica and produce silicates.

The construction of the 'Fortschaufelungs-röstöfen,' will be understood from the accompanying figures, for the drawings of which as also for much information respecting the present practice of lead smelting, the wirter is indebted to Mr. W. Maynard Hutchings, general manager of the lead works of Messrs. Cookson & Co., Newcastle-on-Tyne.

Fig. 12 is a front elevation of the furnace, which is constructed of brickwork with a lining of fire-brick, and stayed together with iron standards and crossbars. In this is also shown the hopper *a* for charging ore, the ten working doors *b*, the door *c* for the withdrawal of the charge, and the door *d* for charging fuel into fire-grate.

Fig. 13 represents a vertical section, showing the fire-grate *e*, the fire-bridge *f*, and bed of the furnace, constructed of iron plates supported by pillars of brickwork, which are cooled by circulation of air below; upon these plates are built the materials composing the bed of the furnace. *g* is the opening in the roof through which the ore from the hopper is discharged into the furnace bed, *h* the flue leading to a series of condensing chambers.

Fig. 14 is a plan of the furnace, and Figs. 15 and 16 are vertical sections through CD and FG respectively.

The charge of unroasted minerals and roasted minerals is carefully prepared so as to attain as nearly as possible the following conditions.

(1) The amount of lead shall not exceed 20–25 p.c., an amount which experience has shown serves well as vehicle for the silver.

(2) The amount of zinc should not exceed 10 p.c., a greater proportion of zinc rendering the separation of slag and matte unsatisfactory owing to the viscosity of the slags.

(3) Silica should be present to the amount of 20–25 p.c., and thus insure the production of slags consisting essentially of iron protosilicates.

The amounts of lead, silver, copper, zinc, and silica are assayed to ascertain whether the above conditions have been fulfilled. The following are two examples of such assays:

—		Lead p.c.	Copper p.c.	Zinc p.c.
No. 1	Before roasting .	22	2·5	—
	After roasting .	21	2·5	10
No. 2	Before roasting .	25	5·5	8
	After roasting .	22	5·4	10

—		Silica p.c.	Silver grams per 100 kilograms
No. 1	Before roasting .	—	75
	After roasting .	27	67
No. 2	Before roasting .	14	100
	After roasting .	20·7	102

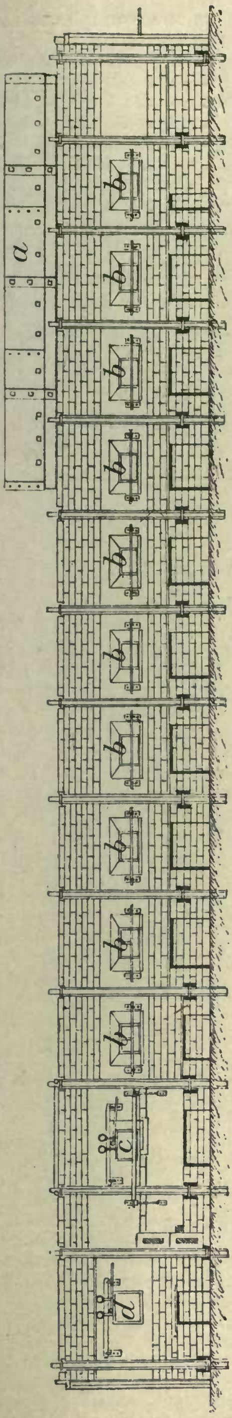

FIG. 12.

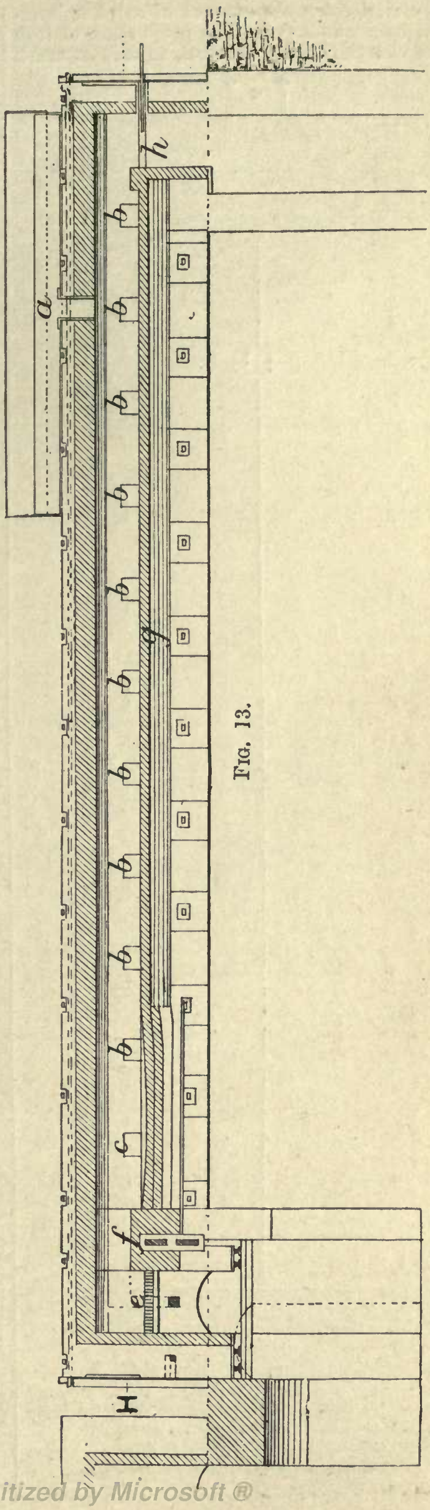

FIG. 13.

By calcination the amount of sulphur is reduced to about 2 p.c. The proportion of iron in the charge is never assayed, in fact as much iron pyrites as possible is added, and in some cases iron ores also.

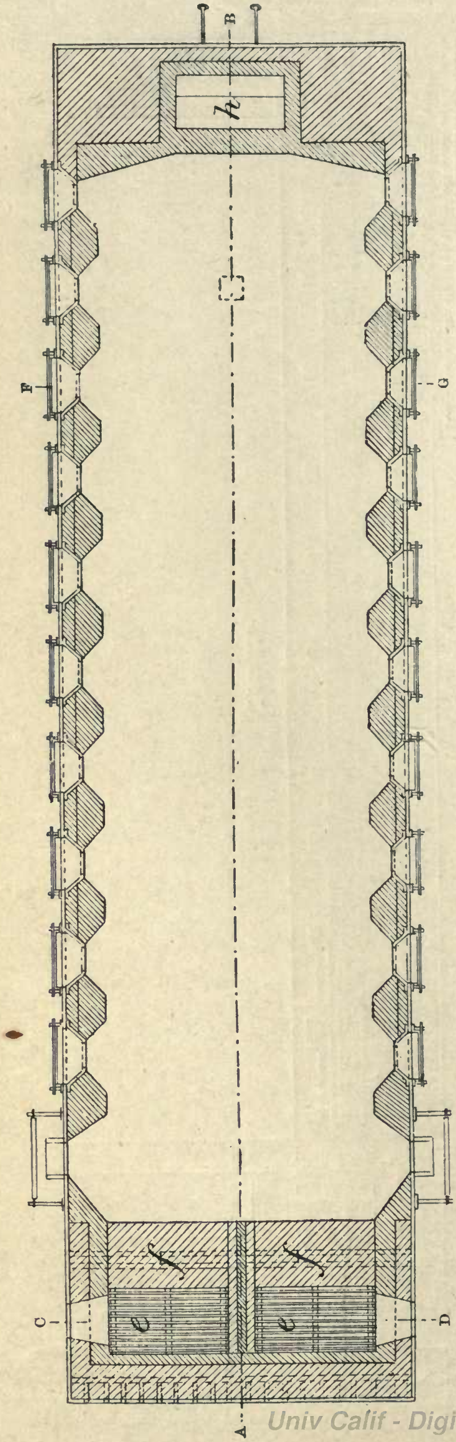

Fig. 14.

The following are two examples of a charge prepared for roasting :

	No. 1	No. 2
Galena . . .	41·00	37·20
Bleiische Erze . .	7·47	11·00
Iron pyrites . .	43·33	40·46
Silicious iron pyrites	4·50	4·81
Silicious minerals .	1·60	6·53
Residues from zinc manufacture . .	2·10	—
	100·00	100·00

The proportions of crude to roasted ore in the above mixture are as follows :—No. 1 : Crude ore 53·88, roasted ore 44·03. No. 2 : Crude ore 60·73, roasted ore 39·27.

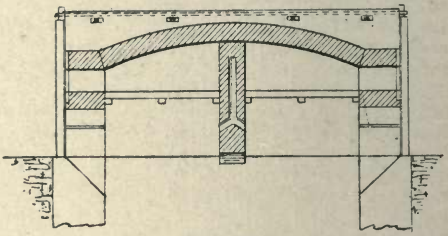

Fig. 15.

The *Fortschaufelungsröstöfen* is an example of the hand reverberatory roasting furnaces. There are, however, a number of forms of mechanical reverberatory roasting furnaces, some with stationary hearths and others with moving hearths, for the detailed description of which the reader is referred to Hofman's Metallurgy of Lead (New York and London, The Scientific Publishing Co.).

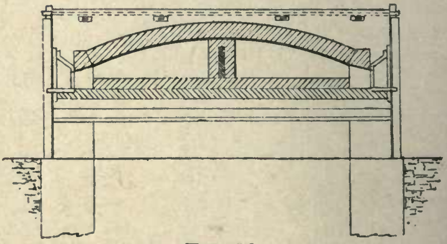

Fig. 16.

In 1896 Huntington and Heberlein introduced a method of treating galena, and concentrates consisting of galena mixed with pyrites and blende ; by this process the ore is rapidly desulphurised and obtained in a condition suitable for the blast furnace, and incidentally the sulphur dioxide produced may be utilised for the production of sulphuric acid. In this process the ore is mixed with from 6 to 15 p.c. of lime, according to the proportion of sulphur in the ore, and heated slowly in a reverberatory furnace. The partially desulphurised material is transferred to a pear-shaped vessel, made of sheet iron, styled a converter, in which it is submitted to the action of a blast of air ; during the blowing in the converter, energetic oxidation takes place, accompanied by other reactions resulting in a rise of temperature sufficient to bring about an agglomeration of the mass. In explanation of the Huntington-Heberlein process it appears, according to W. Maynard Hutchings (Engineering and Mining Journal, 1905, 726), that in the first action the lime is primarily converted into sulphate. 'The strong base, lime, apparently plays the part of "catalyser" in the most vigorous manner, the first SO_2 evolved being instantly oxidised and combined with the lime to sulphate, with so strong an evolution of heat that the operation spreads rapidly.' In the reactions in the converter silica plays an important part, decomposing the sulphates leading to the production of a basic silicate of lead, calcium, and other metals present with the elimination of all the sulphur. This explanation put forward by Hutchings (*l.c.*) is supported by the experiments of Hilpert (Metallurgie, 1908, 537 and 539) on the lead silicates, as also by the observations of Hofman and Mostowitsch (Trans. Amer. Inst. Min. Eng. 1909, 51), on the reactions between silica and calcium sulphate at temperatures between 1000° and 1250°, under which circumstances, it is shown that the sulphate is converted into silicate, sulphur dioxide and oxygen. Further, it is shown that ferric oxide effects a similar decomposition. In the light of these facts the Carmichael-Bradford process, used in Australia, is readily understood. In this method the ore is mixed with dehydrated gypsum and fed into a converter on to a small bed of glowing coal, which is kept glowing by a gentle blast of air. Another modification of the Huntington-Heberlein mode of treatment is the Savelsberg process, in which limestone is used in place of dehydrated gypsum. The new departure of 'blast roasting' or 'lime roasting,' inaugurated by Huntington and Heberlein, has been followed by the introduction of many modifications, amongst which may be mentioned the Dwight-Lloyd sintering process, which is a continuous one, and yields a porous sinter having a coke-like structure, and in a form suitable for treatment in a blast furnace. The essential feature of the Dwight-Lloyd process is that blast roasting is effected by a down-draught. The various types of machines employed embody, according to Hofman (Report of the Seventh International Congress of Applied Chemistry, London, 1909, sect. 111A, 18–23), the following three functions: '(1) a layer of ore is spread mechanically to the thickness of from 2½ to 5, average 4 inches, on a travelling herring-bone grate; (2) the ore stream thus formed passes first under an igniter, placed at right angles to the grate, to become ignited at the surface, and then over a stationary suction box, which, by down-draught, causes the roasting started at the surface to progress downward and be finished when the ore reaches the farther end of the suction box; (3) the sintered ore is discharged automatically in a size suitable for blast furnace treatment.' *Cf.* Bannister, Trans. Inst. Min. a. Metal. 1912.

Smelting for lead in blast furnace.—The roasted ore is next reduced by fusion with coke in a blast furnace, the form which has been adopted at Freiberg being a circular Pilz furnace resembling that used at Clausthal from which it differs in the manner of drawing off the gases and also in the arrangement used for charging the furnaces, and in having the sides of the furnace in the zone of fusion constructed of cast-iron boxes through which water circulates. The accompanying illustrations, Fig. 17 (from Percy's Metallurgy; Silver and Gold, part 1, 542), represent the Pilz furnace used at Freiberg in 1878. It is 25 feet high, is circular in section, 4 feet 11 inches diameter at the hearth, and gradually widening to 6 feet 7 inches at the top, and is supplied with eight twyers.

a, the hearth bottom, composed of four courses of bricks, the lowest common brick, resting on a circular plate of iron 1¼ inches thick, then three courses of fire-bricks, and is encased in boiler-plate, made in segments screwed together and further strengthened by hoops of wrought iron; *b*, channel extending through the brickwork and open at both ends; these channels, of which there are two, at right angles, allow of the escape of moisture; *c c*, brickwork forming the inner and upper part of the hearth; *c′ c′*, brickwork of the boshes; *c″ c″*, brickwork forming the shaft; *d d*, the tap holes, of which there are four; *e e*, two slag lips, along which the slag flows into the slag pot *p*, consisting of a cast-iron conical vessel; *f f*, blast pipes, the horizontal portions of which can be moved to and from the twyer holes; the vertical portions are supplied with a sliding screw by means of which they may be moved up and down; *g g g* are water-jackets made in sections, and of wrought iron, the construction of which is shown in detail in the accompanying illustrations. Water-jackets may also be constructed of cast iron instead of wrought iron, each segment being provided with an aperture for the twyer and also pipes for conveying the cold water and for the outflow of the heated water; *h h*, ring of angle iron, riveted to the outer case, serving for the support of the shaft during the repairing of the lower part of the furnace; *i i*, blast main of cast iron; *k*, ring of iron supported by the four cast-iron pillars *l l*; *m*, cast-iron cylinder, flanged at the top and inserted into the mouth of the furnace, in order that the fume and waste gases may be drawn off by the pipe *n*; *o*, charging floor; *q*, outer iron casing of the furnace. The water-jackets are composed of wrought-iron plates ⅓ of an inch in thickness, and are riveted to angle iron 2⅜ inches by ⅜ inch; *s s* are side plates overlapping by 2¾ inches top and bottom; *t*, pipes for supplying cold water; and *u*, pipe for the outflow of cold water; *v*, twyers, which are 2¾ inches diameter.

The following are four examples of the '*lit de fusion*' for such a blast-furnace, in tons of 1000 kilogs.:—

—	*a*	*b*	*c*	*d*
Roasted minerals . .	40·0	40·0	40·0	35·0
Foreign minerals (crude) .	1·20	0·6	0·6	0·6
Jewellers' sweepings . .	0·8	0·5	1·0	1·0
Residues from the manufacture of arsenic products (roasted)	6·00	6·00	6·00	7·00
Slags	27·5	25·0	27·5	27·5
Matte after a second roasting	1·00	1·00	1·00	1·00
Unroasted matte . .	0·75	0·75	0·75	0·75
	77·25	73·85	76·85	72·85

The products consist of a work-lead, a matte, occasionally a speiss, slags, and fume. The yield of work-lead from each of the above charges was the following :

a.	6 tons	450 kilogs.
b.	7 ,,	760 ,,
c.	7 ,,	940 ,,
d.	5 ,,	850 ,,

The lead contains many metallic impurities —*e.g.* copper, arsenic, antimony, bismuth, tin, iron, and sometimes cobalt and nickel ; the proportion of silver present is very variable, and dependent upon the proportion of foreign rich minerals used in the charge. If above a certain percentage of cobalt and nickel are present in

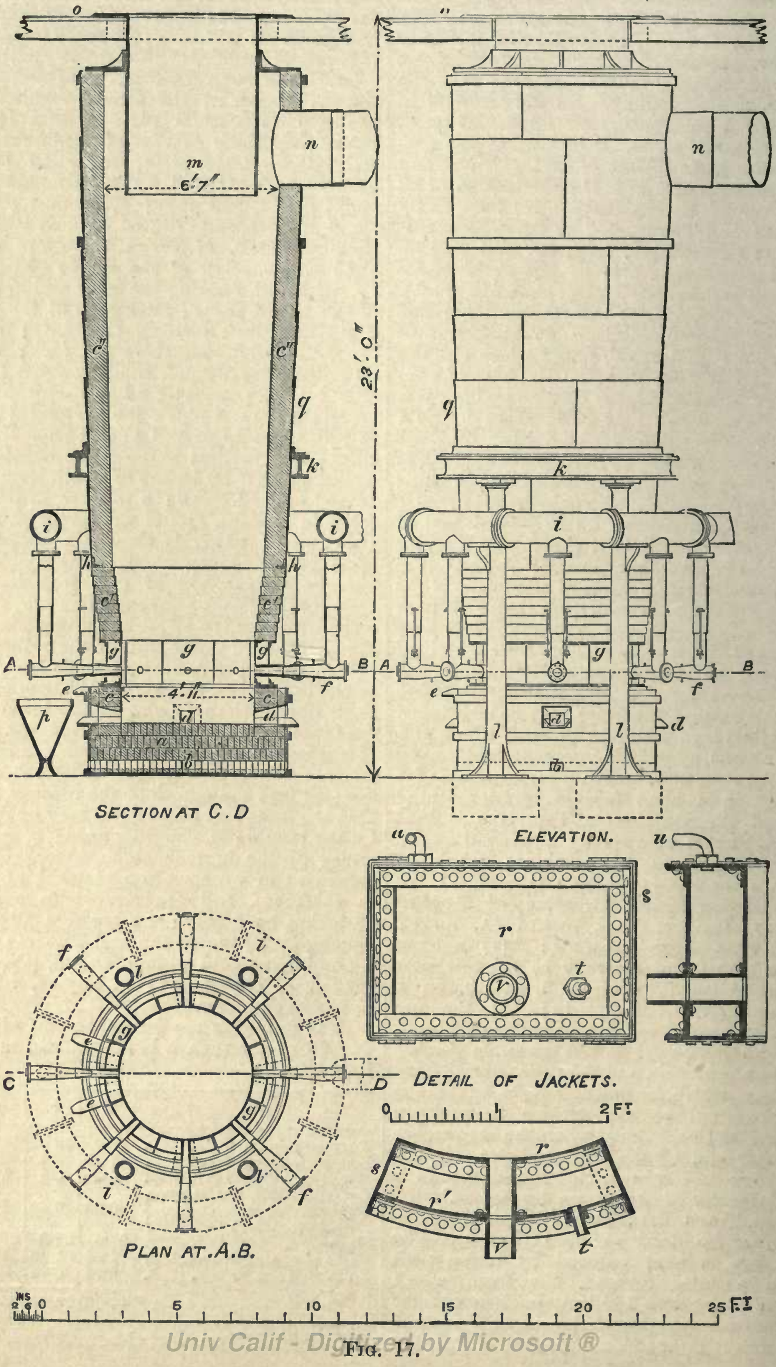

FIG. 17.

the materials smelted, a speiss is produced containing lead, copper, cobalt, nickel, and also silver. The average amount of matte produced from the above charges would be 1 ton 900 kilogs., and would contain from 15 to 20 p.c. of lead and from 10 to 12 p.c. of copper.

The slags produced consist chiefly of protosilicates, and are highly ferruginous. They contain 4–5 p.c. of lead, and, on an average, from 10 to 20 grammes of silver per 100 kilogs., in consequence of which they are in part returned to the blast-furnace and in part used in the subsequent smelting of the matte.

The amount of coke consumed is about 190 kilogs. per ton of roasted ore smelted.

The matte produced in the blast-furnace is first roasted in kilns and then in stalls, and the roasted matte is smelted in a blast-furnace similar to that used in smelting the ores, producing in this way a further quantity of lead, a second matte, and slag. The following is an example of the '*lit de fusion*' for first matte smelting:

	Tons
Slags from ore smelting . .	37·5
Matte (after three roastings) .	6·0
Matte (crude)	0·6
Foreign copper ores . . .	1·8
Slags from previous smelting .	2·5
'Abzug' from liquating furnace	1·6
Cupel bottoms	1·2
Drosses	1·5
	52·7

The amount of lead produced from these quantities was 3 tons 65 kilogs.; this lead is very impure, and contains on an average 400–500 grams of silver per 100 kilogs. The matte called second matte will contain 10–12 p.c. of lead, 12–15 p.c. of copper, and 140–150 grams of silver per 100 kilogs. The slags are usually thrown away; they may contain from 0·5 to 1 p.c. of lead, and 1–2 grams of silver per 100 kilogs. These slags are occasionally used for building purposes. The coke consumed is 116 kilogs. per ton of matte, &c.

This second matte, obtained in the operation described above, is treated in exactly the same manner as matte No. 1, and a further amount of work-lead rich in silver is obtained, which is submitted to liquation, and a third matte containing from 20 to 25 p.c. of copper, which is subsequently treated for the extraction of copper.

The different leads produced in the smelting of ore and of the mattes are very impure, containing about 5 p.c. of total impurities, amongst which are arsenic, antimony, tin, iron, zinc, bismuth, copper—at times cobalt and nickel. The purification and desilverising of the work-lead will be described subsequently.

At Leadville, in Colorado, lead ores are smelted in blast furnaces of the Raschette type, provided with water-jackets and also with a siphon tap which has been introduced into blast furnaces in this country and on the Continent. The siphon tap is a contrivance consisting of an oblique channel penetrating the bottom of the hearth of the furnace, by which the lead rises into a basin placed outside the furnace, and from which as it accumulates the lead is ladled out into moulds. The ores smelted at Leadville are locally styled *sand carbonates* and *hard carbonates*. The former consist of lead carbonate containing silver chloride, whilst the latter are a porous silicious material containing lead carbonate and silver chloride associated with hydrated oxides of iron and manganese. In some cases the ores contain considerable quantities of argentiferous galena, which is frequently covered with a coating of lead carbonate. The chief foreign ingredients, which are but few, are clay, limonite, and silica. Pyromorphite and anglesite are found in small quantities, as are also oxidised compounds of copper, arsenic, and antimony. In some mines bismuth and vanadium ores are found, and silver is found combined with iodine and bromine in addition to chlorine. The fuel used in smelting these ores is coke and charcoal; limestone, hæmatite and limonite are employed as fluxes, but in many cases the ores contain sufficient admixture of iron compounds to enable them to be treated directly in the blast furnace. The pig lead obtained, which is known as *base-bullion*, carries from 100 to 250 oz. of silver per 200 lbs, and from 0·25 to 0·14 oz. of gold; this is treated for silver and gold in the Eastern States. Each unit of lead produced requires the expenditure of 1½ units of fuel.

SMELTING ON SHALLOW HEARTHS.

The furnace known as the 'ore hearth,' or 'Scotch hearth,' is the one chiefly used in smelting galena in the northern counties. It varies considerably in dimensions and in external form at different works, but consists essentially of a shallow rectangular hearth built of cast iron, set in brickwork or stone. Fig. 18 is a vertical section of the 'ore hearth,' A the hearth bottom, 22 inches square, the iron plate being about 3 inches thick; the sides are also composed of iron of the same thickness, and the depth of the hearth will be about 4½–6 inches. In front of the hearth is the work-stone B, sloping from the front edge of the hearth to the metal pot C, in which the lead is maintained in a molten state by a fire below. The work-stone is about 3 feet long, 18 inches broad, and 2½ inches thick; it has a raised border of about an inch high on its two sides and along the front, and a narrow channel 2 inches wide and 1 inch deep runs diagonally across it. The work-stone is embedded in fireclay or a mixture of slime, ore, and bone-ash. At the back of the hearth is a prism of iron, called the back-stone, D, upon which rests the bellows-pipe, and above it is another prism E, called the pipe-stone, with an opening below to receive the bellows-pipe. The blast-pipe enters at a height of some 6½ inches above the level of the upper end of the work-stone, and when in work will be about 4 inches above the

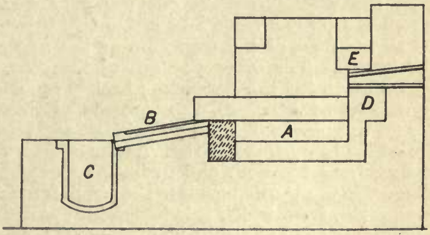

FIG. 18.

level of the metal in the bed. The hearth is covered by a hood of brickwork, opening at the back into a flue leading to the fume condensing chambers. Behind the hearth is a blind flue or pit into which 'hearth-ends' and other matter coming off with the fume may fall and collect, and from which it is removed as required. At the side of the hood is an opening in the brickwork communicating with the hearth, through which the ore and fuel are charged. The opening in front can be regulated by a movable iron plate, which in some cases is in the form of a sliding shutter, and by means of a counterpoise can be raised or lowered in its groove so as to nearly close in the front of the hearth.

The fuel used is either coal or peat, now more usually coal, and the blast is supplied by a Roots blower, and the ore may be either added in the raw state, or, as is more usual, after it has been roasted in a reverberatory furnace. The working of this hearth requires the constant attention of two men, and at the end of each shift the bottom should be nearly filled with lead, which in the molten state forms the bottom on which the charge rests. The mass of agglomerated ore, slag, and coke left at the end of each shift is called the 'browse.' In working, a fire of coal is made on the hearth, and then a moderate blast turned on. Ore is next thrown on, and when the hearth is provided with a shutter, this is closed down. After the lapse of a few minutes, the charge is stirred by a poker and fresh ore and fuel added from time to time. At intervals the shutter is raised and a portion of the charge drawn on to the work-stone, and then the workman picks out the grey slags, which are pushed aside and ultimately thrown on to the floor of the workshop at the side of the hearth. The other portions of the charge drawn on to the work-stone are broken up, and returned to the hearth, the contents of which are set up so as to distribute the blast, and fresh ore added in small quantities. As the lead forms it flows into the well, and overflows along the channel in the work-stone into the pot in front of the hearth, from which it is ladled into moulds. Towards the end of a shift no fresh ore is added, but the 'browse' is thoroughly worked up alone, and when the blast is stopped, the grey slags are separated from it, and a portion of the lead from the metal pot ladled back into the well in the hearth so as to fill it for the next shift. The process is essentially an air reduction process; the object being to oxidise the ore and then by subsequent admixture with ore to bring about the reactions between the unaltered sulphide and the oxy compounds resulting in the formation of lead. Formerly, as has been already stated, the ore was treated in the raw state, but is now more generally submitted to a calcination, by which a portion of the sulphur is removed and the slimes agglutinated, thus enabling them to resist the force of the blast and reduce the amount passing away in the form of 'hearth-ends' and fume. The influence of this previous calcination in reducing the fume and loss, &c., is shown by the following results obtained by the late Mr. Norman Cookson, in smelting 400 tons of ore, yielding on assay 81 p.c. of lead, one half of which was smelted raw and the other half after roasting (*v.* Local Government Report, 1878-9. Supplement containing the Report of the Medical Officer, 1878, 289).

	200 tons roasted	200 tons raw
Lead, first fire . .	73·10	60·80
Lead in grey slags .	2·50	1·80
Lead in fume, hearth-ends, loss, &c. .	5·40	18·40
	81·00	81·00

The American hearth, first introduced at Rossie, New York, is similar in construction and working to the Scotch hearth, from which it differs in having the two sides and back formed into an air chest, through which the air passes, from which it is conveyed by a pipe to a twyer at the back of the hearth. In this way the back and sides of the hearth are kept cool and a hot blast supplied, the latter has not, however, proved an advantage; the loss by volatilisation was found to be greatly increased, a fact which led to the replacement of this form of hearth by what is known as the American water-back ore hearth. The water-back ore hearth resembles the Scotch hearth, but has the three sides of the furnace formed into a water-cooled, cast-iron jacket. For the details of the construction of this and also of the Moffet ore-hearth, the reader is referred to Hofman's Metallurgy of Lead.

Slag hearth.—The various rich slags obtained by smelting in reverberatory furnaces, or in the ore-hearth, are usually smelted in a special blast furnace, known as the slag-hearth. In some establishments the Castilian blast furnace with three twyers is used, whilst in others furnaces similar in type to the Pilz furnace, and provided with water-jackets, are employed.

The ordinary slag-hearth is furnished with one twyer, and has the form of a deep hearth or shallow rectangular furnace. It is built of fire-brick and cast iron, incased in common brickwork, leaving an opening in front. The outer casing is prolonged, forming a shaft which is connected with the flues for condensation of fume, &c. The bottom is formed of a plate of cast iron, styled the *bed-plate*, and laid with a slight inclination forwards; on the bed-plate are placed two cast-iron *bearers*, which carry the side walls of the furnace. In front is a plate of iron, the fire-stone, placed so as to leave an interval of 7 inches between its lower edge and the bed-plate; the back of the furnace below the twyer is formed of another plate of iron. In front of the bed-plate is a cast-iron trough, the lead trough, which is usually divided into two unequal parts by a partition forming a part of the casting. The larger of these divisions corresponds in width with that of the bed-plate, and at the bottom of the partition is a hole through which the molten metal flows into the smaller division of the trough. The slags flow from an opening in the stopping of the breast into the larger division of the lead pan, and flow over from this into a pit sunk in the ground, through which a current of water flows. The outer brickwork surrounding the hearth is supported by iron plates braced together with tie-rods, the twyer passing through the plate which supports the back stone on which the nozzle rests. The outer brickwork is built so as to leave an opening in front of the hearth, and there is also an opening at one side for charging the furnace. The bed-plate is covered to within an inch of the twyer with coarsely sifted coal cinders, thus forming a bottom which slopes with the bed-plate towards the lower edge of the firestone. The space in front of the ash bottom, between the bearers and firestone, is plastered up with clay. The ash bottom serves as a filter to separate the slag from the lead, which percolates through to the bed-plate and then flows through openings in the clay stopping into the lead trough. This also is filled with cinders, through which the lead passes and finds its way to the bottom and through the partition into the smaller division of the trough, whilst the slag flows over into the slag pit, the sudden cooling of which by the water determines its disintegration, and renders easy the separation of any inclosed particles of metal. The fuel employed is coke and peat, and in commencing to work with this furnace, after making the bed of cinders as described, peat is piled up above the bed and ignited, then the blast turned on. When the peat is burning, coke is thrown into the furnace and a layer of grey slags added. This is continued as the operation proceeds, alternate charges of fuel and slag being added; lead is produced and a slag 'black slag,' free or nearly free from lead. Occasionally a bar of iron is thrust through the layer of cinders to liberate the slags and lead. The lead obtained from ore-slags is not as pure as that obtained at the first smelting; it is whiter and much harder, and is afterwards submitted to the calcining process to soften it. In some cases iron slags are added with the fuel and grey slags; especially when the grey slags contain much lime is this addition useful, the formation of an easily fusible slag being in this way promoted.

SOFTENING AND DESILVERISING.

The lead obtained by smelting may contain, in addition to silver, antimony or copper and other oxidisable metals, which may be present in quantities sufficient to interfere with the desilverising process; the metal is, therefore, when necessary, submitted to an operation known as *improving* or *softening*.

The *improving* or *softening* is effected in a reverberatory furnace, the bottom of which consists usually of a cast-iron pan, about 2 inches in thickness, length about 10 feet, width 5 feet 6 inches, and 10 inches in depth. All the angles of the casting are carefully rounded to prevent breakage by expansion or contraction, and the softened lead is drawn off by a hole bored in the bottom, near the outer edge, which is stopped by a well-fitting iron plug held in its place by a weighted lever. Such furnaces are usually made to hold from 8 to 12 tons of molten lead.

The fireplace is about 20 inches wide, and has a length equal to the width of the cast-iron pan, from which it is separated by a bridge 2 feet wide. The height of the furnace above the pan at the bridge end is 16 inches, and at the other end it is 8 inches.

The charge is introduced either in the form of pigs or is first melted in an iron pot set in brickwork at the side of the furnace, and subsequently ladled into a sheet-iron gutter, by which it is conveyed to the furnace. A softening furnace has been constructed with the iron pot for melting the hard lead, built above the calcining furnace, and so arranged that the heat required for the fusion is supplied by the furnace fire. The molten lead is run into the calcining pan by raising a plug at the bottom of the pot, the opening in which is immediately above the pan and a little to one side of the fire-bridge.

In this furnace the molten lead is submitted to the action of heated air, whereby the easily oxidisable impurities are converted into oxides, which, floating on the surface of the bath, are removed by an iron rake; in this way a fresh surface is constantly exposed to the action of the heated gases, and thus the greater portion of the impurity is removed. The progress of the operation is judged by taking a sample in a ladle and casting it in an iron mould; when the calcination has been completed the surface will present a peculiar flaky crystalline appearance. The calcined or softened lead is then tapped into an iron pot, from which it is ladled into the pig moulds, or is run from the furnace by a movable iron gutter into a series of pig moulds placed in readiness in front of the furnace.

In some districts hard lead is improved in a furnace with a slag bottom, which allows the operation to be conducted at a much higher temperature, and more rapidly than in iron pans. In Germany a marl bottom is used, whilst in some establishments these furnace bottoms are constructed of wrought-iron plates in form of a long shallow rectangular pan, the sides and bottom of which are lined with firebrick. Furnaces of this construction are made to hold as much as 70 tons of molten lead.

The calcined dross removed from the lead is reduced with coal, and the slag produced reduced in the slag hearth or in a cupola. In this way a very hard lead is obtained, which is again calcined, and the drosses formed yield on reduction a lead sufficiently rich in antimony to be sold to typefounders.

Leads containing a considerable proportion of copper are submitted to liquation before softening. The liquation is effected by heating the pigs of lead in a reverberatory furnace, the bed of which slopes from the fire-bridge and terminates in a sump or lead-pot at the flue end. The pigs are piled up at the upper end of the furnace-bed and subjected to a low heat; the lead first melts and flows down into the pot, whence, after skimming, it is ladled into moulds. The more refractory dross containing the copper, nickel, and a portion of the arsenic, and also sulphur, is left behind.

SILVER CONCENTRATION—DESILVERISING AND LEAD REFINING.

Concentration of silver in lead.—Before separating the silver from the 'improved' or softened lead it is submitted to a process having for its object a concentration of the silver to an extent sufficient to render its extraction economical. The silver concentration or enriching of the lead is performed by the Pattinson, the Rozan, or the Parkes' process. The first two of these processes are alike in principle, and are founded on the observation made by the late Hugh Lee Pattinson, of Newcastle-upon-Tyne, that when lead containing silver is melted and the molten mass allowed to cool slowly, at the same time being constantly stirred, then, at a temperature near the melting-point of lead, crystals begin to separate out. The crystals so produced are found to contain a smaller proportion of silver than the original lead, whilst the liquid alloy from which the crystals have been separated is proportionately richer in silver. This discovery was made the basis of a patent by Hugh Lee Pattinson, for 'An improved method of separating silver from lead,' the date of the patent being October 28, 1833, and at the meeting of the British Association held at Newcastle-upon-Tyne in 1838 the process was described in a paper by Mr. Pattinson. The introduction of this method of enriching lead has made it possible to extract the silver even when it is present in amounts so small as from 2 to 3 oz. to the ton, the desilverised lead retaining from $\frac{1}{2}$ to $\frac{3}{4}$ oz. of silver per ton. With present prices it would not, however, prove remunerative to Pattinsonise lead containing less than 4 oz. of silver per ton.

Pattinsonising, Pattinsonage, Pattinsoniren. The operation is conducted in large cast-iron hemispherical pans, capable of holding 6–10 tons of molten lead. The small 6-ton pots are now rarely used, and in some establishments pots capable of holding 18 tons of lead are employed, the larger size requiring the use of cranes in working the ladles. A series of nine to twelve of these pots is placed side by side in a line and resting on brickwork supports. Each pot is provided with a separate fireplace, the heated gases from which are conducted round the pan by a circular flue and thence pass into a flue running the whole length of the pots by which the gases are conveyed to the chimney. In addition to the large pots, there are sometimes smaller pots placed at the side between the larger pots, and heated by a separate fire; these serve to hold some melted lead for the purpose of heating and cleaning the ladles. Along both sides of the erection in which the pots are built is a platform on which the workmen stand. The pot at one end of the series is smaller than the others, being about two-thirds the capacity, this is called the *market pot*, which receives the poor lead and from which the lead is run into the pig moulds. The other apparatus used in this process consists of perforated ladles made of iron $\frac{1}{2}$ inch in thickness; when worked by hand the ladle would measure 16 inches in diameter and 5 inches deep, the holes being $\frac{1}{2}$ inch in diameter, whilst when cranes are used the ladle would measure some 20 inches in diameter, 6 inches in depth, and the holes would be $\frac{3}{4}$ of an inch. The handle of the ladle is some 9 feet 6 inches long, and $\frac{1}{2}$ an inch in thickness. In addition to the ladle, a chisel-pointed bar or *slice* is used in stirring the lead.

Fig. 19 shows the arrangement and mode of setting a range of pots.

The method of working will be best understood by supposing the lead to be treated contains some 20 oz. of silver to the ton; the metal in the form of pigs would be charged into one of the pots about midway between the *market pot* and the *rich pot*, the fire is set on and the lead melted; by the melting the surface of

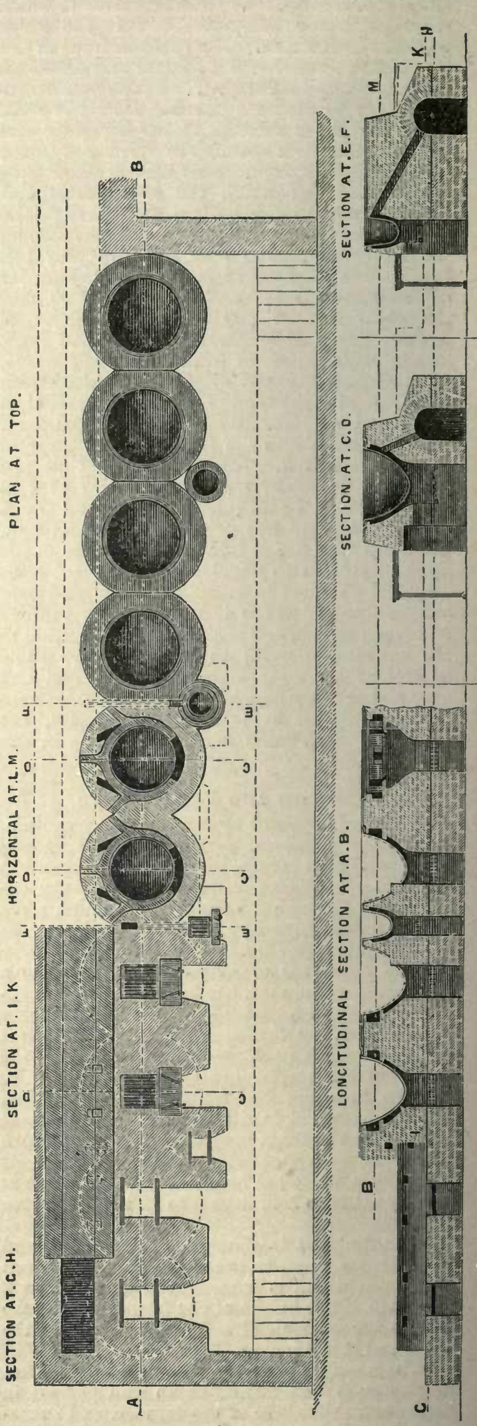

FIG. 19.

the metal is covered with a layer of dross, which is carefully removed by a ladle and the fire withdrawn. Water is sprinkled on the surface of the molten bath to promote cooling, and as the metal cools a cake is formed on the surface, which is detached and broken up by means of the slice, and the pieces stirred into the liquid. As the cooling proceeds the mass is kept continually stirred, and after a time crystals begin to make their appearance. The crystals are now removed by means of the large perforated ladle, which is plunged into the liquid and then gradually raised, the side of the pot serving as a fulcrum; the ladle is raised until it is completely out of the bath and is brought into a tilted position, and while in this position the crystals are allowed to drain. When drained the contents of the ladle are transferred to the next pot on the left, supposing the market pot to be at the left extremity of the range. This operation is repeated until two-thirds of the original charge has been transferred in this way. The remaining third, which represents the rich alloy, would be transferred to the next pot on the right —*i.e* toward the *rich pot*. The rich bottoms, as they are called, will contain 40 oz. of silver to the ton, and any lead that may be on hand having a similar silver content would be added to the enriched bottoms. The poorer lead from this single operation would contain about 11 oz. and similarly any lead to hand of this assay would be added to the metal obtained by this operation. A second charge would be next introduced into the pot in which the first operation was conducted and would yield further quantities of poorer lead and enriched bottoms, the former transferred to the left and the latter to the next pot on the right. The poorer lead would be similarly treated, and from it a further quantity of still poorer lead would be produced, which is passed on to the next pot to the right and so on until the lead which reaches the market pot will contain some 10 dwts. of silver per ton; the enriched lead gradually meanwhile making its way to the *rich pot*, but in the richer pots the separation is less complete than in the poorer ones, and the enrichment is not so rapid. In working the last pot, after two-thirds of the metal in form of crystals have been transferred, the enriched bottoms will consist of crystallised and liquid alloy, and the latter is separated from the former by pressing the mass with the back of the ladle, the fluid portion, the richer in silver, runs through the holes in the ladle and is removed by an ordinary ladle. Working in this manner a market lead is obtained at one end of the range in which the silver is reduced to the amount already stated, and at the other end of the range is produced lead containing from 600 to 700 oz. of silver to the ton, beyond which it is not possible to push the concentration by this method.

In the above description it has been assumed that the method of thirds or the high system was employed. This is the method most usually adopted in practice, but for special purposes the low system or method of eighths is sometimes used, in which seven-eighths of the contents of the pots are transferred to the poorer pot. In some works the method of seven-eighths is used for 'riching up' rich leads to the refinery grade of about 600 oz. In the seven-eighths system the lead should treble itself in assay in each operation, but this is seldom the case. In the two-thirds system each operation is supposed to result in the doubling of the silver content of the lead, but in practice this only obtains with leads ranging downwards from about 50-60 oz. of silver per ton.

As at each melting of the lead the metal is oxidised and a layer of dross formed on the surface, the bath is carefully skimmed after each melting and the drosses collected for future reduction. With a 20 oz. lead, the amount of drosses formed is 25 p.c. of the weight of the metal. The continual drossing of the metal naturally effects a purification of the lead, as the dross produced consists not only of lead oxide, but also of the oxides of the more easily oxidisable metals present. The value of the Pattinson process as a means of not only enriching the lead, but also of purifying it, is shown by the fact that lead to be used for white-lead making is frequently Pattinsonised, although the amount of silver present may be very small. Further, copper and iron are both separated with the silver in this process when the amount of copper does not much exceed 0·025 p.c.

The Rozan process or Pattinsonising by steam.—This process of crystallising by steam was first introduced in the works of Luce and Rozan at Marseilles, and has been described by Rozan in the Berg- und Hüttenmännische Zeitung for 1874, and also by Norman C. Cookson in a paper published in the Transactions of the Newcastle Chemical Society for 1878. In this system steam under pressure is forced into molten lead, and by the continual agitation of the mass produced in this manner the production of crystals poor in silver is favoured, and the separation of an enriched fluid lead facilitated. Cookson, in the paper referred to, is inclined to the opinion that the steam serves a second purpose, producing a chemical effect and aiding in the oxidation of the antimony, copper, iron, and arsenic, and other oxidisable metals present. This oxidation may be due to the air carried into the pot by the steam. In any case leads such as rich Spanish leads containing as much as from a $\frac{1}{2}$ to $\frac{3}{4}$ p.c. of foreign metals may be treated by this system without having been previously calcined or softened. The following is the description of the plant and mode of working taken from the paper already referred to:—

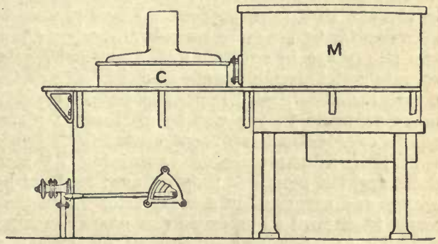

FIG. 20.

'The pot marked M (Fig. 20) is simply a melting-pot, and the lower pot C is the working, or, as it is commonly called, the crystallising pot. To illustrate the working, we will suppose the C pot contains 14 tons lead crystals from a previous operation, assaying, say, 80 oz. of silver per ton, and the M pot 7 tons original lead of similar silver content already melted; a moderate fire is set away in the firegrate of the C pot, and the contents of the M pot are skimmed of their dross; the hot lead from the pot M is then run on to the warm crystals in the C pot, and, with the assistance of the moderate fire already referred to, the whole contents of this pot (now 21 tons) are rapidly brought into a melted and working condition, when the charge is carefully skimmed; the M pot is at the same time charged with 7 tons of lead containing about 40 oz. silver per ton of lead, as this will be the assay of the crystals resulting from the operation shortly about to commence in the C pot. The fire under this pot is next drawn, and a small fire under each of the tapping spouts is set away, the object of this being to prevent the lead setting in them when tapping out the rich lead later on. Steam at 50-55 lbs. per square inch is next admitted through the valve V, and is distributed evenly through the pot by the baffle plate *b* (Fig. 21). To hasten the cooling and consequent crystallisation, thin streams of water are allowed to run on to the surface of the lead. This might be thought to cause the lead to set on the top, but the violent action of the steam entirely prevents this, and the crystals as formed and the liquid lead are uniformly distributed through the pot, and a more perfect crystallisation is effected than can be obtained in the old Pattinson process. When the workman sees that the charge is ready, *i.e.* when about two-thirds are in crystals and one-third liquid, he taps out through spouts at either side of the C pot the rich liquid lead, the poorer crystals being retained in the pot by perforated plates which effectually keep them back. This liquid lead is run into moulds containing 3½ tons each, and the blocks as they set are lifted out by cranes and arranged in a semicircle, where they await their turn to be again and again operated on. This process of crystallising, as in that of Pattinson, is repeated until the crystals are sufficiently poor in silver not to require further treatment, when, being fit for market lead, they are melted and run into pigs of the usual size, or into 3½-ton blocks, according to the purpose for which we require them. As regards the rich lead, it is worked up until its silver contents are of the standard fit for the refinery. A large portion of the foreign metals contained in the original lead is skimmed off in the state of oxides; and any one seeing these oxides for the first time will be struck by the fact that those from the operations in the richer charges will be very dark in colour, some in fact almost black, this being due to the impurities contained, while as they come down in silver contents they have the yellowish colour proper to the oxides of lead. A large portion, however, is carried off up the funnel above the C pot, with the escaping steam, and is deposited in the condensing chambers, of which we have several of good size. These oxides are of various metals, that of lead being in the proportion of 80-85 p.c., the remainder consisting of the oxides of copper, antimony, arsenic, iron, &c., but principally of the two first named.'

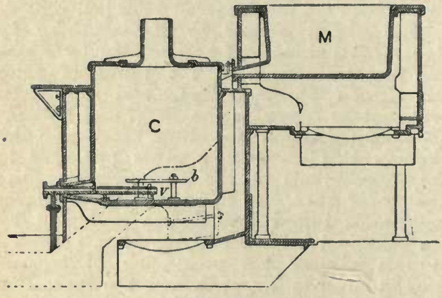

FIG. 21.

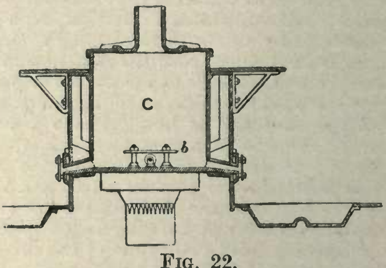

FIG. 22.

In the accompanying illustration of the plant used in the Rozan process, Fig. 23 is the plan of a battery, Fig. 20 is an elevation along the line S T, Fig. 21 a section along the line U V, and Fig. 22 a section along the line X Y.

The following table taken from Cookson's paper gives the silver assays of twelve crystallisations taken from an average of 350 operations:—

Ounces per ton of lead

570-315-202-112·5-62-33·75-19·5-10-5-2·5-1·25-14 dwts.

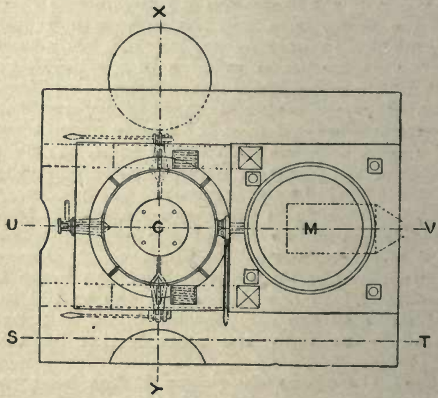

FIG. 23.

Mr. Cookson summarises the advantages of the Rozan system, as follows:—

'1. The entire saving of the cost of calcining all ordinarily hard leads, and in the case of extra hard leads, such as Greek lead, a very large saving.

'2. A cost for labour not exceeding one-fifth.

'3. A cost for fuel of about two-fifths.

'4. A saving of one-third in the oxides produced, which advantage any lead manufacturer will fully appreciate.

'Its defects are:

'1. A large capital outlay.

'2. A constant expense in repairs and renewals.'

The advantages of the system would appear to considerably outweigh the defects. The arrangement of the pots at different levels considerably reduces the labour of working a charge and at Messrs. Cookson & Co.'s establishment at Howden-on-Tyne, the working was still more simplified by having attached to each battery of Rozan pots a hydraulic crane, by which the blocks of lead, which are cast with an iron eye in circular moulds shown in section in Fig. 22, can be raised and lowered into the melting-pot or moved into any position at will. In fact, such is the perfection of the system of hydraulic cranes at this works that from the time the crude lead enters the work until it makes its exit as 'market lead' it is hardly ever touched by hand, but moved from place to place by cranes.

Parkes' system.—The method of desilverising lead by Parkes' process depends on the fact that when lead containing silver is melted with zinc, and the fluid mixture allowed to cool, the portion which first solidifies consists of a mixture of silver, lead, and zinc, and contains nearly the whole of the silver. Patents for this process were granted to Mr. Alexander Parkes, of Birmingham, in the years 1850, 1851, and 1852; and in 1859 the method was put in practice at Llanelly. It was subsequently tried at Tarnowitz, and, owing to the difficulties experienced in its working, finally abandoned at both places. The chief difficulties were (1) the removal of the zinc from the desilverised lead, which could not be performed sufficiently well to make the lead marketable; (2) the separation of the silver from the zinc alloy was attended by considerable loss; (3) the recovery of the zinc from the rich lead was somewhat difficult to accomplish.

The difficulties experienced in the use of this method have led to the proposal of several modifications of the original process, and the method as practised now at several establishments in this country, on the Continent, and in America, is comparatively simple, and is conducted as follows. At a height of some 8 or more feet from the floor level the several pots used in the process are set in brickwork, each being provided with a separate fireplace. The number of these pots will be determined by the quantity of lead to be treated. At one establishment visited by the writer the number of pots was five, two larger ones capable of containing 25 tons of lead, and three smaller ones each holding about 6 tons. The lead is charged into one of the larger pots and melted, and, when melted, a slab of zinc is laid in the bath and the temperature raised until the zinc melts. When this temperature has been reached, the remainder of the zinc to be added at this stage is thrown into the bath and the whole thoroughly well stirred. After stirring for a quarter of an hour the metal is allowed to cool, and, as soon as the crust of zinc alloy has become sufficiently solidified, it is removed by a perforated ladle, and the skimming continued until the lead begins to set. The skimmings are transferred to one of the smaller pots. The lead is again heated to the melting-point of zinc, and a further quantity of zinc thoroughly stirred into it, the cooling and skimming repeated as before, and the skimmings transferred to the smaller pot. After this second addition of zinc the entire operation is repeated with a third portion of zinc, and the pot subsequently carefully skimmed. The proportions of zinc used in the various additions will vary according to different practices. The following may be taken as representative of one method of working. The lead contained 550 oz. of silver; the total zinc required was 1130 lbs., which was distributed as follows: first addition 340 lbs. of zinc, for the second 340 lbs. also, and the remaining 450 lbs. were used in the last. The total amount of zinc used is determined by the richness of the lead, in accordance with the following table, which has been confirmed by experiments conducted at Clausthal:—

Lead containing	250	grams of silver, for 1000 kilos. required	1¼	p.c. of zinc.
,,	500	,, ,,	1⅓	,,
,,	1000	,, ,,	1½	,,
,,	1500	,, ,,	1⅔	,,
,,	3000	,, ,,	2	,,
,,	4000	,, ,,	2	,,

The desilverised lead left in the larger pot after skimming the third time is tapped or siphoned out, and run into an improving furnace placed at a lower level, where it is kept at a red heat for several hours and occasionally skimmed, the progress of the calcination being watched by withdrawing small samples, which are cast in a mould, and from the appearance presented on cooling the state of the lead is determined. When thoroughly calcined the lead is tapped into a cast-iron pot and then run into pig moulds.

For the recovery of the 0·7 p.c. of zinc retained by the desilverised lead Coda (D. R. P. 207104) proposes to add either an alloy of copper or copper-aluminium and lead, *e.g.* 5Cu : 94Pb, to the molten desilverised lead. This alloy has the property of taking up 10 p.c. of its weight of zinc and forms a crust, floating on the lead, which can be readily removed by skimming. From this crust the zinc is recovered by distillation.

The skimmings which accumulate in the smaller pots containing silver, lead, and zinc are gently heated to effect by liquation a separation of a portion of the lead and the argentiferous alloy which is separated from it by a perforated ladle. The liquated lead so obtained is added to the next charge of lead to be desilverised, whilst the solid alloy is next submitted to distillation, by which means the zinc is distilled off and obtained partly in a form in which it can be used over again, and partly in a pulverulent state consisting of zinc and zinc oxide. To this end the alloy is charged into a large fireclay crucible placed in a vertical furnace, heated by coke, and provided with a movable top, consisting of an iron framework with slabs of fireclay, and moved by a small crane. The mouth of the crucible is closed by a hemispherical cover provided with a tubulus for conveying the vapours of zinc to a vertical condenser, which stands on a vessel for receiving the condensed zinc. By this arrangement the crucible is converted into a retort in which the zinc-argentiferous alloy is distilled, the zinc volatilised, leaving behind the enriched lead, which is ladled out of the crucible. In this way some 40 p.c. of the zinc is collected in the metallic state and 20 p.c. in the form of dust mixed with oxide. Both are free from silver. The proportion of zinc recovered varies very much with the amount of zinc used, *i.e.* with the silver assay. Taking for an example the zinc used in the case cited above, 50–55 p.c. of this zinc would be recovered by distillation and a very little of it in the form of powder. Parkes's process, when worked as above described, is stated to cost considerably less than either of the other processes, and yields a market lead containing less silver.

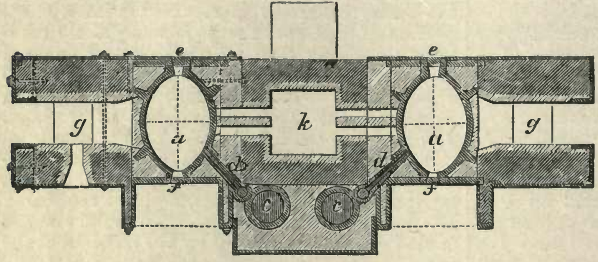

Fig. 24.

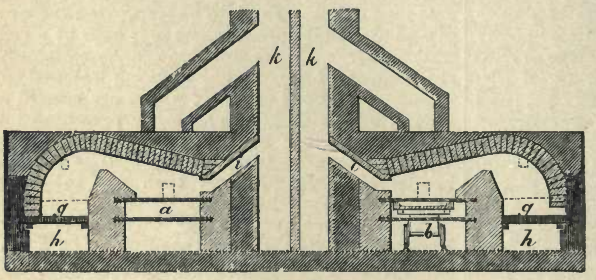

Fig. 25.

Cupellation or Refining.

The enriched lead obtained by either one or other of the above methods is next submitted to the process of cupellation or refining, in which the lead is oxidised and converted into litharge, and metallic silver obtained. In England the refining is performed in a reverberatory furnace, the bottom of which, called the test or cupel, is movable, and into this the lead is fed at intervals from a melting-pot containing the rich lead, and which is poured by a ladle into an iron gutter, serving to convey it to the test. In some cases the 'rich bars' are pushed down 'feed pipes,' so that they project into the furnace and are melted off as required. The oxidation of the lead is effected by means of a blast of air produced by a fan or other blower or by a steam injector. An English refinery in which two cupels can be worked at the same time is represented in Figs. 24 and 25.

a, a are the position of the tests, one of which is shown resting on the iron waggon, *b*; *c, c* the melting-pots for the rich lead; *d, d* the iron gutter to supply the test; *e, e* the point where the blast enters; *f, f* the opening along which the litharge flows into an iron pot placed below; *g, g* the fire-grates and *h, h* the ash-pits; *i, i* the flues, and *k, k* the chimneys.

The test or cupel is made of bone ash finely ground and prepared by moistening with a dilute solution of pearl ashes. This mixture is placed within an oval iron framework, consisting of an iron ring *a, a* (Fig. 26). This ring, known as the test ring, is held together by iron bars, *b, b*.

The mixture of bone ash and pearl ashes is beaten down thoroughly with iron rammers into this framework, and the centre of the mass scooped out by means of a small trowel, giving the test the form represented in the accompanying illustrations, thus forming a reservoir for the molten metals. It has been proposed to mould these tests by presses worked by hydraulic power. The test before use is allowed to dry in the air for some time and then placed on an iron waggon and run into position under the furnace; it is then wedged tightly against an iron ring built in the masonry. The fire is next lighted, and the test slowly and carefully heated, so as to thoroughly anneal it. When perfectly dry, the temperature is raised to a dull redness and the test is filled with rich lead. The lead is first covered by a greyish dross, which, as the heating continues and the temperature rises, gradually gives place to the formation of litharge. The blast is now turned on and the oxidation of the lead takes place, the litharge produced is blown by the blast to the mouth of the refinery and flows over the gate into an iron pot, placed below. These iron pots are built on wheels, and when filled with litharge are removed; the cake of litharge is easily detached after cooling, and is subsequently reduced, as will be described later on. As the oxidation proceeds, fresh lead is added to the test, and if a large stock of rich leads have to be treated, then the refining is only conducted sufficiently far to produce an enriched alloy, in

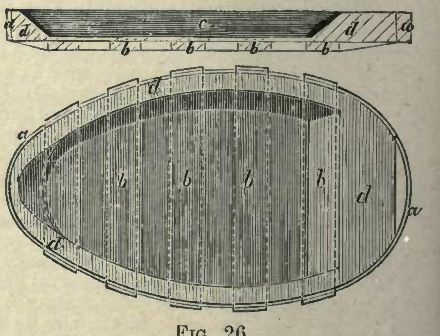

Fig. 26.

which the silver amounts to about 8 p.c. of the contents of the test. The concentrated argentiferous lead is tapped into an iron pot run on wheels, placed under the test bed, which is pierced by a drill. When the concentrated rich lead has been run off, the hole is made up with a pellet of bone ash kept in its place by an iron plate, and another charge is introduced. By this removal of the enriched lead, a distribution of silver through a large quantity of litharge is avoided. The concentrated rich lead is finally refined in another test. The end of the operation is indicated by the appearance of the surface, the brightening of the plate, as it is styled; the blast is then turned off and the fire removed from the grate. When the lead has been completely removed, the silver is usually tapped out into ingots direct, through a hole in the bottom of the test. In some cases the plate of silver is allowed to set, and when this has taken place the wedges are withdrawn and the test is lowered on to an iron waggon, on which it is removed and then allowed to cool. The plate, when solid, is detached from the test, and brushed with an iron brush to remove any litharge, slag, or bone ash.

In an ordinary refinery 4-5 cwt. of lead can be worked off in an hour, and the fuel required would be from 6 to 7 cwts. of coal per ton of lead oxidised. The plate of silver will vary in weight from 10,000 to 20,000 oz., and is usually pure, containing about 99·7-99·8 p.c. of silver. The test bottoms are saturated with litharge and contain some silver; they are usually broken up and those portions free from lead picked out to be used over again, whilst the remainder is smelted in a blast furnace. It has been proposed to extract the test bottoms with acetic acid, thus producing a solution of lead acetate and recovering the bone ash.

German Refinery.

In Germany the rich or enriched argentiferous lead is cupelled in a furnace known as the *Treibofen*, consisting of a reverberatory furnace with a circular hearth, and having a fireplace at one side. The bottom of this furnace is not movable, as in the English refinery, but composed of firebricks, on which lies a solid stratum of slag, and this again is covered by a coating of marl, well beaten down with iron rammers. The bottom is regularly hollowed out from the sides towards the middle, where a hollow is cut about an inch deep for the reception of the silver. The layer of marl is renewed for each operation. A dome of iron, plastered over with marl, covers the bed, and is moved as required by means of a crane. There are five openings into the side of the furnace, one serving to admit the flame from the fireplace, two smaller ones, near together, for the twyers by which the blast of air is forced on to the surface of the metal, and the litharge produced blown towards a fourth opening, by which it escapes in a fused state. The twyers are usually provided with valves, styled 'butterflies,' which serve to diffuse the blast over the surface of the metal. The fifth opening into the furnace is provided for the introduction of the lead. In working with unsoftened lead the charge for one operation would consist of about 5 tons of metal, some three-fourths of which would be introduced into the furnace before lighting up, the remainder being added from time to time as the cupellation proceeds. Much larger charges are treated when softened lead is used. The mode of working is as follows: the charge of lead, in form of pigs, is piled up in the middle of the hearth, and covered with wood, which is ignited by throwing on to it some burning charcoal. The iron dome is next let down and luted all round with clay. The blast is turned on and the fire in the grate made up. In the course of some 3 or 4 hours the lead has melted down and the bath is covered by a layer of dross, which is dark in colour and consists of a mixture of the oxides of the metallic impurities contained in the lead, and is called the *abzug*; it is raked out at the opening for the removal of the litharge. After the removal of the *abzug* the surface of the metal becomes clearer, and in a short time acquires a peculiar circular movement; the dross now rising to the surface is purer and more fluid than the *abzug*. This second product forms what is known as the *abstrich*, and is an impure litharge, which, as it is produced, flows through channels cut in the breast of the furnace. The temperature is kept sufficiently high to maintain the *abstrich* in a state of fluidity. The formation of *abstrich* is succeeded by the production of pure litharge, which flows out of the furnace through the channels already mentioned. After the litharge-stage has commenced, the remainder of the metal to be cupelled is added in small portions at a time; the pigs of lead being so placed that the lead gradually melts and leaves behind the more refractory *abzug* unmixed with the metal. The full charge of metal having been added, the operation is continued and the temperature maintained sufficiently high to keep the silver in a molten state until the greater portion of the lead has been oxidised and the bright metallic surface of the molten silver is observed. The blast is then turned off and the fire is damped down; water is also thrown on to the metal to harden it, and the cake of *blicksilber* is withdrawn from the furnace freed from marl, litharge, &c. The *blicksilber* contains from 90 to 95 p.c. of silver and is refined in small reverberatory furnaces, the beds of which are made of bone ash, or some material serving, like bone ash, for the absorption of the litharge formed by exposing the *blicksilber* at a temperature above the melting-point of silver to the oxidising action of the air.

The cupellation of a charge of 10-15 tons of lead lasts from 70 to 80 hours, and the loss of metal amounts to from 3 to 6 p.c.

Reduction of Litharge and Pot Dross.

The litharge produced in the cupellation of argentiferous lead, as also the various drosses formed in the Pattinson process, are reduced to the state of metal. The reduction is in this country usually performed in a reverberatory furnace, the sole of which slopes from the fire-bridge to a point near the flue, where an iron gutter, built in the furnace bed, serves to convey the molten lead to an iron receptacle outside the furnace. The reducing agent employed is coal. The sole of the furnace is prepared by covering it with small coal which is partially coked by the heat, and thus a porous covering is formed on the brickwork of the furnace bottom. On to this sole, so prepared, the litharge broken into lumps and mixed with coal is thrown, the ignition of the fuel and the reducing gases in the furnace soon effect a reduction of the litharge, and the molten lead trickling through the porous mass gradually finds its way into the metal gutter, by which it is conveyed to the metal pot. The charge is turned over from time to time, and when the reduction is completed the residue, termed *cinders*, is raked out. The litharge cinders are, together with other lead refuse, such as test bottoms, &c., treated in a cupola or slag-hearth, whereby a further quantity of lead is obtained from them.

In some establishments the litharge is reduced in blast furnaces similar to those employed in smelting ores; the fuel used is either coke or charcoal, and the litharge is mixed with slags from a previous reducing operation. The lead produced by reduction of the litharge is softened and desilverised when necessary, and inasmuch as the litharge produced towards the completion of the cupellation is richer in silver than that formed in the earlier stages, it is frequently reduced apart from the rest, and yields a lead containing from 70 to 100 oz. of silver per ton.

Refining lead by electrolysis.—A process, due to Keith, for refining lead by electrolysis, has been in use at New York for some years. The anodes of the electrolysing cells are made of the furnace lead, which is cast in thin plates about 4 feet long, and weighing 45 lbs.; these are inclosed in muslin bags, which serve to retain the gold and silver and other insoluble matters. The cathodes are plates of pure lead, and are placed about 2 inches from the anodes in a bath consisting of a solution of lead sulphate in sodium acetate. The bath is heated by steam to about 38°, and the electricity is supplied by a Weston dynamo, working at 1500 revolutions per minute. When the electric current is passed through such a series of cells the anodes are corroded and dissolved, an equivalent amount of lead being precipitated on the cathodes as a loose crystalline powder, which falls to the bottom of the cell, whilst the matters formed by the disintegration of the anodes are collected in the muslin bags. The action is continued until only 2 or 3 p.c. of the lead forming the anodes remains undissolved. In a series of 48 decomposing cells each containing 50 anodes, 10 tons of 180-oz. silver lead with 2¼ p.c. of antimony and arsenic, can be refined daily by a 12 horse-power steam engine. The precipitated lead contains 11 grains of silver per ton, and is compressed by hydraulic pressure before melting.

Amongst other electrolytic methods of refining lead that devised by Betts is of special interest. The electrolyte is a solution of lead fluosilicate, produced by dissolving the carbonate in aqueous hydrofluosilicic acid. The anodes, consisting of the lead to be refined, are cast in closed or in horizontal moulds; they are 1 inch in thickness and 3 feet long by 2 feet wide. The cathodes are formed of thin slabs of pure metal, cast by pouring molten lead on a sloping iron plate. The electrolyte liquor is contained in a series of vats, arranged in cascade; through these by aid of a pump a continuous circulation of the liquor is maintained. The vats are made of wood coated with asphalt, each vat taking from 22 to 28 anodes, and from 23 to 29 cathodes, separated from one another by a distance of about 1¾ inches. Electricity is conducted along the vats by means of copper bars, to which the anodes and cathodes are suitably attached. The electrolyte is maintained at a temperature of 30°–35°, at which temperature the resistance is 3·6 ohms. per cubic metre. The cathode deposit of pure lead is smooth, dense, and coherent, a condition largely contributed to by the addition of gelatin to the electrolyte, in the proportion of from 400 to 500 grams per 1000 kilogs. of lead deposited. The anode mud, which adheres to the anode, is scraped off, washed, and filtered in a press, from which it is discharged on to trays, and dried. The dried mud subsequently melted down in a reverberatory furnace yields an antimonial slag, a rich silver alloy containing bismuth, and may also give a copper matte containing silver.

The cost of treatment with a plant dealing with from 60 to 100 tons *per diem*, is given at four dollars per ton, and the loss of hydrofluosilicic acid as from 3 to 5 lbs. per 1000 lbs. of lead refined.

It is stated that electrolytically refined lead contains more silver than that refined by Parkes' process, but is free from bismuth (Hofman, Mineral Industry, 1909, 504; *see* also Betts, Lead Refining by Electrolysis, J. Wiley & Sons, 1908).

Condensation of Lead Fume.

In consequence of the volatility of lead at high temperatures a certain proportion of the metal and some of its compounds are carried away by the heated gases in the operations of smelting, refining, reducing, &c. To prevent the loss and minimise the nuisance which would arise from allowing the gases produced in these various operations to pass direct into the chimney, the furnaces are connected with a series of flues or condensing chambers in which the gases are cooled and so deposit some of the solid matter held in suspension, before they issue from the chimney. These flues are cleaned out at stated intervals, and the 'fume' collected. The lead exists in the 'fume' chiefly in the form of sulphate and oxide, and is recovered by roasting and smelting it alone or mixed with ores and slags. A certain proportion of silver is always found in fume lead, the amount being considerably less than that obtained directly from the ores from which it was produced.

The method of fume condensation most usually relied on, and the one stated to be the most efficient, is simply to connect up the various smelting and other furnaces in a works with a series of long flues of large transverse area. In some establishments the flues used for this purpose have an aggregate length varying from 3 to 5 miles, and a cross section of from 6 feet by 7 feet to 8 feet by 9 feet. Jets of steam and water have in some cases been introduced at different points in the flues with the object of facilitating the fume deposition; but lead smelters differ in opinion as to the advantages gained by the use of either steam or water. Various devices have been proposed to effect a condensation of lead fume without the necessity of constructing long flues or large condensing chambers.

Stagg's condenser consists of a large rectangular chamber divided by partitions springing alternately from the top and bottom of this chamber, leaving free spaces above and below; the lower part of the chamber is filled with water, so that the gases pass first down one side of a partition through the water, and rising in the next compartment pass over the next partition and down again through the water. The gases are drawn through the chamber by means of air-pumps attached to the exit flue. The fume is in its passage through the condenser thus drawn through water, and the greater portion of the solid particles is removed, the solid matter collecting in the water is drawn off from time to time into tanks where the fume subsides.

In Stokoe's method of condensing, the gases are drawn off from a flue by means of a fan and are then forced into the condenser, which consists of two chambers placed side by side; these chambers are divided into several compartments by partitions which alternately reach the top and dip below the surface of water at the bottom of the chamber. The chamber is divided horizontally by two floors made of open joists upon which faggots are laid, thus forming filtering beds, which are washed by water in the form of fine spray falling from a cistern on the top of the condenser. The gases extracted from the flue by the fan are forced through the series of compartments of the condenser and meet in their passage with the fine spray of water, and must also pass through the several filtering beds, where the fume as it collects is washed away by the water which accumulates in the lower part of the chamber. When the water has reached a certain height it is drawn off into tanks, and here the solid matter collected by the water gradually separates out.

In 1878 Messrs. Wilson and French patented a condenser, which has been adopted at the Sheffield Smelting Company's works, and was also used by Messrs. Bewick and Partners, Limited, of Hebburn-on-Tyne. At Messrs. Bewick's works the gases from the ore-hearths and slag-hearths and reverberatory furnaces passed first into a long flue, which ascended the ballast hill at the back of the works, and after making a circuit round the top of the hill, the gases were drawn off from the flue down a series of narrow flues to the condensers. In this way the gases are thoroughly cooled before they reach the condenser, and a certain portion of their solid burden will have been deposited in the flues, which were cleaned out from time to time; the remainder is obtained in the condenser. The condenser consisted of a wooden box *aa*, Fig. 27, having a shelving bottom where the solid matter arrested collects, and at the lowest point a tap *b*, by which the contents of the condenser are run off from time to time. The box is filled with water to the level of *c*. The gases are forced into the box by a fan, along the pipe *h*, which opens into a chamber *g*, formed by a partition running parallel with the side of the box. Below, this chamber opens into a series of triangular tubes *i*, running across the box; these tubes are perforated above, and through these fine openings the gases are forced into the water by which the box is partially filled. Near the surface of the water at *d* is fixed a series of three or four copper wire screens, or screens made of wickerwork, and held in position by the supports *e* and *f*. The gases pass out finally by the pipe *j* in the top of the box, and are conducted by flues to the chimney. By this arrangement the gases are forced through a layer of water of a given depth, and further intimate contact between the water and the particles of the fume, &c., is insured by the wickerwork or copper wire screens. The fume, &c., arrested by the water collects in the lower part of the box, and is drawn off into settling tanks, and after removing the greater portion of the water, is dried and smelted. With three wire-gauze screens and a depth of 8½ inches of water, Mr. French states that at the Sheffield Smelting Company's works, the quantity of lead and silver arrested amounts to from 95 to 98 p.c. of that contained in the smoke as it leaves the furnace.

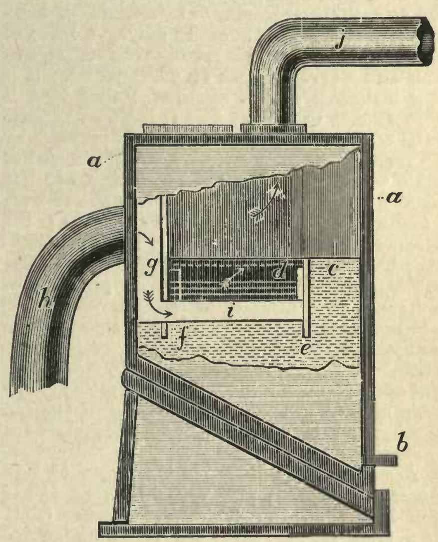

Fig. 27.

The application of electricity to fume condensation has been suggested by Sir O. Lodge, and its use patented by Walker. Experiments made with electricity at the Bagillt works of Messrs. Walker, Parker & Co., Limited, yielded satisfactory results when working on a small scale, but did not prove successful when applied to the flues of the works. One of the chief difficulties was the efficient insulation of the conductors.

Composition of lead fume.—The following analyses taken from Percy's Metallurgy of Lead (p. 451) will serve as examples of the composition of lead fume. The samples analysed were collected from the flues of the lead-smelting works at Bagillt, and represent the fume from reverberatory furnaces and slag hearths.

PROPERTIES AND USES OF METALLIC LEAD.

Properties of lead.—Lead is a bluish-grey metal, the freshly cut surfaces exhibiting a distinct metallic lustre, which soon disappears owing to superficial oxidation. Its crystalline character is well shown by the beautiful fern-like crystalline growths which are seen on the pigs of best market lead, or as they form on the surface of a casting as the molten metal gradually cools. It can easily be obtained in the form of regular octahedrons by melting lead and allowing the molten metal to partially solidify, and pouring off the portion still remaining liquid. It is deposited in arborescent forms, known as the lead tree, by the decomposition of a solution of lead acetate either by zinc or by electricity. Lead is a very soft metal, is easily cut by a knife or scratched by the nail; it readily receives impressions and leaves a streak on white paper. It is very malleable and is ductile. Rolled lead is more ductile than cast lead; both its malleability and ductility are injuriously affected by the presence of impurities. Lead is a metal of feeble tenacity, a wire $\frac{1}{12}$th of an inch will not support a weight of 20 lbs. When struck with a hammer pure lead emits a dull sound; the presence of antimony, however, makes it sonorous, hard lead being easily distinguished from soft lead by this property. The presence of antimony, zinc, arsenic, or silver increases the hardness and brittleness of the metal. The hardness of lead is also increased by repeated meltings; this is stated to be due to the formation and dissolution by the molten metal of the oxide of lead formed by the action of the air. In practice it is found that the lead is improved by every melting.

According to Schweitzer the sp.gr. of lead (Amer. Chem. J. 7, 174) varies between 11·344 and 11·377 at 4°. St. Claire Deville (Phil. Mag. [iv.] 11, 144) gives the following as the results of his observations on lead prepared in different ways:—(1) cooled slowly from fusion, 11·254; (2) cooled quickly from fusion 11·363; (3) electrolytic lead, 11·542; (4) lead obtained by electrolysis, then fused and cooled quickly, 11·225. The influence of pressure on the sp.gr. of lead is shown in the following results obtained by Spring (Ber. 16, 2724). (1) Not pressed, 11·350 at 14°; (2) once pressed, 11·501 at 14°; (3) twice pressed, 11·492 at 16°. The sp.gr. of molten lead is given as 10·37 and 10·65 by Roberts-Austen and Wrightson (Ann. Chim. Phys. [v.] 30, 181), and 10·952 by Quincke (Pogg. Ann. 135, 642).

Lead begins to melt at 325° and is completely fused at 335°; its boiling-point has been determined by Carnelley and Williams (Chem. Soc. Trans. 1879, 35, 566) and is stated by these observers to lie between 1450° and 1600°.

The specific heat of lead according to Regnault is 0·0314 at temperatures between 10° and 100°, and for molten lead according to Person it is 0·0402 between 380°–450°. The latent heat of lead is such that 1 part by weight of lead in solidifying gives out heat sufficient to raise the temperature of 5·369 parts by weight of water by one degree centigrade. It is a poor conductor both of heat and electricity.

Lead is tasteless, but emits a characteristic odour when rubbed between the fingers. It can be welded in the cold by pressing the clean surfaces together.

Lead is easily oxidised by exposure to the air, and in the finely divided state, as obtained by the decomposition of the tartrate by heat, is pyrophoric. Pure dry air, freed from carbon dioxide, has no action upon lead, nor is it attacked by air-freed water; but easily suffers corrosion under the combined influence of air and moisture, or of water and air. By the action of air and water lead hydroxide is produced, which dissolves in the water and is converted into a basic carbonate by the carbonic acid present. The action of water on lead is materially influenced by the presence of small amounts of salts dissolved in the water; nitrates are supposed to further the action—this is especially true of ammonium nitrate—whereas chlorides, sulphates, carbonates, and phosphates are said to retard the action. Chlorides, sulphates, and carbonates, especially the latter, diminish the solvent action of nitrates and in some cases destroy it altogether. The action of distilled water on lead is reduced by addition of chlorides, sulphates, and carbonates. Water saturated with carbon dioxide under ordinary pressure has but little solvent action on lead, but when saturated with carbon dioxide under a pressure of six atmospheres, the solvent action is considerably increased. In this case also the presence of ammonium nitrate and of potassium carbonate tends to retard the action. These conclusions are drawn from a series of observations on the influence of salts on the solvent action of water on lead, made by Muir (Chem. News, 33, 102, 125, 145; 34, 223, 324), who has also studied the influence of salts on the solubility of the basic carbonate

$$(PbCO_3)_2,Pb(OH)_2,$$

which is formed on the surface of the exposed lead or deposited at the bottom of the vessels. The order of the solubility of the basic carbonate agrees very nearly with that of metallic lead in solutions of the same salts (Muir, Chem. Soc. Trans. 31, 660). The influence of small quantities of free sulphuric acid on the corrosion of lead by water has been studied by W. Carleton Williams (J. Soc. Chem. Ind. 6, 111). In these experiments distilled water saturated with air was used to dissolve certain salts, and to these solutions sulphuric acid in amounts equivalent to from 1 to 5 grains per gallon was added, and the amount of lead dissolved from pieces of sheet lead immersed in these different solutions was determined. The presence of 1 grain per gallon of free acid notably increases the action, a greater quantity of lead in a given time being found in the solution than when the salt solutions are used alone. The total action as measured by the loss of lead is less in presence of free sulphuric acid than with the salt solutions alone. Allen (Chem. News, 46, 145) found that water taken direct from the main in one town in Yorkshire, and having an acid reaction, when left in contact with lead, dissolved an amount of lead equivalent from 0·42 to 0·56 grains per gallon, but after the water had been made slightly alkaline the amount of lead dissolved was equivalent to 0·14 grains per gallon only. Crookes, Odling, and Tidy refer the activity of water towards lead as due to a deficiency of silica, and are of the opinion that from 0·5 to 0·7 parts of silica per 100,000 is sufficient to prevent the action. In many cases the corrosion of the lead pipes would appear to be due to the presence of a free acid in the water supply, as is apparently the case with one of the water supplies of Sheffield, and also the water supply at Huddersfield (Allen, *l.c.*, also Chem. News, 46, 88). The waters most liable to act upon lead are those obtained from upland gathering grounds, waters which are soft and usually of remarkable purity. The activity of such waters is by many attributed to the presence of free acid (*cf.* P. F. Frankland, J. Soc. Chem. Ind. 8, 241) (*v.* WATER).

Inasmuch as air facilitates the solvent action of water, an intermittent water supply is favourable to the contamination of the water, and as lengthened contact with lead in the case of an active water will naturally result in a considerable proportion of the metal being dissolved, it is advisable to run off the water that has been standing over night in the pipes, as such water may, by the long contact with lead, be unfitted for drinking purposes.

Lead is dissolved easily by dilute nitric acid; the action of concentrated acid is arrested by the formation of lead nitrate in white granular crystals. Dilute hydrochloric and dilute sulphuric acids do not attack lead, but it is dissolved by boiling concentrated hydrochloric and sulphuric acids, lead chloride and lead sulphate being formed.

Composition of commercial lead.—Market lead is usually pure, containing traces of antimony, copper, iron; occasionally zinc, tin, bismuth are found, and small but varying amounts of silver are usually present. The following analyses serve to show the impurities in commercial lead :—

(*a*) Bleiberg. (*b*) Newcastle; both analysed by Hampe. (*c*) Lead manufactured by Foster, Blackett and Wilson, Newcastle-on-Tyne, analysed by Michaelis (1868) (Kerl, Hüttenkunde, 19). (*d*) and (*e*) Schweitzer (*l.c.*). (*f*) Lead from Upper Hartz, purified by Pattinson's process. (*g*) Freiberg lead, refined by Pattinson's process. (*h*) Lead from Ems, desilverised by zinc and refined by steam. *f*, *g*, and *h* are quoted from analyses given by Kerl (Hüttenkunde).

Lead is largely used in building construction in the form of sheets, gutters, spouts, &c., also for the manufacture of pipes for gas and water, for making shot and solders. Its power of resisting the action of acids, &c., renders it of great service in the construction of chemical plant, *e.g.*, sulphuric acid chambers. The lead preferred for the construction of sulphuric acid chambers is that obtained by remelting old lead, which is hardened by a small amount of antimony. Experiments of Johnson and Calvert (Compt. rend. 56, 401), of Hasenclever (Wag. J. 1872, 239), and of Bauer (*ibid.* 1875, 364) have shown that ordinary leads resist the action of sulphuric acid more effectively than pure lead.

Sheet lead.—For the manufacture of sheet lead, market lead is cast in a plate several inches in thickness by running molten metal into a mould consisting of a large rectangular iron framework. When the plate is somewhat cooled it is transferred to the rolling mill, which consists of a pair of massive iron rollers, about 18 inches diameter and some 8 feet wide, which are worked by engines with reversing gear. The rolls are placed in the middle of a long bench, a little wider than the rollers, and about 3 feet high; at intervals of a foot along the bench are placed wooden rolls on the same level as the rollers, which serve to facilitate the movement of the sheet to and fro. By passing and repassing the plate between the rollers it is gradually extended into a sheet, which, when too long for manipulation in the ordinary way, is cut into smaller sheets which are rolled separately. Or the sheet may be doubled over, the surface being previously chalked to prevent the adhering of the two sheets, and the doubled sheet rolled out to the required thickness. The lead having been rolled out, the edges and ends of the sheets are cut straight and the sheet wound on to a cylinder at the end of the bench.

Lead pipes are usually made in machines worked by hydraulic pressure. Over the piston of the press is a reservoir which contains the metal, and which may be heated by an annular fireplace. The reservoir is filled with molten lead by a spout through an aperture in the top; when filled the spout is withdrawn and the aperture closed tightly by an iron plug, kept in position by an iron key. The size of the pipe is regulated by a steel die of the diameter of the outside of the pipe fitted at the top, the internal diameter of the pipe being determined by a mandril which passes directly through the centre and is moved upwards by the rising piston, the semi-molten metal being at the same time forced through the die. As the pipe passes out at the top it is coiled on to a drum. The pipes used for gas-services are usually made of metal to which either tin and antimony have been added directly, or these metals may be supplied by the addition of a harder lead containing them.

Lead shot is made by alloying the metal with arsenic, which is added either in the form of white arsenic or arsenical dross from the improving furnace. The addition of arsenic serves to impart a greater fluidity to the metal and increases the tendency of the metal to assume a spherical form in passing through the air. The molten metal is made to run through cullenders pierced with holes, and to fall through a considerable height into vessels holding water. The height required for the fall is either secured by means of a shot tower, or, as in some places, by means of a deep well, the shaft of an old coal pit being in some cases adapted for this purpose. The size of the shot is determined by the size of the holes in the cullender, by the height from which the lead falls, and by the temperature and consequent fluidity of the molten metal.

The shot, taken from the vessel in which it has solidified, is sorted by sieving into different sizes, and the imperfect ones separated by causing the shot to roll down an inclined polished metal surface, the globular ones running down easily, and are collected in a box at the bottom of the inclined plane, whilst the imperfect ones remain on the sides of the plane. The shot is finally polished by shaking with a little plumbago in a cask revolving on a horizontal axis.

Lead Compounds used in the Arts.

Lead oxide, lead monoxide, or *plumbic oxide* PbO. The two commercial varieties of this compound are *massicot* and *litharge.* The former is obtained when molten lead is heated at a moderate temperature in the air, the molten lead being constantly stirred. It is the product formed in the first stage of the manufacture of red lead. After grinding and levigation it is obtained as a brownish-yellow powder. Another variety is obtained as a lemon-yellow powder by heating white lead (the basic carbonate).

Litharge is produced when the oxidation of the lead takes place at a temperature sufficiently high to melt the oxide formed, as in the cupellation process of which it is one of the products. When litharge is manufactured for sale, the purest lead is submitted to cupellation; if the lead used is not quite pure, then the portions of litharge first formed and that produced towards the end of the operation are rejected. The litharge as it forms is collected in large iron pots fitted on wheels, in which it is allowed to cool slowly. When the pots are emptied, the litharge 'falls,' the central portions which have cooled more slowly being somewhat lighter in colour and possessing a scaly crystalline structure. The more friable portion is broken up and passed through a circular temse or screen, the litharge collected and packed in casks and sold as *flake litharge.* That portion of the litharge which does not fall, but remains in hard coherent masses is ground between horizontal stones in a stream of water, by which the powdered litharge is carried into settling tanks in which it accumulates. The litharge after separating from the water is dried at a low heat in a reverberatory furnace, packed, and sold as *levigated litharge.* The colour of lead oxide varies from lemon-yellow to reddish-yellow, and on heating it becomes brownish-red. The sp.gr. of different varieties of lead oxide are given by Geuther (Ann. Chim. Phys. 19, [ii.] 60–61) as follows: yellow cryst. 9·29 at 15°; red cryst. 9·126 at 15°; red cryst. 9·125 at 14°; red powder, 9·09 at 15°; and red, very pure, 8·74 at 14°.

Litharge is used in the manufacture of flint glass; as a glaze for earthenware; for the preparation of lead acetate, lead nitrate, lead plaster, and for drying oils.

Red Lead, Minium, or *Plumbic Tetroxide* Pb_3O_4. The manufacture of red lead consists in the oxidation of lead, which is effected in two stages, the first process being the conversion of the lead into massicot or the 'drossing' of the lead, and the second the conversion of the monoxide into tetroxide or a red lead of the required shade. These operations are usually conducted in two different furnaces. The first of these, the drossing oven, is a low-arched furnace with a bed of fire-brick laid on a bed-plate of cast iron having raised borders on each side and at the back. The bed of the furnace is made to slope slightly towards a median line, and also from back to front. On either side of the furnace bed is a low wall, the spaces between which and the wall of the furnace form the two fireplaces. In front are three openings closed by hinged doors of cast iron; the two side ones communicate with the fireplaces, and serve for the introduction of fuel, whilst the central one, which is larger than the other two, serves for the introduction and the working of the charge, as also to allow of the escape of the products of combustion, which pass into an arched space or hood of brickwork in front of the furnace, this hood forming in fact the base of the short vertical chimney attached to each furnace. In front of the working door is hung a chain with a hook at the end; this serves as a fulcrum for the rabble used in working the charge. Below the working door a space is formed by two vertical plates of cast iron on brick walls, resting on a slab of stone or plate of iron on the floor, and supported by the iron plate which forms the lower part of the front of the furnace. This space in front serves to collect any of the oxidised product which may fall in transferring it to the waggons. The length of the furnace is about 11 feet, and the width between the bridges is about 8 feet 4 inches. The 'colour oven' is in most essentials similar to the 'drossing oven;' the bottom is flat and the slope from back to front not so great as in the latter. Coal is used as fuel in these ovens; in some cases where the ovens are constructed with fire-grates and ash-pits, small coal may be used.

The mode of working is as follows. A charge of from 22 to 31 cwt. of pig lead is introduced into the furnace, and a dam is made across the furnace of rough oxide intermingled with lead obtained from the grinding, &c., of a previous charge. The temperature is so regulated as to melt the lead, which forms a pool behind the dam; the molten lead is agitated by means of a rabble and splashed over the furnace bottom. In this way the oxidation is promoted, and as the oxide forms it is pushed toward the back of the furnace, the still unoxidised lead flowing to the front, and as the oxidation proceeds the pool becomes smaller and smaller. The oxidation is promoted by adding some slag lead from time to time, the antimony contained in it being favourable to a rapid drossing. This addition of slag lead, whilst it curtails the length of the operation, is not permissible in the manufacture of the better varieties of red lead, such as are used in the manufacture of flint glass; the red lead used for this purpose should not contain copper. In practice it is found the oxidation of the lead is so materially promoted by the use of slag lead, that in many works special alloys of antimony and lead are prepared and used to replace slag lead in the manufacture of the best varieties of red lead.

When the oxidation is completed the charge is raked out into iron waggons, and in these allowed to cool. It is next passed to the grinding mill, where it is ground between millstones with a regulated supply of water. The heavier particles of lead oxide and metallic lead which sink in the troughs leading to the settling cisterns are collected and used in the drossing oven to dam up the charge of lead. The finely ground massicot is carried by the stream of water into settling tanks where it subsides, and after the water has been run off, it is transferred to iron barrows, in which it is conveyed to the 'colouring' oven, upon the bed of which the contents of the barrows are emptied. The mass is thus quickly dried, and is then spread out over the bed of the oven in furrows and ridges resembling a ploughed field, and heated at a carefully regulated temperature for some hours, until it has assumed the required shade. The oxidation is aided by stirring the mass from time to time, and the progress of the operation watched by withdrawing a sample by means of a paddle, and from the appearance presented by the sample the completion of the operation is determined. When hot, the red lead has a rich purple tint, which, when the oxidation is completed, assumes a bright red colour on cooling.

A variety of this same compound, styled orange lead, is made by submitting white lead to a similar process. The lighter particles of white lead which form as a froth in the grinding and levigating white lead are collected, and when heated in the red lead ovens yield a very soft and bright coloured orange lead.

The red lead is withdrawn from the ovens, and after cooling is re-ground and dried, and after sieving is packed in barrels. Orange lead is ground and levigated, as the decomposition of the carbonate requires a temperature so high that some of the oxide of lead produced is partially fused.

Red lead is a granular crystalline powder, the colour of which varies somewhat, this variation is supposed to be in part due to the presence of orange lead formed from the lead carbonate contained in the massicot, and produced by the absorption of carbon dioxide from the air, but in all probability it is to be accounted for by the difference in composition of the lead from which the red lead is made. When heated, red lead assumes a darker shade of red, becoming violet and ultimately black, regaining its original tint on cooling. The sp.gr. of red lead, as given by different observers, varies from 8·62 to 9·19 (Clark's Constants of Nature, 47). When strongly heated it yields oxygen, and is converted into the monoxide. It is decomposed by nitric acid, lead nitrate and the puce-coloured peroxide PbO_2 being formed; when digested with nitric acid and a little sugar, the red lead is completely dissolved. Red lead is used as a pigment, in the manufacture of flint glass, as a cement in making steam-joints, and in the manufacture of secondary batteries. Commercial red lead may contain some metallic lead, lead sulphate, and also oxides of antimony tin, copper, and iron.

White lead, Céruse, Blanc de Plomb, Bleiweiss. The commercial article known as white lead is essentially a basic lead carbonate, of the formula $2PbCO_3{\cdot}Pb(OH)_2$, which is produced by the decomposition of a basic lead acetate by means of carbon dioxide. The method of manufacture which according to experience yields a white lead best adapted for the production of paint, one of the chief uses of white lead in the arts, is a modification of the old Dutch process.

The Dutch method consists in exposing thin sheets of metallic lead, rolled into coils and placed in earthenware pots containing a small amount of vinegar, to the combined action of the acetic acid contained in the vinegar, air, moisture, and carbon dioxide; the carbon dioxide and the heat necessary to further the corrosion of the lead being obtained by the fermentation of horse manure and stable litter, in which the earthenware pots and their contents are embedded. The 'blue' or metallic lead is gradually corroded and converted into white lead, which after being separated from the unaltered metallic lead, is ground and washed.

The English method differs from the Dutch method chiefly in the replacement of horse dung and stable litter by spent tan in a state of fermentation, and the substitution of dilute acetic acid, prepared from pyroligneous acid, for the vinegar. The substitution of spent tan for stable litter minimises the risk of discolouration of the white lead by the production of sulphuretted hydrogen, but the fermentation is somewhat slower, and consequently the conversion of the 'blue' lead into white lead requires a greater length of time. The lead used for the manufacture of white lead should be of the purest and softest description, and the manufacturer usually purifies the lead used for this purpose by the Pattinson, the Rozan, or the Parkes process already described. The presence of small amounts of copper or antimony tends to produce a white lead having a dull grey tint. A red or pink colour, at times observed in the manufacture of white lead, has been attributed to the presence of a suboxide of lead by Bannow and Kraemer (Ber. 1872, 545; 1873, 21), an explanation admitted by Lorscheid, whilst according to Baker the colouration is caused by the presence of finely divided oxy compounds of silver. The lead is cast into thin sheets of lattice work or gratings, so as to expose a large surface to the corrosive action of air and acid vapours, &c., by pouring molten lead on to a sloping grooved iron plate, from which, on solidifying, the crates, buckles, plates, straps, or wickets, as they are variously styled, are easily detached. Some of this lead is cast in thin circular discs or stars. In some of the works in this country and in America, the 'plates' and 'wickets' are cast by machinery. The machine consists of an endless band of square plates of iron linked together, each plate being a mould, into which the lead is poured as the plates are slowly moved under the spout of the lead-pot. The castings are delivered at the end on a leather belt covered with plates of sheet iron to prevent the hot lead injuring the leather, and are thus carried away from the machine. This machine can make from 50–60 castings per minute. The corrosion of the lead is effected in what are known as stacks, built in brickwork chambers, a series of which are usually built side by side along one side of a shed. The dimensions of the chambers vary at different works, the most convenient dimensions being an area of 12 feet by 20 feet, or 16 feet square, and a height of some 25 feet. The front wall of the chamber is provided with an opening, 4 feet wide, running from the top to the bottom, serving for the introduction of the materials used in the construction of the stack. As the building of the stack proceeds the opening is closed by boards fitting into slots. The stack is built up as follows. First, the floor of the chamber is covered with a layer of ashes, upon this is spread spent tan, already in a state of fermentation; the height of this first bed of tan is some three feet. The tan is beaten down and the surface levelled, and on the bed so formed is placed a series of earthenware pots, partially filled with a 2 to 3 p.c. solution of acetic acid. These pots are placed together, leaving a space about 6 inches wide between the outside rows and the walls of the chamber. The pots ordinarily used are of two sizes; the larger ones, which are provided with a rim on the inside, are placed on the outer edges of the series, and in the mouths of these pots are placed the discs of metallic lead, resting on the rims already mentioned. These larger pots serve to support the wooden bearers which carry the flooring boards used to cover in the bed. In some establishments, pots of one size only are used, and the flooring boards are supported by blocks of wood. On the top of the earthenware pots are placed the crates of metallic lead, so as to form a layer of lead about 5 inches in depth; between the lead and the cover of flooring boards is left a space of from 6 to 8 inches. The space between the walls of the chamber and the pots is filled in with tan on all sides, the opening in front being closed by boards. On the bed so constructed another bed is built in exactly the same way, with the exception that in the construction of the upper beds the layer of tan is only about 1 foot in thickness. In this way the chambers are filled up to a height of some 20 feet or more, with beds consisting of pots, lead, and tan, the topmost bed being covered with a layer of tan. In stacks of an area of 12 feet by 20 feet, a bed will represent 3 tons of lead, which will lie on about 1000 pots of 5½ inches diameter, containing 200 gallons of diluted acetic acid. The weight of lead in a stack will vary with different practices, with the size of stack and weight of wickets. In stacks 28 feet by 14 feet, each bed might represent as much as 7 tons of lead, and with twelve beds the total lead being 84 tons. As the building of the stack proceeds the opening in front is gradually built up with loose boards, and when the stack is completed the opening at the top is left unclosed, so that the stack may be examined from time to time, and if necessary the tan rearranged, as during the fermentation the system of beds gradually falls away from the side walls. In some cases it is usual to provide ventilation in the form of wooden spouts placed in the corners of the chamber; these spouts are pierced with holes which may be closed by tan. Such ventilators are only used in stacks of large area, and they provide an escape for the steam which is produced in considerable amounts during the first stages of the fermentation; in the case of smaller stacks this takes place with sufficient regularity at the surface of the side walls. After the stack is built it is left to itself for about three months, and during this time the fermentation of the tan proceeds producing heat, the temperature in some cases rising to 140°F., which serves to volatilise the acetic acid and water, and at the same time develop carbon dioxide. Under the combined influence of these agents the blue lead is gradually converted into white lead. At the end of the time mentioned above, the stack is unloaded, the top covering of tan is removed, the bark which is not mouldy is used to add to fresh tan in the construction of another stack. As the covering of boards is removed, the corroded crates and discs are loaded into trays and carried away to the mill, in which the white lead is separated from the unaltered metallic lead. The 'corrosions' preserve the form of the castings of the metal, but are more bulky, and present a white opaque appearance, and vary in texture. The best corrosions are hard and porcellanous, and can be easily handled without crumbling, whilst the poorer are of a floury character and crumble easily when touched. In places the white lead is discoloured; the discolouration may be either due to the tarry matter present in the acid used or to the droppings of water from the tan. Before removal of the corrosions from the stack, each layer as it is exposed is thoroughly moistened with water. The white lead taken direct from the bed is not uniform in composition; it consists mainly of a basic carbonate $2PbCO_3 \cdot Pb(OH)_2$, but some of the corrosions approximate more nearly to the formula $3PbCO_3 \cdot Pb(OH)_2$, whilst in some cases the composition is very nearly that of the normal lead carbonate $PbCO_3$. All white lead corrosions contain some lead acetate locked up in the particles, and this is dissolved out in the washing and grinding to which the corrosions are next submitted. It is usual to find the earthenware pots quite empty and dry, or at the most a few may contain a little water; the pots are washed and drained, and when dry are used over again. The pieces of white lead which fall on the bed of tan are picked up by hand, the surface of the bed is also raked and a further quantity of white lead is got from the tan by washing it on sieves in a stream of water.

The trays of corrosions are taken from the stack to the grinding mill, where the unaltered or blue lead is separated from the white lead and the latter finally ground into an impalpable powder. The mode of conducting the grinding and levigation varies in different works; the trays are usually sunk in a cistern of water and the contents are directed by means of rakes between corrugated rollers running under a stream of water. The emptying of the trays is effected in this manner to insure a complete soaking with water, and thus further obviating the production of clouds of poisonous dust. The production of dust in the treatment of the corrosions is greatly reduced by watering them before they are removed from the stacks. After the blue lead has been separated, the white lead is crushed by passing through a pair of smooth rollers, made of gun-metal, and raked about over a perforated plate under a constant spray of water. The coarse white lead next passes to horizontal grinding stones, to which it is fed by a ladle or by an endless band. After passing through these stones, the white lead issues in the form of a thick white mud, and is again passed through other grinding stones until it has been reduced to a state of subdivision so fine that it is carried along by the stream of water to the settling tanks; the white lead which settles out in the troughs used to convey the water to the tanks is returned to the grinding stones. The grinding and levigating are conducted in such a way that the water may be used over and over again, and is usually found to contain lead salts in solution, which, before discharging the water, are precipitated by sodium carbonate. In the tanks the white lead gradually settles and forms a thick white paste, from which the water is siphoned off, and when the mud has attained a sufficient consistence it is ladled out into the dishes used for drying it. The dishes are shallow clay saucers, 12 ins. diameter and 3 ins. deep, and made of clay similar to that employed in making flower pots. The dishes are stacked in drying stoves upon shelves made of iron bars, the stoves are heated by iron pipes made to circulate round the floor of the stove, and connected with a fireplace outside the stove, the products of combustion from the fire passing through the pipes. In this way the pulp, which contains some 25–30 p.c. of water, is gradually dried, the temperature of the stoves should not rise above 180°F. The white lead when dry is taken from the stoves and either packed in casks or ground and mixed with oil to form a paint. Boiled linseed oil is used for this purpose, from 8–9 lbs. of oil is needed for every hundredweight of white lead. During the grinding, some manufacturers add a small quantity of a blue colouring matter such as Prussian blue or indigo to the white lead to modify the somewhat yellowish tint due to the stains from the bark.

To obviate the dangers attending the method of drying the pulp, as described above, drying in vacuum pans has been used in some places, but where the white lead is to be made into paint, the method patented by Ismay (Eng. Pat. 23969, 1895) has been adopted with considerable success. In this process, the white lead pulp is mixed with oil and thoroughly agitated in a pug-mill, with the result that the greater portion of the water is displaced by the oil; the last portion of water is driven off by using a pug-mill, provided with a heating jacket, in which the mixture may be subjected to heat in a partial vacuum. In this process, the drying in stoves is entirely obviated.

The explanation given by Liebig in his Handwörterbuch der Chemie of the chemical changes which take place in the corrosion of the lead in the stacks, has been practically substantiated by the experiments of Hochstetter. These experiments demonstrate the first change to be the conversion of the lead into a basic acetate by the agency of air and acetic acid vapours. The basic lead acetate is next converted into white lead and normal lead acetate by means of carbon dioxide and aqueous vapours. The normal acetate is next converted into white lead, and acetic acid liberated by the combined action of carbon dioxide and aqueous vapour. The acetic acid so liberated is free to take part in the corrosion of a further quantity of blue lead, the conversion of which into a basic acetate precedes the formation of the basic carbonate. The basic carbonate $2PbCO_3{\cdot}Pb(OH)_2$ is, according to Hochstetter, not only the product of this combined action, but is also formed when carbon dioxide is passed into a solution of the basic lead acetate. Further, this compound resists the action of carbon dioxide alone, and can only be converted into the normal carbonate in presence of free acetic acid. In the light of this investigation, white lead would appear to consist of lead carbonate and hydroxide in the proportion of two molecules of the former to one of the latter, and the increased proportion of the carbonate frequently observed is to be explained as due to an admixture of normal carbonate produced by the action of carbon dioxide in presence of acetic acid vapours upon the basic carbonate. All white lead corrosions contain some normal acetate, but the amount of this compound will be less in white lead made by the Dutch or English methods than that produced by the German method in which the production of carbon dioxide, acetic acid, and aqueous vapour ceases simultaneously.

The proportion of lead corroded when working in stacks is from 50–70 p.c., the average result will be about 65 p.c.; the increase in weight is 20 p.c. of the lead used. The uncorroded lead is collected and after drying is weighed and remelted to be used over again.

The percentage of corrosion is chiefly determined by the thickness of the wickets, some manufacturers prefer to cast heavy wickets, and get a low percentage corroded, as it is found that the ‘blue’ lead is so much more efficiently separated from the ‘white’ lead.

The German method, as practised at one time at Krems, and now chiefly at Klagenfurt, consists in exposing thin sheets of metallic lead suspended in wooden boxes to the action of the vapours produced from a mixture of wine lees and vinegar, which is spread over the bottom of the boxes. The boxes are packed in stoves heated to about 85°F. This mode of procedure has been modified by suspending the sheets of lead in heated chambers, on the floors of which are placed vessels containing diluted acetic acid, air and carbonic acid gas being led into these chambers.

Whilst this method is much more rapid than the English method, it labours under the disadvantage that the white lead produced does not compare favourably with that produced by the older and slower procedure.

French or Clichy method.—The process by which white lead is manufactured in France is due to Thenard, and consists, first, in the production of a solution of basic lead acetate by digesting litharge with a pyroligneous acid of a sp.gr. 1·056; the litharge is added to the acid in a vessel in which it is kept constantly agitated by mechanical means until the sp.gr. of the solution is 1·145. The liquor is then run into another vessel, in which insoluble matter, such as lead, lead sulphate, silver chloride, &c., settles out, and the clarified solution is conveyed into a vessel where it is exposed to the action of carbon dioxide, which is forced through it by means of a fan and distributed throughout the liquid by a series of small pipes. The carbon dioxide used is produced by heating a mixture of coke and chalk in a kiln, the gases from the kiln passing into a vessel in which they are washed, and are then drawn off by a fan and forced into the decomposing vessel. The gas is passed through the solution of acetate for 12 to 14 hours, the white lead produced is allowed to settle, and the solution of normal acetate pumped back to the vessel, in which it is digested with litharge and converted into basic acetate. The white lead is run off into a tank and repeatedly washed with water; the first washings, as they contain lead acetate, are used over again for the production of basic acetate.

Milner's process.—This method of manufacturing white lead consists, first, in the production of a basic lead chloride by the mutual action of litharge, common salt, and water; the change takes place when these substances are mixed at the ordinary temperature; the mixture swells up, becoming gradually white and pasty. The reaction is attended by a considerable evolution of heat, and the solution becomes alkaline. This decomposition is, on the large scale, effected in a pug mill made of white pine, the arms of American elm; the litharge used is flake litharge which has been carefully ground and levigated; it is mixed with salt and water in the proportion of 1 of salt, 4 of litharge, and 16 of water. These materials are mixed with one another, the agitation being continued for 3 hours, as it is found that unless a sufficient time is allowed, the mass becomes stiff and pasty, and has to be removed from the mill by hand, whereas if the mixing be continued for the time specified, the mass obtained is more fluid, and can be easily removed. The mixture of basic lead chloride and caustic soda so obtained is next run into a large iron cylinder with spherical ends, the cylinder is lined with lead, and is 16 feet high and about 8 feet diameter. In the top end of the cylinder are two openings, one serving to introduce the mixture from the pug mill, and the second is closed by a valve by which the pressure is regulated. In this vessel the conversion of the basic lead chloride into a basic carbonate is effected by means of carbon dioxide, which is introduced by a pipe, the portion inside the vessel being provided with a number of perforations for the distribution of the gas. At one side of the lower part of the cylinder is a tap for the withdrawal of the white lead and of samples, which are taken from time to time during the carbonation. The carbonator is supplied with paddles or stirrers attached to a horizontal shaft running across the cylinder, and set in motion by machinery. As in the Clichy process, the carbon dioxide is produced by heating a mixture of limestone and coke in a kiln, from which it passes up a coke tower, in which it is washed by a stream of water and then forced by a pump or fan into the carbonator. The fluid mixture of basic chloride, caustic soda, &c., is submitted to the action of carbon dioxide until it is completely converted into white lead and common salt. The completion of the conversion is ascertained by the appearance and properties of samples withdrawn from the carbonator. The end of the reaction is shown by the liquid no longer exhibiting an alkaline reaction, the mixture forming a viscid, homogeneous mass, which, when shaken up in a glass vessel, which it partially fills, coats the sides, forming a uniform very thin layer, like frost on a window pane, and after standing a few seconds, the clear liquor separates from the carbonate, leaving arborescent patterns on the sides of the glass. If after this point has been attained the gas be passed through the mixture, the product loses its value, becoming granular and no longer coats the glass, but settles out rapidly. At the end of the carbonation the charge is run off into cisterns in which it is thoroughly washed with water to free it from salt, and, when completely washed, it is drained and dried in the usual manner. The white lead made by Milner's process resembles in composition that produced by the methods already described, and, like these products, is well adapted for use as a paint. This method of white lead manufacture was in operation at the Sankey White Lead Company's works, near Warrington, and at one time employed at one of the white lead establishments on the Tyne, but has been abandoned at both places.

Many processes have been devised for the manufacture of white lead; the production of white lead by the decomposition of a basic lead nitrate with carbon dioxide has been made the basis of one of the proposed methods. Another proposal is to submit a pasty mixture of litharge and lead acetate solution to the action of carbon dioxide, and it has been suggested to utilise the corrosion of finely divided granulated lead by air, water, and carbon dioxide as a method of making white lead. Attempts have also been made to manufacture white lead by precipitating solutions of basic lead acetate with solutions of sodium carbonate. These and many other processes have been suggested and patented; and whilst basic lead carbonates, or mixtures of the normal carbonate and lead hydroxide, are yielded by these methods, none has proved sufficiently successful to supplant the older methods, the greater portion of white lead manufactured at the present time being that produced by the English method, which, despite the slowness of the first stage and the dangerous character of several of the subsequent operations, maintains a supremacy. It would appear that the slow conversion of lead into white lead, such as obtains in the Dutch and English methods, is favourable to the production of this substance in a form possessing high covering properties, and specially adapted for use as a pigment. To perfect this mode of manufacture, what is needed is a method of detaching the corrosions, of washing and drying the white lead, which will minimise the risks of poisoning to the workpeople. Despite the regulations in force at all white lead manufactories in this country and the constant medical examination of the individuals engaged in these processes, cases of lead-poisoning are not infrequent, and in some instances these terminate fatally. Careful and frequent medical examination and immediate attention to the first symptoms of lead-poisoning have proved in the experience of a manufacturer with whom the writer is acquainted that it is possible to produce white lead by the English process without serious consequences to the people employed. No doubt one of the chief obstacles in the enforcement of the sanitary regulations is the negligence and carelessness of the workpeople themselves.

Properties of white lead.—White lead is a white, earthy, heavy powder, which, from its behaviour to polarised light, undoubtedly possesses a crystalline structure. Examined under the microscope, it appears to consist of rounded, circular, or oval grains. The grains are transparent; they vary in diameter from 0·0001 to 0·00004 of an inch. Commercial white lead varies in composition, and is apparently a mixture of the basic carbonate $(PbCO_3)_2{\cdot}Pb(OH)_2$ and normal lead carbonate, $PbCO_3$. This view of the constitution of white lead is not only supported by the observations that samples of white lead have been found on analysis to have a composition represented by the formulæ $3PbCO_3{\cdot}Pb(OH)_2$ and $5PbCO_3{\cdot}Pb(OH)_2$, and in some cases to consist of nearly pure $PbCO_3$, but is borne out by the investigations of Hochstetter, already referred to. For Hochstetter has shown the basic carbonate $(PbCO_3)_2{\cdot}Pb(OH)_2$ to be the product of the action of carbon dioxide on a solution of the basic lead acetate, and also of the action of sodium or potassium carbonates on the solution of the basic acetate. This compound is also produced by the action of carbamide on a solution of the basic lead acetate (Bourgeois, Bull. Soc. chim. [ii.] 50, 83; Chem. Soc. Abstr. 1889, 21). Further, this basic carbonate is converted into the normal carbonate by carbon dioxide in presence of acetic acid, and it is conceivable that in the stacks the compound $(PbCO_3)_2{\cdot}Pb(OH)_2$ should be in part converted in this way into the normal carbonate, and thus the varying composition of commercial white lead may be explained. The presence of the basic carbonate, or at any rate of a proportion of lead hydroxide, would appear to be essential to a white lead in order that it may be useful as a pigment and of good covering power. This conclusion is borne out by a series of experiments made by Wigner and Harland, who, by artificially preparing mixtures of lead carbonate and lead hydroxide, have shown that the covering power, the opacity, and the ease with which it can be applied as a pigment are greatly impaired when the proportion of carbonate to hydroxide exceeds that of three molecules of the former to one of the latter. In mixing white lead with oil, a considerable rise in temperature is observed, and it is supposed by white lead makers that a portion of the oil is saponified in this process. If this be the case, then it is probable that the lead hydroxide takes part in this decomposition of the oil, and an explanation is given of the fact that those corrosions, which consist mainly of the normal carbonate of lead are practically worthless as pigments. The covering power of white lead is further dependent upon the density; the greater the density the smaller the amount of oil absorbed and the thicker the colour. The covering power may be tested by triturating equal weights of the samples to be compared with equal quantities of linseed oil, and then determining the weights of equal volumes of the pigments thus obtained; that having the greater density will possess the higher covering power.

Weise (Monatschr. des Gewerbe-Vereins Cöln; also Dingl. poly. J. 208, 434) has examined different corrosions obtained by the German method, and concludes from the analysis of the same that the best varieties are those approximating most nearly to the composition of the basic carbonate $2PbCO_3{\cdot}Pb(OH)_2$, and that an increase in the proportion of normal carbonate results in a reduction of covering power. The following are the analytical results obtained by Weise:

	Lead oxide	Carbon dioxide	Water	
1.	86·80	11·16	2·00	Best quality
2.	86·24	11·68	1·81	Seconds—still good as a paint
3.	86·03	12·28	1·68	Thirds—useful as a paint
4.	84·69	14·10	0·93	Residue from washing apparatus
5.	83·47	16·15	0·25	Useless for paint
6.	93·70	5·31	0·90	„

The following represent the composition of the normal carbonate and of the basic carbonate:

	Lead oxide	Carbon dioxide	Water
Normal carbonate	83·52	16·48	—
Basic carbonate $2PbCO_3{\cdot}Pb(OH)_2$	86·32	11·36	2·32

The pigments known as Venetian, Hamburg, and Dutch whites are made by mixing white lead with heavy spar, Hamburg white containing these materials in the proportion of 1 to 3, and Dutch white in the proportion of 1 to 2.

Substitutes for white lead.—Several proposals have been made to replace the basic lead carbonate by other compounds of this metal. Amongst these may be mentioned lead oxychloride which was at one time manufactured at Washington, in the county of Durham, by a process patented in 1849 by the late Hugh Lee Pattinson. In this process, lead chloride is produced by treating finely ground galena with concentrated hydrochloric acid; the lead chloride formed in this way separates out by reason of its sparing solubility in water. The lead chloride is collected and dissolved in hot water, and this solution is treated with a quantity of milk of lime sufficient to neutralise any free acid and precipitate any iron that may be present, the solution during this operation being maintained at a temperature sufficiently high to keep the lead chloride in solution. After allowing the iron oxide to settle, the clear liquor is run off into a vat, and then treated with half the quantity of lime required to decompose the lead chloride. The lead oxychloride so produced is collected, drained, and washed, and finally dried in stoves on porous earthenware plates. The composition of the lead oxychloride is represented by the formula $PbCl_2{\cdot}Pb(OH)_2$ or $PbCl(OH)$; it is a white solid, possessing considerable covering power, and at one time was used as a paint. The manufacture of Pattinson's white lead at Washington has been given up for many years.

Lead sulphate is another of the compounds which it has been proposed to utilise as a white lead. In 1839, Richardson suggested the preparation of this compound by decomposing with sulphuric acid a solution of lead acetate, made by dissolving litharge in acetic acid. The pigment styled 'galenite' is said to be a basic lead sulphate, and can be made by treating finely powdered galena at a low red heat in open retorts or furnaces. Lead fume consists chiefly of lead sulphate, and occasionally a paint of a greyish shade is made with the fume collected in French's and other forms of fume condensers.

Hannay's 'white lead' is essentially a lead sulphate produced directly from galena, which is placed with live coke in a furnace of special construction, and volatilised and oxidised by a blast of air. The fume thus produced is conducted into specially constructed condensers, which are very similar to French's condenser, where it is collected. The material is washed, and finally dried. The patentee also describes the treatment of this condensed fume with various oxidising agents, such as *aqua regia*, to complete in this way the conversion of the sulphites and other similar compounds into sulphate. By this method a powder of great whiteness is obtained, which is stated to have considerable covering power and to form a useful paint when mixed and ground up with oil.

If, as has been already mentioned, a partial saponification of the oil by white lead takes place when the white lead is mixed with oil, it is not easy to understand how any normal salt of lead can efficiently replace white lead.

LEAD POISONING.

The salts of lead, more especially the soluble ones, are strongly poisonous, and since lead is a cumulative poison its salts and compounds, such as the oxide and carbonate, produce serious results if taken into the system even in minute quantities for any length of time. One of the forms in which lead is introduced into the system is by the use of drinking waters, some varieties of which easily attack the lead of the pipes used for conveying the water. Again, the workpeople engaged in the manufacture of lead and lead compounds, more especially white lead, are liable to suffer from the poisonous action of the compounds of this metal. In course of time the disease becomes chronic, the symptoms of which are pain in the abdomen, constipation, loss of appetite, thirst, a nervous prostration known as lead palsy, epileptic fits, and total paralysis. One of the signs of chronic lead poisoning is a blue line at the edges of the gums, due to the deposition of lead sulphide. This line is frequently seen in the case of painters and decorators, who are liable to this form of poisoning, produced in their case by the white lead used in making paint. The blue line is also to be observed in the workpeople engaged in the manufacture of white lead, or in manufactures in which this compound is employed. A portion of the lead taken into the system is excreted by the kidneys, and in cases of chronic lead poisoning it is stated that the administration of potassium iodide aids in the elimination of lead from the system. The mode in which the compounds of this metal are distributed in the different organs of the body is illustrated by the following results of an examination made by the writer in conjunction with Dr. Drummond and Sir Thomas Oliver in the cases of three workpeople who succumbed to the influence of this form of poisoning:—

Description of organ, &c	Lead found expressed as metallic lead in parts per million			Lead in grains calculated on total weight of organ

P. P. B.

OTHER COMPOUNDS OF LEAD.

Oxides. Besides the two oxides described above several others exist.

Lead suboxide Pb_2O is formed when lead oxalate is heated in the absence of air at a temperature below 300°; or when lead oxide is reduced with carbon monoxide at 300° (Brislee, Chem. Soc. Trans. 1906, 154). It is a black velvety powder of sp.gr. 8·342 at 18°, which is readily decomposed into the metal and the monoxide when heated or when treated with caustic soda or acids.

Lead sesquioxide Pb_2O_3 is generally considered to be a compound of the mono- and di- oxides $PbO{\cdot}PbO_2$, into which it is decomposed by acids. It is a yellowish-red powder, formed by adding a solution of sodium hypochlorite to a cold potash solution of lead oxide or by precipitating an acetic acid solution of red lead with dilute ammonia.

Lead peroxide (*Lead dioxide* or *Puce-coloured oxide of lead*) PbO_2 is found native in *plattnerite*, which crystallises in black hexagonal prisms of sp.gr. 9·4. It may be prepared by the action of nitric acid on red lead, by the action of chlorine on a lead salt in the presence of an alkali or better by the action of bleaching powder on lead chloride (Fehrmann, J. Soc. Chem. Ind. 1882, 407). A lead peroxide suitable to the requirements of the aniline manufacturer may be obtained by adding the required amount of lead oxide to molten caustic soda at the highest possible temperature, with constant stirring, and then sufficient sodium nitrate for oxidation. The mass is then extracted with hot water, washed and dried (Minor, J. Soc. Chem. Ind. 1894, 940).

Normal or basic lead sulphate may be converted into lead peroxide, by mixing it with magnesia, suspending the mixture in water and passing in chlorine. It is purified by treatment with boiling 10 p.c. caustic soda, then with hot nitric acid. The yield is almost theoretical, and the oxide is of 97 p.c. purity, containing only traces of chlorine (Friedrich, Mallet, and Guye, Monit. Scient. 1906, 20, 514).

The reaction may be represented thus:

$$PbSO_4+MgO=MgSO_4+PbO\,;$$
$$PbO+MgO+Cl_2=PbO_2+MgCl_2.$$

Lead peroxide may also be obtained electrolytically when water containing less than 1 p.c. of acid, alkali, or salt is electrolysed, using a lead sulphide anode: $PbS+H_2O+5O=PbO_2+H_2SO_4$ (D. R. P. 162107; *see* also D. R. P. 124512; Eng. Pat. 12186, 1901; J. Soc. Chem. Ind. 1897, 743; *ibid.* 1902, 620; Hollard, Compt. rend. 1903, 136, 229). (For other methods of preparing the peroxide *see* Eng. Pats. 11962, 1889; 6954, 1903; Warren, Chem. News, 1896, 144.) Lead peroxide is a dark brown, almost black, powder of sp.gr. 8·9–9·2, which is said to keep best when moist (Fehrmann, *l.c.*). It loses oxygen readily on heating, forming the monoxide, and on exposure to sunlight forms red lead. It has a powerful oxidising action, taking fire when triturated with sulphur, and igniting sulphuretted hydrogen when the latter is passed over it, the heat of this reaction being such that explosives like guncotton or picrate can be fired and metallic powders ignited by its aid (Vanino and Hauser, Ber. 1900, 33, 625). A large number of organic compounds when triturated with it also cause an evolution of heat and light. It decomposes or oxidises some mineral acids, forming the corresponding lead salt with, often, a violent evolution of gas. Lead peroxide is often employed as an oxidising agent in the analysis of organic compounds containing sulphur, and it has also been used in inorganic analysis for the removal of excess of sulphuretted hydrogen or ammonium sulphide (Bogdan, Bull. Soc. chim. 1903, 29, 594). Lead peroxide has been used as a mordant and also for the precipitation of other oxides on the fibre (Bonnet, Bull. Soc. Ind. Mulhouse, 1894, 69; Compt. rend. 1893, 117, 518). It has also been used in the voltaic battery and in electrical and metallurgical operations (Eng. Pat. 16608, 1886; J. Soc. Chem. Ind. 1888, 37). Lead peroxide acts as a weak basic oxide, forming unstable tetravalent lead salts and also as an acid-forming oxide yielding the *plumbates. Orthoplumbates* of the composition M_4PbO_4 and *metaplumbates* $M_2PbO_3,3H_2O$ or $M_2Pb(OH)_6$ have been prepared (Fremy, Ann. Chim. Phys. 1844, [iii.] 12, 490; Grützner and Höhnel, Arch. Pharm. 1895, 233, 512; Bellucci and Parravano, Gazz. chim. ital. 1905, 35, ii. 500).

The orthoplumbates evolve oxygen when strongly heated, and on this fact has been based a method of obtaining oxygen on a large scale; the calcium salt has also been used as an oxidising agent (Kassner, Arch. Pharm. 1890, 228, 109; *ibid.* 1894, 232, 375; *ibid.* 1895, 233, 501).

When calcium meta- or orthoplumbate is heated in a current of air at 200°–280°, *calcium perplumbate* $CaPb_2O_6$ is formed (Kassner, Arch. Pharm. 1899, 237, 409; *ibid.* 1900, 238, 449).

When potassium plumbate is treated with water at the ordinary temperature it is completely hydrolysed, and *plumbic acid* H_2PbO_3 remains in solution in the colloidal state (Bellucci and Parravano, Atti. R. Accad. Lincei, 1906, v. 15, ii. 542, 631; Parravano and Calcagni, Gazz. chim, ital. 1907, 37, ii. 264).

Lead hydroxide $Pb(OH)_2$ is formed when potassium nitrate is electrolysed, a lead anode being used (Lorenz, Zeitsch. anorg. Chem. 1896, 12, 436). It may also be prepared by heating lead carbonate with water or steam (Eng. Pat. 9521, 1893), or by treating lead sulphate with excess of alkali hydroxide (U. S. Pat. 787541, 1905; *see* also U. S. Pat. 808141, 1905; Fr. Pat. 401473, 1909). It acts as a very weak acid (Hantzsch, Zeitsch. anorg. Chem. 1902, 30, 308; Rubenbauer, *ibid.* 331), and has also been obtained in a colloidal form (Sziland, J. Chim. Phys. 1907, 5, 636). The action of lead hydroxide on sugars is similar to that of the alkali hydroxides, inducing molecular rearrangement (Lobry de Bruyn and Eckenstein, Rec. trav. chim. 1896, 15, 92; U.S. Pat. 726130, 1903).

Two *basic lead hydroxides* are known, $2PbO{\cdot}H_2O$ or $PbO{\cdot}Pb(OH)_2$ and $3PbO{\cdot}H_2O$ or $2PbO{\cdot}Pb(OH)_2$. The former is obtained as a white powder by the action of air and water on the metal or by precipitating a lead salt with a small quantity of alkali or ammonia. It may also be obtained in hexagonal crystals by exposing a cold solution of lead monoxide in caustic potash to the air (Lüdeking, Amer. Chem. J. 13, 20). The latter basic hydroxide has been prepared by precipitating basic lead acetate with ammonia (Payen, Ann. Chim. Phys. 1866, [iv.] 8, 302). It forms a white crystalline powder or glittering octahedra, according to the method of preparation.

Halogen compounds of lead. *Lead chloride* (*horn lead, plumbum corneum*) $PbCl_2$ occurs native in the craters of volcanoes as the mineral *cotunnite*, and may be prepared readily by treating the oxide or carbonate with hydrochloric acid or by precipitating a fairly concentrated solution of a lead salt with a soluble chloride. On a large scale it may be prepared by heating litharge with a slight excess of hydrochloric acid at 200° and 25 atmos. pressure, in an autoclave lined with an acid-resisting material (Eng. Pat. 12953, 1895; *see* also Eng. Pats. 16213, 1889; 8914, 1895; J. Soc. Chem. Ind. 1890, 941; *ibid.* 1895, 873; *ibid.* 1896, 357). In a colloidal form it can be obtained by mixing together lead acetate or the lead salt of any other organic acid with an alkali, or alkaline earth chloride (van de Velde, Chem. Zeit. 17, 1908).

Lead chloride forms a white crystalline precipitate or white silky rhombic needles of sp.gr. 5·8. When heated in absence of air it melts at about 485°, and volatilises at 861°–934°. It is less soluble in dilute hydrochloric acid and in solutions of chlorides than in water, but dissolves more readily in concentrated hydrochloric acid (André, Compt. rend. 1883, 97, 1302; Lichy, J. Amer. Chem. Soc. 1903, 25, 469). It dissolves in alkali acetates and in thiosulphates, forming a lead thiochloride $Pb_4S_6Cl_2$ (Hofmann and Wolfl, Ber. 1904, 37, 249).

Lead chloride forms double salts with ammonium and other metallic chlorides (André, Compt. rend. 1883, 96, 435; Lorenz and Ruckstuhl, Zeitsch. anorg. Chem. 1906, 51, 71; Ephraim and Barteczko, *ibid.* 1909, 61, 245; Foote and Levy, Amer. Chem. J. 1907, 37, 119; J. Soc. Chem. Ind. 1909, 707).

A large number of lead oxychlorides are known. The compound $PbCl_2,PbO$ occurs in nature as the mineral *matlockite;* it forms long thin colourless needles, decomposing at 524° into a mixture of $PbCl_2,2PbO$ and PbO, which fuses completely at 615°. $PbCl_2,2PbO$ occurs as *mendipite,* and forms long glistening needles, m.p. 693°. The compound $PbCl_2,4PbO$ has m.p. 711°, and forms glistening lamellar crystals, which give an intense yellow powder (Ruer, Zeitsch. anorg. Chem. 1906, 49, 365; *see* also Strömholm, *ibid.* 1904, 38, 429; Berl and Austerweil, Zeitsch. Elektrochem. 1907, 13, 165). The compound known as *Cassel yellow* has the approximate composition $PbCl_2,7PbO$, together with a little lead, and is usually prepared by fusing together 1 part ammonium chloride, and about 10 parts massicot, white lead, or minium. It is used as a pigment.

Lead tetrachloride $PbCl_4$ may be formed by passing chlorine into lead chloride, suspended in strong hydrochloric acid at 10°–15°. On adding ammonium chloride, *ammonium plumbichloride* $(NH_4)_2PbCl_6$ separates (Hutchinson and Pollard, Chem. Soc. Trans. 1899, 212; Seyewetz and Trawitz, Compt. rend. 1903, 136, 686; Bull. Soc. chim. [iii.] 29, 261; Elbs and Nübling, Zeitsch. Elektrochem. 1903, 9, 776).

When this ammonium compound is added little by little to ice-cold concentrated sulphuric acid, lead tetrachloride separates as a yellow highly refractive oily liquid, which fumes in air, smells like hypochlorous acid, and induces a sweet taste in the mouth. It has sp.gr. 3·183, is stable under sulphuric acid, but is liable to explode, especially when heated, forming chlorine and lead chloride. It solidifies at −15° to a transparent yellow crystalline mass. With hydrochloric acid it forms a crystalline compound H_2PbCl_6, which dissolves on further addition of acid, and is decomposed by water into lead dioxide and hydrochloric acid (Friedrich, Monatsh. 1893, 14, 505; *see* also Ber. 1893, 26, 1434; de Coninck, Bull. Assoc. belge Chim. 1902, 16, 94).

Lead chlorite, chlorate, and *perchlorate* are also known.

Lead bromide $PbBr_2$ is obtained by treating lead oxide with aqueous hydrobromic acid or by precipitating a lead salt with a soluble bromide. It forms white shining needles, which darken when exposed to sunlight (Norris, Amer. Chem. J. 1895, 17, 189); sp.gr. 6·6. It resembles the chloride in properties.

It forms double bromides and oxybromides.

Lead iodide PbI_2 is formed by dissolving lead in hydriodic acid or by precipitating a solution of a lead salt with a soluble iodide. It forms yellow crystals of sp.gr. 6·1, which on heating become yellowish-red, bright red, and finally brownish-black. It also forms double salts and basic salts.

The chloride, bromide and iodide yield double salts with pyridine and quinoline (Elbs and Nübling, *l.c.*).

A number of mixed halogen compounds are known (Thomas, Compt. rend. 1898, 126, 1349; *ibid.* 1899, 128, 1234, 1329; Fonzes-Diacon, Bull. Soc. chim. 1897, [iii.] 17, 346; Hertz and Bogg, J. Amer. Chem. Soc. 1897, 19, 820).

Lead fluoride PbF_2 is formed in the same way as the corresponding iodide. It is a white powder, almost insoluble in water and in hydrofluoric acid, but readily soluble in hydrochloric and in nitric acid. It yields a basic fluoride and a chlorofluoride (Fonzes-Diacon, *l.c.*).

Lead tetrafluoride PbF_4 is said to be formed in a colloidal state by the action of strong sulphuric acid on the *acid plumbifluoride* $3KF,HF,PbF_4$, but has never been obtained pure (Brauner, Chem. Soc. Trans. 1894, 393). The above acid plumbifluoride is obtained by the action of hydrofluoric acid and potassium fluoride on lead tetracetate.

Lead and nitrogen. *Lead nitrate* $Pb(NO_3)_2$ is formed by dissolving litharge in nitric acid of sp.gr. 1·35. The solution is evaporated until it has the sp.gr. 1·6, and is then allowed to cool. It forms milk-white crystals of sp.gr. 4·5 and dissolves in water with a reduction of temperature. It has an astringent metallic taste, detonates with brilliant sparks when thrown upon red-hot charcoal and deflagrates when triturated with sulphur. When heated it commences to decompose at 283°, and in a sealed tube at 357°, it decomposes thus:

$$Pb(NO_3)_2 \leftrightarrows PbO+O+2NO_2$$

(Baekeland, J. Amer. Chem. Soc. 1904, 26, 391; Morgan, J. Phys. Chem. 1904, 8, 416; Colson, Compt. rend. 1909, 148, 837). Lead nitrate is used in dyeing and calico printing, for the preparation of mordants and of chrome yellow. Several basic lead nitrates are known (Senderens, Bull. Soc. chim. [iii.] 11, 365; Mailhe, Compt. rend. 1902, 134, 233; Peters, Zeitsch. anorg. Chem. 1896, 11, 116).

Basic lead nitrate is said to be a very useful decolorising agent for sugar solutions (Herles, Zeitsch. Zuckerind. Böhmen, 1896, 21, 189; Neuman, *ibid.* 183; Zeitsch. angew. Chem. 1897, 123; Pellet, Bull. Assoc. Chim. Sucr. Dist. 1897, 14, 794; *ibid.* 1905, 23, 638; Horne, *ibid.* 635).

Lead nitrite $Pb(NO_2)_2$ is obtained by decomposing silver nitrite with lead chloride and concentrating the solution in a vacuum (Lang, J. 1862, 100; *see* also Chilesotti, Atti. R. Accad. Lincei, 1908, [v.] 17, i, 824). It forms yellow prisms, soluble in water, the solution on evaporation losing nitric oxide and yielding a basic nitrite. A number of these basic salts are known (Chilesotti, *ibid.* 1908, v. 17, ii. 173, 288, 377, 474; Meldrum, Chem. Soc. Proc. 1908, 97).

Lead hyponitrite $Pb(NO)_2$ is a yellow crystalline powder, which explodes on heating (Kirschner, Zeitsch. anorg. Chem. 16, 424; Divers, Chem. Soc. Trans. 1899, 121).

Lead nitrohydroxylamine PbN_2O_3 is an unstable salt (Angelico and Fanara, Gazz. chim. ital. 31, [ii.] 15).

Lead imide PbNH is obtained by the action of potassamide on lead iodide in liquid ammonia. It is a reddish-brown explosive substance. If the lead iodide be in excess, a white basic salt $NPb_2I{\cdot}NH_3$ is formed (Franklin, J. Amer. Chem. Soc. 1905, 27, 820).

Lead nitride PbN_6 is said to be formed by the action of aqueous ammonia or of nitrides on lead salts (Curtius and Rissom, J. pr. Chem. [ii.] 58, 261).

Lead cobaltinitrite, lead cyanide, and cyanate, the corresponding thio- compounds, and lead ferro- and ferri- cyanides are known.

Lead Phosphates. *Tribasic lead phosphate* $Pb_3(PO_4)_2$ is an amorphous white powder obtained by precipitating an excess of lead acetate with a small quantity of sodium phosphate at 100° or by boiling the dibasic salt in water for 5–6 hours.

Dibasic lead phosphate $PbHPO_4$ is prepared by precipitating a somewhat dilute solution of lead nitrate with hot dilute phosphoric acid at 100°. It forms a fine crystalline powder.

Monobasic lead phosphate $Pb(H_2PO_4)_2$ is formed by dissolving the dibasic salt in strong phosphoric acid by the aid of heat and allowing the solution to crystallise. It may then be recrystallised from phosphoric acid. It forms fine needles stable in air, and is decomposed by cold and even more readily by boiling water, forming first the dibasic and finally the tribasic salt (Alders and Stähler, Ber. 1909, 42, 2261).

Lead pyrophosphates, a number of complex phosphates and *thiophosphates* (Gerhardt, Ann. Chim. Phys. 1848, [iii.] 22, 505; Ouvrard, Compt. rend. 1890, 110, 1334; Friedel, *ibid.* 1894, 119, 260; Ferrand, *ibid.* 1896, 122, 886), and also *lead phosphites* (Amat, *ibid.* 1890, 110, 901), have been prepared.

The following are naturally occurring lead phosphates and arsenates isomorphous with apatite, a portion of their chlorine often being replaced by fluorine:

Pyromorphite $Pb_3(PO_4)_2Pb_2ClPO_4$; *Polysphærite* $(PbCa)_3(PO_4)_2(PbCa)_2ClPO_4$; *Mimetesite* $Pb_3(AsO_4)_2Pb_2Cl(AsO_4)$; and *Kampylite* $Pb_3[(As,P)O_4]_2Pb_2Cl[(As,P)O_4]$.

Lead arsenate may be formed by suspending litharge in a solution of arsenic acid in the presence of nitric or acetic acid as catalyst (U.S. Pats. 892603, 903389, 1908; J. Soc. Chem. Ind. 1908, 1019, 1203), or by roasting a mixture of white arsenic and a lead salt in combining proportions in the presence of oxygen or an oxidising agent (U.S. Pat. 929962, 1909).

Lead arsenate is used as an insecticide and is largely employed in the United States for the protection of fruit trees from the larvæ of the gypsy moth. For this purpose, it is said to be best prepared by adding a solution of lead acetate or nitrate to sodium arsenate until an iodine test paper shows the presence of excess of lead (Haywood and McDonnell, J. Soc. Chem. Ind. 1910, 1027; *see* also Pickering, Chem. Soc. Trans. 1907, 312). For spraying plants, it is often mixed with lime-sulphur solution; in this case, the normal lead salt should be employed, and it is best to avoid using water containing much alkali carbonate, as the tendency of the latter is to make the arsenic soluble (Brady and Tartar, J. Ind. Eng. Chem. 1910, 2, 328; *see* also Griffen, *ibid.* 1909, 1, 659; Moreau and Vinet, Compt. rend. 1910, 150, 787).

Lead silicates. Silica fuses with lead oxide forming a yellow glass. Lead silicate also forms a constituent of flint glass. Two silicates have been isolated (Cooper, Shaw, and Loomis, Amer. Chem. J. 1909, 42, 461). *Lead orthosilicate* Pb_2SiO_4 forms colourless hexagonal tablets, and has m.p. 746°.

Lead metasilicate $PbSiO_3$ has m.p. 766°, and has been found to exist naturally in Mexico as *alamosite.* It is analogous to *wollastonite*, calcium silicate, and occurs in radial aggregates of colourless transparent fibres (Palache and Merwin, Amer. J. Sci. 1909, 27, 399; *see* also Hilpert and Weiller, Ber. 1909, 42, 2969; Hilpert, Metallurgie, 1908, 5, 535).

Lead silicofluoride is formed by heating galena or other lead-containing material with hydrofluosilicic acid, air being blown through the mixture and water being then added (U.S. Pats. 754667, 1904; 779091, 779092, 1905). (For the use of lead silicate in glazes *v.* FRITTS and GLAZES.)

Lead borates and lead boric glasses have been prepared (Faraday, Phil. Trans. 1830, 1).

Lead and **sulphur.** *Lead sulphide* PbS occurs in nature as *galena*, usually in the form of cubes, possessing a bluish-grey colour, and sp.gr. 7·25–7·7 (Hannay, J. Soc. Chem. Ind. 1894, 639). It may be formed by passing sulphur vapour over lead, by fusing lead oxide with excess of sulphur, or, in an amorphous condition, by passing sulphuretted hydrogen into a solution of lead nitrate. When heated in a current of certain gases, it sublimes in cubes, whilst if fused with potash and sulphur, it forms octahedral crystals. In a current of sulphur dioxide it has been said to form the compound PbS_2O_2; but this has been disputed (J. Soc. Chem. Ind. 1894, 813).

Lead sulphide has m.p. 1120°±10° (Friedrich, Metallurgie, 1907, 4, 479; *ibid.* 1908, 5, 23); according to Lodin (Compt. rend. 1895, 120, 1164), the m.p. is 935°. It is converted by nitric acid into nitrate and sulphate, and is decomposed by hot strong hydrochloric acid, sulphuretted hydrogen being evolved. Lead sulphide forms double compounds with the halides of lead (Hünenfeld, J. pr. Chem. 1836, 7, 27; Parmentier, Compt. rend. 1892, 114, 299; Lenher, J. Amer. Chem. Soc. 1895, 17, 511; *ibid.* 1901, 23, 680), and also with bismuth sulphide (Ducatte, Compt. rend. 1902, 134, 1061). The reactions between lead sulphide and its oxidation products have been studied in detail by Schenck and Rassbach (Ber. 1907, 40, 2185, 2947; *ibid.* 1908, 41, 2917).

A *polysulphide* PbS_5 is formed as an unstable purple-red precipitate by precipitating lead nitrate at 0° with calcium pentasulphide and washing the precipitate with carbon disulphide (Bodroux, Compt. rend. 1900, 130, 1397).

Lead sulphate is found native as *lead vitriol* or *anglesite*, in transparent rhombic crystals isomorphous with *celestine* and *heavy spar.* It may be obtained as a white powder by precipitating a lead salt with sulphuric acid or with a soluble sulphate, or by the action of sulphur dioxide on lead peroxide (Marino, Zeitsch. anorg. Chem. 1907, 56, 233). It may also be obtained crystalline (Manross, Annalen, 1852, 82, 360). Lead sulphate has sp.gr. 6·2–6·3, and is said to melt without decomposition at a red heat, but according to Schenck and Rossbach (*l.c.*) it does not melt below 1100°. It is soluble in pure water to the extent of 0·0824 gram of lead sulphate per litre or 1 in 12135 at all temperatures, but the solubility diminishes on addition of sulphuric acid (Sehnal, Compt. rend. 1909, 148, 1394; *see* also Dolezalek and Finckh, Zeitsch. anorg. Chem. 1906, 51, 320). Lead sulphate is also soluble in alkalis, in ammonium and in calcium acetates, and in a number of other salts (Long, Amer. Chem. J. 22, 217; Reichard, Chem. Zeit. 1903, 27, 924, 943; Fox, Chem. Soc. Trans. 1909, 878). It forms double salts with the sulphates of tin (Weinland and Kühl, Ber. 1906, 39, 2951); with potassium (Belton, Chem. News, 1905, 191); and with arsenic (Kühl, Arch. Pharm. 1907, 245, 377).

Lead disulphate or *Plumbic sulphate* $Pb(SO_4)_2$ is obtained at the anode when pure sulphuric acid, of sp.gr. 1·7–1·8 is electrolysed between lead electrodes. It is a white or faintly greenish-yellow crystalline powder, giving a green solution in strong sulphuric acid. It is decomposed by water, forming sulphuric acid and lead peroxide, and is a powerful oxidising agent. It forms double salts with the alkali metals and also with aniline and with dimethyl and diethyl aniline (Elbs and Fischer, Zeitsch. Elektrochem. 1900, 7, 343). On the preparation and use of basic lead sulphate, *v.* above.

Lead sulphite and *lead thionates* are also known.

Lead selenide (Pélabon, Compt. rend. 1907, 144, 1159); *selenites* (Marino, Zeitsch. anorg. Chem. 1909, 62, 173); and *selenates* (Mathers, J. Amer. Chem. Soc. 1908, 30, 1374), also exist.

Lead organic compounds. The lead alkyl compounds are prepared by the interaction of alkyl iodides and lead-sodium or by the action of lead chloride on zinc alkyls (Buckton, Annalen, 1859, 109, 222; Cahours, *ibid.* 1862, 122, 65; Ghira, Gazz. chim. ital. 24, i. 44. 320; Frankland and Lawrance, Chem. Soc. Trans. 1879, 245; Klippel, J. 1860, 383).

Lead ethoxide $Pb(OEt)_2$ has been prepared by suspending thin sheets of lead over absolute alcohol through which a stream of ozone is passed. When washed with alcohol and dried *in vacuô* over sulphuric acid, it forms a light yellow friable powder, soluble in, but readily hydrolysed by water (Perkin, Chem. Soc. Proc. 1908, 179).

Lead tetraphenyl may be obtained by the action of lead chloride on an ethereal solution of magnesium phenyl bromide (Pfeiffer and Truskier, Ber. 1904, 37, 1125; Polis, Ber. 1887, 20, 3332).

A number of other aromatic and aliphatic alkyl and halogen alkyl compounds have been prepared (Pfeiffer and Truskier, *l.c.*; Polis, *l.c.*, and 717).

Lead thiocarbamide halides $Pb(CH_4N_2S)_2X_2$ ($X=Cl,Br,I$) are described by Rosenheim and Meyer (Zeitsch. anorg. Chem. 1906, 49, 13).

For the lead salts of organic acids, *see* the respective acids. Z. K.

LEADHILLITE. A rare mineral approximating in composition to the formula

$$PbSO_4·2PbCO_3·Pb(OH)_2.$$

The monoclinic crystals have the form of six-sided plates or pseudo-rhombohedra with a perfect basal cleavage and pearly lustre. As indicated by variations in the optical characters and chemical composition, there appear to be at least three varieties or modifications. The mineral is found in the upper oxidised portions of veins of lead ore at but few localities, notably at Leadhills in Scotland. It has also been met with in lead slags left by the Romans. 'Susannite' is a variety from the Susanna mine at Leadhills, and the name 'maxite' has been applied to crystals from Sardinia. L. J. S.

LEAF GREEN. *Chrome Green* (*v.* PIGMENTS).

LEATHER. When the skins of animals are treated with infusions containing any of the vegetable tannins, the gelatinous tissue is converted into the tough imputrescible substance known as leather, while the process by which it is made is called 'tanning.' Certain mineral salts, as well as oils and fats which undergo oxidation in the skin, have a somewhat similar effect, and more recently, aldehydes, and especially formaldehyde, have been successfully employed. It is proposed in the following article first to describe the structure and chemical composition of skin, and the preliminary processes it has to undergo to deprive it of hair and to render it fit for tanning, and then to deal with the different tanning materials and the various processes by which they are employed in practice.

The skin, as it exists on the animal is much more than a mere covering, and contains a variety of organs, both of sense and of secretion, and some knowledge of its anatomy is necessary to a proper understanding of the tanning process.

The skin consists of two layers, which arise in embryonic development from the inner and outer layers of the ovum, and which throughout retain the strongly marked differences which correspond to this diversity of origin. The *epidermis* or outer layer of the skin is derived from the outer layer (epiblast) of the ovum, while the inner layer, *corium*, *derma*, or *cutis*, together with all the other connective tissues of the body, takes its rise from the middle of the ovum (mesoblast). Though the skins of different animals differ in details, that of the calf, of which a section is illustrated in Fig. 1, may serve as a type of most of those used in the manufacture of leather. The outer layer or *epidermis* consists, as has been said, of simple nucleated cells, which at the surface are dead, hardened, and flattened, but where they rest on the *corium* are soft and spherical, and constitute the so-called 'mucous layer' (*rete mucosum*). This is not supplied directly with blood-vessels, but derives its nourishment from the fluids of the *corium*. Here growth takes place, and the cells probably multiply by fission, though this has not been actually observed. The hairs, though deeply rooted in the *corium*, are really products of the *epidermis* which surrounds them and passes down into the *corium* in the form of a bulb-shaped sheath. The nourishment of the growing hair is supplied by a knob of connective tissue called the hair-papilla, furnished with blood-vessels, and passing up into the centre of the hair-bulb. The hair itself is composed of modified and hardened cells, forming exteriorly irregular overlapping scales, giving the outline a serrated appearance, which is especially marked in wool. Within this 'hair-cuticle,' as it is sometimes called, is the fibrous portion of the hair, composed of long spindle-shaped cells, and sometimes in the centre of this is a cellular pith containing air. The hair, except in white animals, contains a good deal of pigment, and some is also present in the epidermis cells forming the hair-sheath. The new hair, both in fœtal development and in ordinary growth, begins as a thickening of the *epidermis* layer, forming a knob which gradually sinks into the *corium*, and becomes a bulb in which the hair is developed and forces its way to the surface much as an onion does to the surface of the ground. In animals which change their coats in spring, the young hair generally originates in this way from a new bulb formed below the old one, and passes up into the old sheath. This deep-seated origin explains the great difficulty found in removing these young hairs for technical purposes. Besides the hairs, sudoriferous and sebaceous glands are similarly developed from the *epidermis*. The sebaceous glands are seated round the stems of the hairs, and their ducts discharge oily matter which serves as a lubricant into the hair sheaths near the surface of the skin. The sudoriferous glands are more deeply placed, usually extending even below the hair roots; they are less convoluted than in man, and discharge through narrow sinuous ducts to the surface.

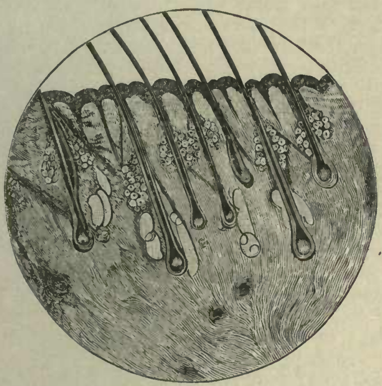

FIG. 1.

The *corium* consists mainly of connective tissue, which, on boiling with water, readily dissolves, and is wholly converted into gelatin. In most animals the principal part of the hide (*pars reticularis*) is composed of bundles of interlacing fibres, each of these bundles being formed of a multitude of fine fibrils. Towards the outer surface these bundles disappear, and the separate fibrils combine in a closely-matted felt (*pars papillaris*), which is technically known as the 'grain.' In the pig, and possibly also in the seal, this close-textured part is thick, and is all that is valuable for tanning, the reticular part being so slightly developed as not to be distinguishable from the looser fatty tissue (*panniculus adiposus*), which underlies the true skin. Consequently, these skins are remarkable for extreme toughness. In addition to this gelatinous structure, the true skin contains certain yellow fibres called 'elastic,' and distinguished by their very difficult solubility in boiling water, acids, and alkalis.

Between the *corium* and the *epidermis* is an extremely fine membrane, known as the hyaline layer. This is very difficult to demonstrate microscopically, but has been separated in some technical operations, and is probably the cause of the clear brown or buff colour of the grain surface of tanned leather, while the finely matted tissue below it remains nearly white.

The *corium* has also blood-vessels, nerves, and minute muscles for erecting the hairs; but none of these is of much technical importance, and for further details the reader may be referred to Procter's Leather Industries Laboratory Book, Principles of Leather Manufacture, or to the larger anatomical works.

A few words must, however, be said about the practical microscopic examination of skin. For this purpose it is necessary to produce extremely thin sections, and the skin must be previously hardened. To this end it may be cut into strips about ½ inch long by ¼ inch wide, with their length at right angles to the direction of the hair, which should be cut short with scissors, with which also the loose fatty subcutaneous tissue should be removed. The strips are placed in a closed vessel with several times their volume of methylated spirit diluted with an equal quantity of water. The next day this must be replaced by stronger alcohol, and finally by absolute. In 4–8 days, the hide will be hard enough to cut, and may be held between the finger and thumb, and shaved by a drawing cut with a very sharp razor flooded with alcohol and resting on the tip of the forefinger. The cut should begin at the grain side, and must be exactly parallel with the hairs to give good results. For this reason a microtome is of very little service, as it is more difficult to adjust the fragment of hide in it than to make the sections by hand. They are floated off the razor in alcohol, and must be stained in order to make the details visible. Various methods of staining are described in the microscope text-books, one of the simplest being to immerse in aqueous solution of picrocarmine. The carmine stains the connective tissue and the nuclei of the cells red, while the structures derived from the *epidermis*, the *erectores pili* muscles, and the blood-vessels, absorb the picric acid only, and become yellow. The section may now be soaked in glycerol to clear it, and examined in a drop of glycerol under a thin cover-glass; or may be permanently mounted in glycerol or Farrant's fluid; but for this purpose it is generally better, instead of clearing with glycerol, to soak the sections again for some time in absolute alcohol containing a little picric acid, till quite deprived of water, clear in clove oil, and mount in a drop of solution of gum dammar in benzene, or of Canada balsam.

Kathreiner has described a method which, while it is less striking for demonstration of the different tissues, is better adapted for practical work when a knowledge of the general appearance of the structures has been attained. The fresh hide (and it is important in preparing type specimens that the animal should not have been killed more than a few hours) is cut into small strips as described, and then immersed for 4–8 days, according to the thickness of the hide, in about twelve times its volume of an aqueous solution containing 1 p.c. of osmic and 2½ p.c. of chromic acids. This solution must be kept from light and dust in a stoppered bottle and in a cool place. Care must be taken to avoid the fumes, which cause severe catarrh of the mucous membranes. The hide pieces must now be soaked in about twelve times their volume of absolute alcohol several times renewed for 4–8 days, and are then cut as described. No further staining is required, as the chromic acid colours the tissues yellow, while all traces of fat, as for instance, the oily matter of the sebaceous glands, are stained grey or black by the osmic acid. They may be cleared at once with clove oil, in which they may be examined, or mounted in dammar.

A third method may be mentioned which is very useful for rapid observations, especially when it is desired to ascertain how far the cellular structures have been affected in preparing the hide or skin for tanning. The section, which need not be so thin as when intended for more detailed study, may be cut either after a short hardening in alcohol, or in the case of hide swollen with lime, simply by cutting a small strip ¾ through from the grain, and turning it back so as to put the tissue on the stretch, and then cutting from flesh to grain with a razor flooded with distilled water. If the wet section be placed in a drop of water on a slide under a cover glass, and examined by reflected light with a 1-inch objective, the fat glands will be seen as yellow masses embedded in the white fibrous tissue. If now the section be moistened with a mixture of equal parts of glycerol and glacial acetic acid, the connective tissue will become quite transparent, and the glands and hair-roots may be examined, even with a moderately high power, by transmitted light.

The principal chemical constituents of the skin are proteids, fats, and water; and the most important of these is collagen, of which the white fibres, forming the main fabric of the hide, are composed, and which, on boiling with water, is converted into gelatin (glutin). The remaining proteids (keratins, elastins) are mostly albuminoids, but glycoproteins (mucins) and those of the blood and lymph (serum albumens, hæmoglobin, &c.) are also present.

The *epidermis* and its products, hair, horns, hoofs, &c., all belong to the class of keratins, which are allied to coagulated albumen, but differ in their composition (*e.g.* in their percentage of sulphur), and in their behaviour towards chemical reagents. They can hardly be said to be soluble in water, though by prolonged boiling under pressure they are finally dissolved to an extract which does not gelatinise on cooling. The softer structures are easily soluble in dilute caustic alkalis in the cold, whilst hair and horn are gradually softened, but only yield to strong solutions aided by heat. They are reprecipitated by acids, and these precipitates mixed with oil have been proposed as a ‘filling’ for alumed leather in place of flour and egg-yolk, but have not come into practical use. Lime and other alkaline earths act like the alkalis, and hence milk of lime, while it scarcely attacks the hair, easily loosens it, by dissolving and softening the *epidermis* and root-sheaths. Strong solutions of the alkali and alkaline-earth hydrosulphides, on the other hand, seem to attack the harder tissues by preference, and reduce the hair to pulp without affecting the *epidermis* cells so much as milk of lime.

Collagen forms nearly 95 p.c. of the dry matter of the *corium* and is insoluble in cold water, dilute acids, and common salt solution (Reimer's statement that it is soluble in 10 p.c. solution of NaCl has not been confirmed), and it is but slowly attacked by dilute alkaline solutions, but strong acids and alkalis have a hydrolysing action, yielding soluble products. Boiling water has a similar effect, the first stage in this case being gelatin, which is slowly further attacked, continued hydrolysis yielding hemicollin and semiglutin, and later gelatoses and glutin peptones.

Hofmeister, who has studied these changes, proved that the production of gelatin from collagen is merely hydrolytic, with an increase of weight of about ¾ p.c. As final products of prolonged hydrolysis, ammonia, and amino-acids are formed, among the latter, glycine (amino-acetic acid), glutaminic acid, leucine (amino-caproic acid) arginine, lysine, and α-proline being the most important, while tyrosin and tryptophan are absent. Thus all the products of collagen belong to the antigroups of proteids, and aromatic groups are almost absent, in this respect showing a marked difference from keratin and the albumins.

Hydrolysis of collagen is also produced by pepsin (in slightly acid solutions), but trypsin has no dissolving action on collagen if the latter has previously been treated with water at 70° or with acids. Putrefactive bacteria rapidly lead to the final products of hydrolysis (amino acids, &c.).

Elastins form the substance of the ‘yellow’ or ‘elastic’ fibres which act as a sort of soft framework to the connective tissue, and are remarkable for their great resistance both to putrefaction and to chemical reagents.

Mucins are present both in the mucous layer and in the substance which cements the fibrils into fibre-bundles. The nature of this interfibrillar substance, called coriin by Reimer, has been much disputed. Rollet,[1] who first studied it, considered it of a mucous nature, but Reimer [2] claimed that it differed from mucins, and was a hydrolysis-product of the fibres themselves. Körner [3] held a similar view, taking it to be collagen rendered more soluble in alkalis by swelling and hydration. Both Halliburton [4] and Van Lier,[5] on the contrary, favour its mucin character, and the latter names it coriomucoid (in distinction from tendo-mucoid).

The mucins are easily soluble in even dilute alkaline solutions, and are dissolved during the process of liming, allowing the epidermis to be mechanically removed and isolating the fibrils.

Fats.—A distinction must be made between those of the *epidermis*, which are largely unsaponifiable, and consist mainly of cholesterols and liquid waxes; and those of the fat-cells of the *corium*, which are almost entirely triglycerides like most ordinary fats. The former exist not only as products of the sebaceous glands (wool-fat, &c.), but are combined with the keratins, rendering the *epidermis* more resistant, and thus fulfilling a similar function to the waxes in plants (Liebreich [1]). The fats of the *corium*, like those of the body, vary in composition, and especially in the proportion of olein to stearin and palmitin, with the age, sex, and food of the animal, but are usually of lower melting-point than the corresponding internal fats. They are liquid during life but in warm blooded animals solidify after death.

Fresh hides and skins contain 50–70 p.c. of water of which the larger proportion is in the *corium*, and the total is highest in young animals. In the adipose tissue below the skin, the proportions of fat and water are approximately equal.

Hides and skins reach the tanner in various states. Most of those from animals killed in this country are either fresh or very slightly salted, but those from greater distances are treated in various ways to preserve them. Perhaps the simplest and best is the use of salt, either sprinkled on the flesh side repeatedly, or used in the form of brine. In this way most European hides, and many of those from North and South America, are cured. In countries remote from the sea, hides are frequently first salted and then dried, so as to save weight in carriage, and at the same time to preserve them better. This is called 'drysalting.' A still commoner method, especially where salt is scarce and costly, is simply to dry the hide or skin either by hanging in the shade or by stretching on the ground in the sun. Many hides from Texas and Central and South America are thus treated, as well as smaller skins from more temperate countries. The hides of the small cattle of India, called 'kips,' are dried and then plastered on the flesh side with a mixture of a sölute saline earth containing sodium sulphate and water, to preserve, and incidentally, to weight them. Sometimes a portion of arsenic is used to prevent the ravages of insects. It has been proposed in Germany to substitute sodium sulphate for common salt in the curing of skins, both on account of the tax on salt, and because the former retains water, and consequently increases the weight of the hide. The advantage of this to the tanner does not seem obvious. In Russia and other cold climates, hides are sometimes preserved by freezing.

Preparation of hides for tanning.—Preliminary to any other treatment, it is necessary to soften hides and skins, and to free them from blood and dirt. When fresh, a few hours, or at most a day or so in one or two changes of fresh water is sufficient to accomplish this; and for sole leather the cleansing does not need to be so thorough as for the finer sorts, whilst too long soaking is apt to lead to incipient decomposition, and to yield a soft and light-weighing product. Where goods are salted, a much more thorough washing is desirable, and it is advisable to give three or four changes of water to remove the salt as rapidly as possible, and to swell the tissue, which is more or less dehydrated by salting.

When hides have been dried, a mere soaking is in most cases insufficient to produce complete softening, and in addition mechanical and chemical means have to be employed. Eitner has pointed out that the higher the temperature at which the original desiccation took place the greater is the difficulty of softening; calfskin which has been dried at 60° refusing to soften sufficiently for tanning either by soaking or mechanical means. This is analogous to the fact that gelatin dried at 130° becomes insoluble even in boiling water. For thin skins, such as calf or sheep, dried in the open air in temperate climates, a simple soaking of some days in cold fresh water, assisted by working over the beam with a blunt knife, is enough. On the other hand, for the sun-dried kips of India or the heavy ox hides of Texas and South and Central America, such treatment would be quite ineffectual, and the method was formerly adopted in this country of soaking for 2 or 3 weeks in water, which being seldom changed and highly charged with organic matter from previous parcels of hides, was in a state of active putrefaction. Such soaks will soften much more rapidly than fresh water, and are effectual where even prolonged treatment with it would fail. In India, hides are softened by the native tanners within 24 hours, by plunging them into pools in which all the refuse of the tannery is allowed to collect and putrefy. It has, however, come to be recognised by observant tanners that this putrid soaking is very dangerous and unsatisfactory, especially where the hides are destined for sole leather, since it has always a destructive effect on the tissue, and it is found that a much more rapid and satisfactory softening may be effected by the use of very dilute solutions of sodium hydroxide, or sodium sulphide, or of weak organic acids. When the hides or kips were so far softened that they could be bent sharply without danger of breaking the fibre, they were worked in the 'stocks' or 'hide-mill,' which is a machine in which two large hammers or plungers work the hides with a sort of kneading action, but this violent treatment has been rendered unnecessary by the chemical treatment, and at most a drumming with warm or tepid water in a rotating 'tumbler' like an immense barrel-churn is all that is needed. A machine in use on the Continent for the same purpose consists of two rollers studded with rounded pegs, or of which one is grooved and the other pegged. The hides are passed back and forwards between these, and undergo a sort of kneading action. A solution of sulphurous acid of about N/20 strength followed by cold water, has also been successfully used, and from its antiseptic effect, seems particularly suited for hot climates. When the hides or skins are thoroughly softened they are ready for depilation.

Depilation.—With a few exceptions, which scarcely come properly under the head of

---

'leather,' it is necessary to remove the hair preparatory to the tanning process. Probably the oldest way of doing this is by putrefaction, or as it is technically called, 'sweating.' This was formerly accomplished by leaving the hides or skins, folded or laid together, in a warm and moist place, till the destruction of the *epidermis* liberated the hair. But though the *corium* was somewhat more resistant to putrefaction than the mucous layer of the *epidermis*, the putrefactive change frequently spread into it, and injured at least its surface. This simple form of sweating may now be considered obsolete, and where putrefaction is still employed, it is by what is known as 'cold sweating,' which, though little used in England, is still employed in America in the treatment of dried hides. In this method the hides are suspended from tenterhooks in well-ventilated chambers, usually almost buried in soil or spent tan, so as to maintain an equable temperature (which is generally somewhere between 15° and 20°, the higher the more rapid being the action). The air is kept saturated with moisture, and the temperature regulated by admitting steam under a false bottom, or a spray of water from pipes provided for the purpose. The hides, which if dried must previously have been thoroughly softened, are ready for unhairing in 3–7 days, and during the latter part of the time must be examined from hour to hour, and, as soon as the hair is loosened, taken down and placed in piles on the floor. As the thick parts take longer to unhair than the thinner, and the process proceeds more rapidly at the top than the bottom of the chamber, the position of the hides must be altered as the action progresses. When the hair is fully loosened, it is removed either by scraping with a blunt two-handled knife on a sloping 'beam,' or by fulling with stocks. Some American tanners now give a light liming before unhairing to slightly plump the goods and check the decomposition. A similar process is largely employed in Europe for unwoolling sheepskins; in this case to avoid the injurious effect of lime upon the wool. The process is not wholly bacteriological, since ammonia, which is largely evolved, acts as a caustic alkali on the epidermis and is itself capable of loosening the hair without putrefaction.

In England, both for sole and dressing goods, the hair is almost universally loosened by the use of lime. The pits are usually, though by no means invariably, worked in sets of three, of which one is old and nearly exhausted, the second fairly good, and the third freshly made or strengthened. The duration of the process is very variable, ranging from 4 or 5 to 14 days or more, and the quantity of lime used is yet more indefinite, being variously stated at from 1 lb. to 12 lbs. per hide. The fact is, that, lime being very scantily soluble in water, any quantity beyond that required to maintain a saturated solution has but little effect. Lime is only soluble to the extent of about 1¼ oz. per cubic foot, but of course is continuously absorbed by the hide, so that an excess is required which may be less the more often the hides are moved and brought in contact with fresh portions of the lime liquor. Hides lime well and rapidly, suspended from frames in pits, especially if rocked or frequently shaken, and in any case the more frequently they are moved, the better and more uniform is the action; mechanical motion is largely in use on the Continent, and to a limited extent in England. In America, the hides are usually tied together by the shanks and wound from one pit to another over a 'reel' or skeleton drum, turned by hand or power. The old lime liquors become charged with ammonia and organic products from the hides, which materially modify their action, rendering more lime soluble, but diminishing its plumping effect. One result of this is that hides unhair more readily out of a somewhat old lime than they do out of one freshly made, and a change from an old into a newer and stronger lime sometimes actually sets the hair firmer at first, by plumping the tissue and so grasping the root-bulbs. Experiments seem indeed to render it probable, however, that lime alone in the complete absence of putrefaction, will not loosen the hair in any reasonable time. If hides be limed for 1 to 4 days in a sharp new lime in which they are frequently drawn, and are then transferred into a pit of water maintained at a temperature of 40°–50° for some hours, they will part readily with their hair, and at the same time be to a considerable extent freed from lime. This plan, which is of American origin, and is sometimes called the Buffalo method, may be highly recommended for sole leather, giving good weight and colour and a firm solid texture. Of course, the relative amount of liming and hot water may be varied to a considerable extent.

Unhairing may also be hastened by warming the limes themselves. The heat increases the solvent power of the lime, but at the same time checks the plumping, and the tendency is to produce a soft and porous leather. Hence the method is ill adapted for sole, and even for dressing leather is undesirable, since the same effects are obtained better in other ways.

It has naturally been proposed to substitute the caustic alkalis for lime, and it is probable that it might be done in some cases with advantage, or at any rate that small quantities might be added to the limes to hasten their action; but so far their use has not found much favour with tanners, except as constituents of such secret preparations as 'Inoffensive.' One cause of this is probably that from their easy solubility and powerful action, great care is required, and where used by 'rule of thumb,' serious injury is readily done to large quantities of costly raw material. It is one of the virtues of lime that, from its very limited solubility, it is almost impossible to destroy a pack of hides by its use, and the injury which it does when carelessly handled is often attributed to other causes. Naturally it might be thought that the alkalis would be easily removed from the hide by simple washing, and that the solubility of their soaps would favour the removal of grease; but it is found that alkalis form a sort of compound with hide-fibre, from which they can scarcely be removed until they have first been neutralised with acid, while practically the grease is not saponified but merely emulsified, and for this purpose lime answers just as well as a stronger alkali.

In liming sole leather the principal object is to enable the hair to be removed and to free the hide from grease with as little solution of its fibrous structure as possible. The English tanner frequently desires also to raise or swell the hide, and so to split up the fibrous bundles into their constituent fibrils as to prepare it for tanning, though this may also be done by the presence of acid in the earlier tanning liquors, or in some cases by the direct use of an acid bath. It is a question on which there has been much difference of opinion whether the unhairing is best accomplished by the use of strong fresh limes for a short time, or of old limes charged with ammonia for a longer period. It is now, however, generally recognised that the continued action of old limes is too dangerous, usually injuring the grain surface of the hide or skin, and the compromise is usually adopted of beginning the process in the older limes and finishing in fresh ones. It is very dangerous in hot weather to let limes get too stale and loaded with organic matter, as in this case even the presence of caustic lime does not prevent putrefaction, which is fatal to the manufacture of plump and solid leather. In fact, by microscopic examination of such stale limes it is easy to detect the presence of active bacteria. It is a mistake to suppose that such limes are 'weak,' since the excess of lime is always sufficient to maintain them as saturated solutions, and in addition they contain much dissolved lime as organic salts, and considerable quantities of ammonia and bacterial enzymes, which, though they prevent swelling, assist in the solution of the hide. If in any case the liming is too low, it will be impossible to eradicate grease from the hides of very fat cattle, although the leather may be of excellent quality. In the manufacture of dressing leather a somewhat more thorough liming is generally desirable, since it is not only required to remove the hair but to dissolve a proportion of the cementing matter of the fibrous tissue, and so render the leather softer and more pliable. This is especially true in the manufacture of glove or 'glacé' kid and lamb leather, in which the property of stretching in any direction is largely dependent on a proper liming. In the continental manufacture of these goods it is customary to 'sharpen' the limes by the addition of realgar (arsenic sulphide). This produces, with the lime, calcium hydrosulphide, sulpharsenate, and some metallic arsenic, and considerably hastens the unhairing. The hydrosulphide seems to be the active agent, V. Schroeder and Delimitz-Dumont (Dingl. poly. J. 1896) having shown that the arsenic compounds are inoperative and not even antiseptic; and, many years since, the desirability of finding a substitute for the very poisonous red arsenic led Böttger to propose the use of calcium hydrosulphide, prepared directly by passing sulphuretted hydrogen into milk of lime. This produces a paste which is greenish from the presence of traces of iron sulphide, and which acts as a rapid depilatory, and if applied as a paste on the hair-side will in a few hours reduce the hair to a pulp, whilst from the rapidity of the action, the hair bulbs and the various glands are much less affected than with an ordinary liming. Mixed with lime in smaller proportion and used in pits in the ordinary way, it loosens the hair rapidly without actually destroying it, principally by attacking the mucous layer, since the harder part of the epidermis frequently comes off with the hair roots in it in sheets of considerable size. Unfortunately for its use in practice, for which otherwise it is excellently fitted, it keeps very badly, and must be freshly made as required which is both costly and troublesome. A concentrated solution of calcium hydrosulphide was formerly produced by the Washington Chemical Company, and promised to be a valuable depilatory; but unfortunately its manufacture proved unremunerative. Gas-lime, which often contains a considerable quantity of calcium hydrosulphide, has been used as a substitute, but is too uncertain in its composition to be satisfactory, and has been almost superseded as a gas-purifying agent by oxide of iron. None of these disadvantages attends the use of sodium sulphide, which has been strongly advocated by Eitner, a director of the Austrian Government Research Institute at Vienna, to whom the leather trade probably owes much of its impulse to scientific improvement. It is now manufactured commercially, in a crystallised form; it keeps well and possesses great depilatory powers, both alone and in union with lime, with which it forms calcium hydrosulphide and caustic soda. A paste containing 2–4 lbs. to the gallon of water, and thickened with lime to a soupy consistence, will, if painted on the hair side of a hide, completely destroy the hair in a few hours, so that it may be swept off with a stiff brush. This mode of proceeding has been much recommended for sole leather, and it makes a firm and solid article, but the difficulty of getting it so thoroughly brushed into the hair that it will destroy every part of it, is very considerable, while, if any part has been missed, the short hair is very difficult to remove. For this reason, and because it leaves all the hair-roots and glands in the skin and so prevents a clean buff, it is only suitable for very common classes of leather, though it will do good service on dried hides instead of the cold sweat. Such a paste is also much used for unwooling sheepskins, being in this case applied to the flesh side and allowed to penetrate the skin. Used in pits with lime to the extent of $\frac{1}{4}$–$\frac{1}{2}$ lb. per hide, sodium sulphide does not materially injure the hair, while it quickens the unhairing and yields good weight and excellent quality; but it must be borne in mind that sulphides do not swell the hide so much as caustic alkalis, so that the after process of tanning must be so arranged as to get the plumping in the liquors. Where plumpness is not desirable, but a tough, solid texture is required, as in some descriptions of light leathers, its use would promise special advantages. Since sodium sulphide, however, dissociates in solution to sodium hydrosulphide and sodium hydroxide, the effect of the latter leads to more swelling of the grain than is desired, and it is found that this may be lessened by the addition of an equivalent quantity of calcium chloride which substitutes calcium hydroxide for sodium hydroxide with formation of common salt.

The total soda existing in commercial sodium sulphide as sulphide, carbonate or hydroxide may be determined with standard acid, using methyl-orange as an indicator, since this colour is quite unaffected by the presence of either hydrogen sulphide or carbon dioxide. The sulphur is advantageously estimated by ammoniacal zinc solution, using alkaline lead tartrate as an indicator by placing drops of it and of the solution being tested near each other on filter paper. Solutions containing sodium sulphide together with dissolved sulphur and polysulphides obtained by boiling sulphur with caustic soda or soda ash and lime possess considerable depilatory power, but it is not easy to determine the amount of available sulphur. Somewhat similar solutions are obtained by forcing air through the 'tank waste' of alkali works, suspended in water, or, naturally, in the 'bog-liquor,' which in some works drains from the waste-heaps, and where these can be cheaply obtained, they may in some cases be used advantageously.

Examination of lime liquors.—Considerable information may often be obtained by a simple examination of lime liquors. Free ammonia may be determined by rapid distillation of, say, 30 c.c. of the filtered liquor, preferably with the addition of a little magnesium sulphate to remove caustic lime. The ammonia is absorbed in a measured quantity of standard acid which is titrated back with caustic alkali. If it be desired to estimate free lime in the same sample, the magnesium sulphate must be omitted, which, if the distillation is short, does not lead to serious error. The sample should be drawn from the middle of a lime pit well plunged up, and rapidly filtered in a funnel covered with a clock-glass.

The caustic lime in the portion from which the ammonia has been withdrawn may now be estimated with normal or decinormal acid, using phenolphthalein, and the total lime (and any other alkalis present) existing in a free state or in combination with organic matter and weak organic acids with methyl orange or red as an indicator. Litmus is unsuitable for the purpose from the presence of these weak organic acids, which render its end-reaction quite indefinite, but do not affect methyl-orange so much. For the same reason this indicator will be found very useful for many determinations required in a tannery. Phenolphthalein cannot be accurately used in presence of ammonia. An estimate of the organic matter present is obtained by evaporating 50 c.c. of the filtered liquor to dryness in the water-oven in a platinum crucible, weighing, and then igniting and estimating by loss. This method can of course lay no claims to strict accuracy, but is sufficient to give valuable information as to the condition of the liquor; and, if a uniform course of liming be adopted, as to the amount of matter dissolved out of the hides in the process, or the comparative quantities by different liming methods. For more accurate work the liquor may be evaporated to dryness or very small bulk in a flask with the addition of a little excess of sulphuric acid to retain ammonia, and the nitrogen estimated by Kjeldahl's method. It is easy to calculate very approximately the amount of matter which the nitrogen represents, since both the gelatinous and horny tissues contain about 17·5–18 p.c. of nitrogen.

Bateing and drenching.—If lime or other alkalis have been used in depilation, they must be removed before tanning, and in sole leather it is desired to do this with as little loss of pelt as possible. Formerly a mere suspension in water was considered sufficient, and when the water is hard, a little lime was added to remove the free carbonic acid and calcium hydrogen carbonate present, which would form insoluble carbonate with the lime contained in the hide, and afterwards by combining with tannin would produce bad coloured leather. A further cleansing may be effected by 'scudding,' or working the grain-side with a blunt knife on a beam, which expresses much of the *débris* of hair-roots and fat glands, as well as lime. When a clean buff is desired this precaution should never be omitted.

It is, however, impossible really to remove the whole of the lime by soaking in water, since it forms a sort of loose compound with the fibrous tissue, from which it can only be dislodged by the aid of acids, and at present, even for sole leather, acids are usually employed after removal of as much lime as possible by washing in 'softened' water.

Very dilute sulphuric acid will perform the service satisfactorily, although great care has to be used to keep the hides in constant motion, to add the acid in small successive doses as it is absorbed by the hides, and to avoid even a small excess. Some trouble is often experienced in the use of commercial acids from the precipitation of the iron which they contain as an impurity on the fibre of the hide, where it subsequently produces stains by combining with the tannin. The ammoniacal salts of the stronger acids may also be used, but boric, formic, acetic, lactic, and other organic acids are generally employed in solutions not exceeding about N/20 strength. For sole purposes, hydrochloric acid should be avoided, as the chlorides have a great effect in preventing the plumping of the hide which is so desirable in this class of leather. Instead of actually removing the lime it might be sufficient in many cases to convert it into a neutral and insoluble form, as, for instance, by the action of acid or neutral phosphates, oxalates, or arsenates. Some of the sulphonic acids of various coal-tar products have also been tried for the purpose with some success; and they are, at the same time, powerful antiseptics.

In the case of most light leathers where softness is aimed at, it is found necessary to use, either alone or as a supplement to some process of removing the lime, a putrefactive or fermenting bate, which has the effect of reducing ('abateing') the plumpness of the hide, and at the same time of softening it by attacking the fibrous tissue. Either an infusion of dung (pigeons', hens,' or dogs') called *bate* or *puer* (the latter probably having some connection with the French *puant*), or of bran (drench), and frequently both, are used successively. Probably the putrefactive organisms themselves or their products are active agents of the process, and the problem has been partially solved by Wood in England, and by Popp and Becker in Germany, who have introduced an artificial puer under the name of 'erodin,' consisting of a suitable culture of selected bacteria and a dry powder which when dissolved in water forms a suitable nutritive fluid for their rapid multiplication.

Dr. Röhm, following up an experiment of Wood's, has also introduced under the name of 'Oropon,' a mixture of ammonium chloride with a small quantity of the pancreatic ferment, which, for some of the finer leathers, has been very successful.

In the preparation of 'shaved' and 'dressing' hides, a bate may contain about 1 peck of hen or pigeon dung to 25 or 30 hides, in which they are handled frequently for 3–7 days. This time may be much shortened by warming the bate and working the goods with a drum or paddle tumbler. The latter consists of a tank or pit, generally having a curved bottom to favour the motion of the liquid, and agitated by a paddle-wheel with 6–8 floats. A short 'stocking' out of the bate is also sometimes employed. Tumbling with warm water before bateing will wash out a good deal of lime and reduce the plumpness, and so save both time and material; and French tanners make excellent shaved hides and calf-skins without bateing by careful working at the beam, long washing with cold water (during which probably a slight putrefactive action takes place), and the use of weak and stale liquors. Shaved hides are so called because, after the bateing, the thicker parts of the butt are reduced by shaving on an upright beam with a currier's knife having a turned edge.

Still lighter and more flexible sorts of leather, such as morocco and kid, are usually puered with fermented dog-dung, infused in hot water, and strained through a basket. This is frequently followed, after scudding, by a drench made by pouring boiling water on bran, and allowing to ferment. In this case, lactic acid is the most active product, although its plumping action is controlled by some putrefactive fermentation going on at the same time. Wood (J. Soc. Chem. Ind. 9, 27) has shown that starch is destroyed by the active ferment, and considerable quantities of methane evolved. In hot and thundery weather the lactic ferment is liable to be replaced by another, partially the butyric, when the skins plump rapidly and become transparent, and are finally perforated or dissolved. The best precautions are to scald out the tubs thoroughly, and to wash the bran before using with cold water to remove the flour, which furnishes the nourishment required by the butyric ferment.

In the brief space available it is impossible to give more detail as to these preparatory processes, which are, however, of the first importance from a practical point of view. From the scientific aspect, it must be noted that the plumping and 'falling' which the fibrous tissue suffers through the action of various reagents, is closely connected with osmosis, and is at least as much a physical as a chemical phenomenon.

Tanning materials. Before speaking of the actual tanning process, a few words must be said about the chemistry of the vegetable products on which the operation depends.

The tannins, or tannic acids, are widely distributed through the vegetable kingdom, and form a large and varied class, differing considerably in chemical constitution as well as in properties. The one point which they all have in common is the power of precipitating gelatin from its solution as an insoluble compound. They are also all derivatives of the aromatic series of carbon compounds, and, so far as is known, all contain either pyrocatechol $C_6H_4(OH)_2$ or pyrogallol $C_6H_3(OH)_3$, and sometimes the isomeride of the latter, phloroglucinol. This difference usually corresponds to well-marked differences in constitution. As a rule, the pyrogallol tannins give a blue-black with ferric salts, and a whitish deposit on the surface of the leather, well known to the tanner as 'bloom'; whilst the pyrocatechol derivatives give a greenish black, and deposit red insoluble matters, probably anhydrides of the tannins. All catechol tannins give insoluble precipitates with bromine water, and with formaldehydes in presence of hydrochloric acid. Oak bark occupies an intermediate position, yielding both bloom and reds, and apparently containing both pyrogallol and pyrocatechol. In such cases, however, it is not very certain whether we have to deal with a complicated tannin or with a mixture of two dissimilar ones, since tannins, being neither crystallisable nor volatile, are very difficult to separate. It is known that many of the bloom-yielding materials, such as myrobalans, contain gallotannic acid, which yields no bloom, and ellagitannic acid, which yields a copious bloom of ellagic acid.

It is, of course, only the pyrogallol tannins which yield gallic acid as a decomposition product, while the pyrocatechol tannins contain the corresponding protocatechuic acid. Many of the pyrogallol tannins yield glucose on decomposition, but in the pyrocatechol class it seems to be absent.

A complete list of tannin-yielding plants would embrace a large part of the vegetable kingdom, but the following are those in most extensive practical use. (*Cf.* art. TANNINS.)

Oak bark is one of the oldest and best of tanning materials, producing excellent but not heavy leather; and, from its comparative weakness in tannin (8–12 p.c.) its action is somewhat slow. It yields a good deal of whitish bloom.

Valonia, the acorn cup of the *Quercus Ægilops* (Linn.) and *Q. Macrolepis* (Kotschy), contains up to 35 p.c. of a tannin very similar to that of oak bark, but giving more bloom and a darker colour, and at the same time a heavier leather.

Myrobalans, the fruit of *Terminalia Chebula* (Ratz.) (India), contains 25–35 p.c. of gallotannic and ellagitannic acids, and, consequently, blooms freely. It gives good colour and fair weight, and though alone it yields a porous and soft leather, it is very useful in mixture with dark coloured materials, such as hemlock extract, for sole leather, and as a cheaper substitute for sumach, on the lighter descriptions.

Divi-divi, pod of *Cæsalpinia coriaria* (Willd.) (S. America), contains 30–50 p.c. of a tannin somewhat similar in effect to that of valonia. It produces a heavy-weighing leather, but is dangerously liable to a sudden fermentation, which produces a deep-red stain on all leather in contact with it.

Sumach, the pulverised leaves of *Rhus Coriaria* (Linn.), &c. (Sicily), yields 20–30 p.c. of tannins very similar to those of myrobalans, but paler in colour. It is principally used for light leathers, though warm sumach liquor is used to brighten the colour of heavy tannages. There are also several American species used for tanning.

Mimosa bark, the product of several species of *Acacia*, principally Australian, contains 20–40 p.c. of a red tannin derived from pyrocatechol, and yielding no bloom, but giving considerable weight and firmness to the leather. An extract has recently been introduced into commerce. Babool bark from *Acacia arabica* (Willd.) is one of the principal tanning materials of India (*A. Catechu* (Willd.) and *A. Catechu* var. *Sundra*, see below).

Cassia auriculata (Linn.), Turwar or Tanghadi bark, from a leguminous bush allied to senna, is the principal tanning material for sheep and goat skins (so called ‘persians’) in Southern India.

Hemlock bark, known in this country principally in the form of extract, is produced by the hemlock pine, *Tsuga* [*Abies*] *Canadensis*, (Carr.) of North America. The bark contains 8–10 p.c., and the extract 20–30 p.c. of a tannin similar to that of mimosa, but giving a larger proportion of red anhydrides, and consequently a heavier leather, but at the same time one of a still more pronounced colour, which is less easily modified by other agents. It is the staple tanning agent of North America.

Gambier (*Terra Japonica*), pale catechu, an inspissated extract from the leaves of *Uncaria Gambier* (Roxb.) of the East Indies, contains 30–40 p.c. of a peculiar catechol tannin, which penetrates leather rapidly, but has less astringency and adhesion to the hide fibre than most other tannins. These properties make it very valuable in certain stages of the tanning process, although alone it produces a leather of very inferior quality. Cutch (dark catechu), though somewhat similar in its chemical relations, is a very different product practically, and is derived from the wood of *Acacia Catechu* (Willd.) and *A. Catechu* var. *Sundra*, and, consequently, more allied to the mimosa bark, which has already been described. Gambier comes to this country in blocks of about 2 cwt., covered with mat and pasty in the centre, and also in cubes of about an inch square, which are much purer, and internally are quite white with crystals of catechin. Cutch comes in masses of a glossy dark-brown fracture, and is principally used for dyeing.

Quebracho wood from *Quebrachia Lorentzii*, (Griseb.), a large tree of South America, and especially of the Argentine Republic, contains about 20 p.c. of rather difficultly soluble catechol tannin, principally used as extracts which are often decolorised and rendered soluble with bisulphites.

Mangrove barks from various species of *Ceriops* and *Rhizophora*. Extracts principally manufactured in East Indies. Barks vary a good deal in strength but may contain up to 40 p.c. of a dark red but fairly soluble catechol tannin.

Mallet bark from *Eucalyptus occidentalis* (Endl.) or ‘flat-topped yate’ of Western Australia. Rich in a brown catechol tannin producing rather hard leather if used alone.

Ulmo bark, said to be from *Eucryphia cordifolia* (Cav.) of Chile, produces a dark red extract strongly resembling mangrove.

Exhaustion of tanning materials.—Most tanning materials require to be ground before lixiviating. This is accomplished either by a mill, on the principle of the ordinary coffee mill, with grooved iron or steel cones, or by one of the numerous forms of ‘disintegrator,’ in which the grinding is done by dashing the material against a serrated or grated casing, by beaters revolving 2000 or 3000 times a minute. Valonia and myrobalans are frequently crushed between fluted or toothed steel rollers. The grinding should not be so fine as to render percolation difficult. The actual exhaustion takes place in this country mostly in large square sunken vats, constructed like the other pits of the tannery and worked in series, the liquors being either pumped from one to the other or allowed to run through wooden boxes, connecting the space below the perforated ‘false bottom’ of one pit with the top of the next. In America the ‘leaches,’ as the extracting vessels are called, are usually immense circular tubs, fitted with perforated ‘false bottoms’ and heated by steam coils. These are generally employed in groups of 6 or 8, water or weak liquor being run on the most nearly exhausted, and forced or pumped round the series to the newest and strongest vat. Hot extraction is more rapid than cold, and usually more complete, but the liquor is darker in colour, and contains more non-tanning matters, and the question of temperature must be decided by the particular material and conditions, some tannins being decomposed at temperatures which are not injurious to others.[1]

Tanning extracts now form an important portion of the materials used by the tanner, and in many cases render available materials which from their bulk and low percentage, or their remote origin, would not pay for transit, or yield sufficiently concentrated liquors for modern requirements. Among those of leading importance may be mentioned those of the woods of oak, chestnut, and quebracho, and of the barks of mangrove and hemlock pine. Valonia, myrobalans, and sumach are also extracted. The materials are prepared and extracted as above described, woods being previously reduced to chips or shavings by machines similar to those employed for dyewoods, and heat, occasionally under pressure, being freely used in extraction, especially with the weaker materials, such as oakwood, which only contains 2–3 p.c. of tannins. When this is done, decolorising methods are frequently employed to remove the dark and difficultly soluble matters dissolved by heating; the most approved method being partial precipitation by blood or blood-albumen, dissolved in the warm infusion, which is then heated beyond the coagulation temperature. Metallic precipitants are also sometimes used, and sulphurous acid and bisulphites, not merely as bleaching agents, but to render the phlobaphenes and ‘reds’ more soluble. A so-called ‘pinewood extract’ is on the market, made by concentration of the sulphite liquors of cellulose manufacture, which analyses well, but contains no true tannin and is used mainly as an adulterant. After settling or filtering the decolorised liquors, they are concentrated in the vacuum pan to 50–60 p.c. of water for liquid extracts and 20–25 p.c. for those intended to solidify, the Yaryan evaporator being largely used for concentration up to about 20Bé.

Imperfect exhaustion is one of the most serious sources of waste in tanning, and the residues deserve more careful testing than is usually given to them.

Quantitative determination of tannins.—Many methods have been proposed for the

---

[1] J. Soc. Chem. Ind. 1895, 635; 1898, 116.

purpose, several of which are capable of application under special conditions, but the only two that have stood the test of general practical work, and are valuable for different purposes, are the hide-powder method, which is the gradual development of the work of several chemists, among whom Simand may be specially mentioned, and the permanganate and indigo process of Löwenthal.

The first of these permits an actual gravimetric determination of the matters absorbable by hide, but these include colouring matters, acids, and other substances not strictly tannins. It has been found that the absorption of these matters is lessened by a light preliminary chroming of the hide-powder, and it must also be remembered that the method is purely empirical, and must therefore be carried out with absolute adherence to the smallest details if comparable results are to be obtained.

The following is the method of the International Association of Leather Trades Chemists, which is the official standard in Europe and only differs in minor details from that of the American Leather Chemists' Association.

Preparation of infusion.—Such a quantity of material shall be employed as will give a solution containing as nearly as possible 4 grams of tanning matter per litre, and not less than 3·5 or more than 4·5 grams. Liquid extracts shall be weighed in a basin or beaker and washed with boiling distilled water into a litre flask, filled up to the mark with boiling water, and well mixed, and rapidly cooled to a temperature of 17·5°, after which it shall be accurately made up to the mark, again well mixed, and filtration at once proceeded with. Sumach and myrobalans extracts should be dissolved at a lower temperature.

Solid extracts shall be dissolved by stirring in a beaker with successive quantities of boiling water, the dissolved portions being poured into a litre flask, and the undissolved being allowed to settle and treated with further portions of boiling water. After the whole of the soluble matter is dissolved the solution is treated similarly to that of a liquid extract.

Solid tanning materials previously ground till they will pass through a sieve of 5 wires per centimetre, are extracted in Koch's or Procter's extractor with 500 c.c. of water at a temperature not exceeding 50° and the extraction continued with boiling water till the filtrate amounts to 1 litre. It is desirable to allow the material to soak for some hours before commencing the percolation which should occupy not less than 3 hours, so as to extract the maximum of tannin. Any remaining solubles in the material must be neglected, or reported separately as 'difficultly soluble' substances. The volume of liquid in the flask must be made up accurately to 1 litre after cooling.

The *total solids* must be determined by drying a weighed portion of the material, or a measured portion of its uniform turbid solution at a temperature between 98·5° and 100° in shallow flat-bottomed basins, which shall afterwards be dried till constant at the same temperature, and cooled before weighing for not less than 20 minutes in an air-tight desiccator over dry calcium chloride. *Moisture* is the difference between 100 and the percentage of total solids, and *insolubles* the difference between the *total solids* and *total solubles.*

Filtration.—The infusion shall be filtered till optically clear (see below). No correction for absorption is needed for the Berkefeld candle, or for S. & S. 590 paper if a sufficient quantity (250—300 c.c.) is rejected before measuring the quantity for evaporation; and the solution may be passed through repeatedly to obtain a clear filtrate. If other methods of filtration are employed the average correction necessary must be determined in the following manner. About 500 c.c. of the same or a similar tanning solution is filtered perfectly clear, and after thorough mixing 50 c.c. is evaporated to determine 'total soluble No. 1.' The remainder is now filtered in the exact method for which the correction is required (time of contact and volume rejected being kept as constant as possible), and 50 c.c. is evaporated to determine 'total soluble No. 2.' The difference between No. 1 and No. 2 is the correction sought, which must be added to the weight of the total solubles found in analysis. An alternative method of determining correction, which is equally accurate and often more convenient, is to filter a portion of the tanning solution through the Berkefeld candle till optically clear, which can generally be accomplished by rejecting 300 or 400 c.c. and returning the remaining filtrate repeatedly; and at the same time to evaporate 50 c.c. of clear filtrate obtained by the method for which correction is required, when the difference between the residues will be the correction sought.

(Note.—It is obvious that an average correction must be obtained from at least 5 determinations. It will be found that this is approximately constant for all materials, and amounts in the case of S. & S. 605, 150 c.c. being rejected, to about 5 mgr. per 50 c.c. and where 2 grams of kaolin are employed in addition, to 7½ mgr. The kaolin must be previously washed with 75 c.c. of the same liquor, which is allowed to stand 15 minutes and then poured off. Paper 605 has a special absorption for a yellow colouring matter often contained in sulphited extracts.)

The *total solubles* must be determined by the evaporation of a measured quantity of the solution previously filtered till optically clear both by reflected and transmitted light; that is, a bright object such as an electric light filament must be distinctly visible through at least 5 cm. thickness and a layer of 1 cm. deep in a beaker placed in a good light on black glass or black glazed paper must appear dark and free from opalescence when viewed from above.

Hide-powder shall be of woolly texture, thoroughly delimed, preferably with hydrochloric acid, and shall not require more than 5 c.c. or less than 2·5 c.c. of N/10 NaOH or KOH to produce a permanent pink with phenolphthalein on 6½ grams of the dry powder suspended in water. If the acidity does not fall within these limits, it must be corrected by soaking the powder before chroming for 20 minutes in 10–12 times its weight of water to which the requisite calculated quantity of standard alkali or acid has been added. The hide-powder must not swell in chroming to such an extent as to render difficult the necessary squeezing to 70–75 p.c. of water, and must be sufficiently free from soluble organic matter to render it possible in the ordinary washing to reduce the total solubles in a blank experiment with distilled water below 5 mgr. per 100 c.c. The powder when sent out from the makers shall not contain more than 12 p.c. of moisture, and shall be sent out in air-tight tins.

The detannisation shall be carried out in the following manner :—

The moisture in the air-dried powder is determined and the quantity equal to 6·5 grams actual dry hide-powder is calculated, which will be practically constant if the powder be kept in an air-tight vessel. Any multiple of this quantity is taken according to the number of analyses to be made, and moistened with approximately ten times its weight of distilled water.[1] ·2 grams per hundred of dry powder of crystallised chromic chloride $CrCl_3,6H_2O$ [2] is now dissolved in water and made basic with 0·6 gram Na_2CO_3 by the gradual addition of 11·25 c.c. of N/1 solution, thus making the salt correspond to the formula $Cr_2Cl_3(OH)_3$. This solution is added to the powder and the whole churned slowly for 1 hour. In laboratories when analyses are frequently made it is more convenient to use a 10 p.c. stock solution, made by dissolving 100 grams of $CrCl_3,6H_2O$ in a little distilled water in a litre flask, and very slowly adding a solution containing 30 grams of anhydrous sodium carbonate, with constant stirring, finally making up to mark with distilled water and well mixing. Of this solution, 20 c.c. per 100 grams or 1·3 c.c. per 6 5 grams of dry powder should be used.[3]

At the end of one hour, the powder is squeezed in linen to free it as far as possible from the residual liquor, and washed and squeezed repeatedly with distilled water, until on adding to 50 c.c. of the filtrate, 1 drop of 10 p.c. K_2CrO_4 and 4 drops N/10 $AgNO_3$, a brick red colour appears. Four or five squeezings are usually sufficient. Such a filtrate cannot contain more than 0·001 gram of NaCl in 50 c.c.

The powder is then squeezed to contain 70–75 p.c. water, and the whole weighed. The quantity Q containing 6·5 grams dry hide is thus found, weighed out and added immediately to 100 c.c. of the unfiltered tannin infusion along with (26·5–Q) of distilled water. The whole is corked up and agitated for 15 minutes in a rotating bottle at not less than 60 revolutions per minute. It is then squeezed immediately through linen, stirred and filtered through a folded filter of sufficient size to hold the entire filtrate, returning until clear, and 60 c.c. of the filtrate is evaporated and reckoned as 50 c.c. or the residue of 50 c.c. is multiplied by $\frac{6}{5}$. The non-tannin filtrate must give no turbidity with a drop of a 1 p.c. gelatin 10 p.c. salt solution.

One gram of kaolin free from solubles must be used either by mixing it with the hide-powder in the shaking bottle or with the liquid before filtration.

All evaporation shall be rapidly conducted at steam temperature in shallow, flat-bottomed basins of not less than 6·5 cm. diameter to apparent dryness; and shall be subsequently dried between 98·5° and 100° in a water or steam oven until of constant weight, and shall be afterwards cooled in small air-tight desiccators over dry calcium chloride for at least 20 minutes, and then weighed rapidly. Not more than two basins shall be placed in one desiccator, and the basins must not be wiped after removal from the desiccator. The residue is 'non-tannins.' The difference between these and 'total solubles,' is 'tanning matters.'

The Löwenthal method is volumetric, and, as very much weaker infusions can be employed, a larger quantity of water can be used in extraction, or it may be applied to very weak infusions without concentration. It has gone out of use for commercial analysis, but the comparison of its results with the hide-powder method is sometimes useful in the detection of mixtures in extracts; and as a control method in tanning (*cp.* Procter and Hirst, J. Soc. Chem. Ind. 1909, 294).

The method depends on the oxidation of the tannin by permanganate in presence of excess of sulphonated indigo, which serves both as an indicator and regulator of the reaction.

The indigo solution is made by dissolving 5 grams of pure sodium or potassium indigo-sulphonate (Gehe's *Carminum cœrul. op.* answers well) in a litre of distilled water, adding 50 c.c. of concentrated sulphuric acid and filtering; or a solution of 1 gram 'Indigo pure B. A. S. F.' may be dissolved in 25 c.c. of concentrated sulphuric acid, and made up to 1 litre with water and a further 25 c.c. of acid. Samples which give a brownish instead of a pure yellow solution after oxidation are useless. The solutions keep well, but the weak permanganate is best made up as required, by diluting 100 c.c. of a 5 gram per litre solution to 1 litre.

The titration is best carried out in a beaker of 750–1000 c.c. capacity placed on a white tile; and if many titrations are to be made, should be provided with a screw-vaned stirrer driven by a turbine or other motor; but in any case the stirring must be vigorous and constant. 20–25 c.c. of the indigo solution, according to its strength, and 400 c.c. of good water free from organic impurity are introduced into the beaker, and permanganate solution is added from the burette as rapidly as it can be dropped until near the end-point. Uniformity in stirring and in the rate of dropping is of prime importance.

The colour changes first to green, and then to pure yellow, and as it approaches the latter, the flow must be checked and the last drops added very cautiously. The quantity of permanganate used will be that required to oxidise the indigo. If the process be now repeated with the addition of 5 c.c. of the tannin infusion, the excess required to destroy the blue will correspond to that required to oxidise the astringents added, and must not exceed two-thirds of that required for the indigo alone. A second estimation should not differ from the first by more than 0·1 c.c.; and the results added together will correspond to the total astringents in 10 c.c. of the infusion. But as gallic acid and other bodies always present in tanning materials are oxidised like tannin itself, it is necessary to make a second titration after removing the tannin, and estimate by loss.

---

[1] Very woolly powders require slightly more than 10 times their weight of water. A powder may be considered 'woolly' if it cannot be poured like sand from a beaker.—H.R.P.

[2] 'Chrom-sesquichlorid cryst,' Kahlbaum.

[3] The solution sometimes changes colour slightly by keeping; but this has been shown to have no influence on results.—H.R.P.

For this purpose hide powder, either white or chromed, may be used as in the previously described process, or to 50 c.c. of the liquor 25 c.c. of a fresh 2 p.c. gelatin solution and 25 c.c. of a saturated solution of salt containing 50 c.c. of concentrated sulphuric acid per litre. The mixture is shaken with a teaspoonful of kaolin for 15 minutes, filtered, and 10 c.c. titrated. The results of the gelatin method in the separation of gallic from gallotannic acid are nearly exact, but probably by a compensation of errors.

As it is impossible to obtain *pure* tannins against which to standardise the results, which can only be compared with others obtained by a precisely similar mode of titration, pure recrystallised gallic acid has been found the most convenient and reliable standard, 5 c.c. of a freshly made solution of 0·1 gram per litre being titrated in place of the tannin solution. If it be desired to calculate from gallic acid to the results of the gravimetric method, the following figures may be employed, but it must be remembered that except in the case of gallotannic acid the comparison is not with a chemical individual, and the results only represent an average. 1 gram gallic acid = 1·34 gram gallotannic acid, 1·65 gram of the tanning matter of chestnut wood, 1·89 gram of that of oak wood, 1·73 gram of myrobalan, 1·69 gram of quebracho, and averaging all ordinary materials 1·76 gram. Further details are given by Procter and Hirst (*l.c.*).

Tannage of sole leather. As this is a simple and typical case of vegetable tanning it may be described in some detail. Knapp, in his classical essay on the Nature and Methods of Tanning (Natur und Wesen der Gerberei, Munich, 1858), adduces reasons for believing that leather is not an actual chemical combination of the gelatinous fibres of the hide with tannin, but rather that the action is a surface one in which they are coated with an insoluble matter which protects and makes them resistant to solvents and decay. Though this conclusion is probably not wholly true, it at least describes a reaction which is specially important in the case of sole leather. Whether the actual conversion of hide fibre into leather is the result of a strictly chemical combination, or of the formation of an adsorption compound, its solidification is certainly largely a case of surface action. It has been said that both acids and alkalis swell the fibrous bundles and split them into finer fibrils, so offering a larger surface and more finely divided texture, and to produce a heavy and solid tannage it is found necessary that this should take place either before or during the tanning process. The English sole-leather tanner usually accomplishes it by the action of lime in depilation; the American, who unhairs by sweating, has to secure it by a separate treatment with sulphuric acid, while in other cases where sulphides or low liming are the agents of depilation, it is partly accomplished by these and partly by the organic acids present in the earlier tanning liquors. The avoidance of stale or old limes is important, as they plump badly and cause serious loss of weight, but sodium sulphide is useful as shortening the process. When a hide swollen with lime is brought into tanning liquors the weak acids present rapidly neutralise the alkali, and the hide, previously plump and firm, becomes soft and flaccid and falls in thickness. If little acid is present in proportion to tannin this action takes place very gradually, and the tannin, which penetrates rapidly in the alkaline state of the hide, fixes the fibre in a swollen condition, and a plump rapid tannage is obtained, which, however, is often deficient in colour from the tendency of the lime to form tannates which darken in drying. If, on the other hand, the hide, comparatively freed from lime, is brought into liquors where acid predominates over tannin, the tissue, at first soft and flaccid, swells gradually and combines with the tannin in an acid condition, again producing a plump leather and of good colour, since lime tannates are easily soluble in the acids present. But if, on the other hand, the unswollen hide comes into liquors which have insufficient acid to plump it, or if, having been swollen by lime, it is allowed to fall back as before described, the tannin will fix it in this fallen condition, and it will be impossible afterwards to plump it or to make thick leather.

(The free acid capable of dissolving lime tannate in a liquor is easily determined directly by adding saturated lime-water from a burette to a measured quantity of liquor, till it forms a permanent cloudiness; 10 c.c. of liquor should require from 5 to 15 c.c. Some of the acids which dissolve lime are too weak to produce any perceptible plumping effect on the pelt.)

For common sole and strap leather the first of these methods may be adopted with satisfactory results, though a previous deliming of the surface with weak solutions of boric, acetic, lactic, or some other weak acid is becoming increasingly common. If this is not done the hides or ‘ butts ’ (from which the bellies and shoulders have been trimmed in the beam-house) are simply suspended in lime water to remove the scud and loosely adhering lime, and are then brought into weak liquors, which have already lost most of their strength in previous use, and which may advantageously contain a considerable proportion of gambier, which has the property of penetrating quickly without much contracting or drawing the grain. These liquors should be contained in deep pits in which the hides may be freely suspended, if possible without touching each other, and in which they may be kept in constant motion, at least for the first day, without exposure to the air, which would darken them by oxidising the alkaline tannates. This is best accomplished by suspension from frames to which an oscillating or traversing motion is given by power, but shaking frequently by hand will answer the same purpose. The butts or hides rapidly colour, and must be moved gradually forward into stronger liquors as the grain becomes set. It is difficult at this stage to state the suitable strength of liquor, since the specific gravity of these old liquors depends more on the impurities than on the tannin present, but they may range from 15° to 20° of the barkometer (sp.gr. 1·015–1·020) or even more in mixed tannage, and the liquor should contain no acids strong enough to redden methyl-orange, but should give a purplish red to litmus paper.

If, on the other hand, it be desired to make a leather of first-rate colour and quality, the hides should be freed as perfectly as possible from lime by scudding and the use of some of the other methods already mentioned, and should come into weak liquors of oak bark, gambier, or other bright coloured materials, which must contain a sufficient proportion of free acid to prevent entirely the rapid colouration which has been mentioned; the butts should colour much more slowly and then take rather a brown than an orange tint. This acidity may be obtained by using in the later parts of the process such materials as ferment and produce acetic and other acids, as for instance light oak bark, and myrobalans, but it will sometimes be difficult to secure sufficient without the direct addition of acetic or other vegetable acid. Mineral acids, such as sulphuric and hydrochloric, must be avoided; but formic, butyric, and lactic acids are suitable, and oxalic acid may be used in small quantities to remove lime and to liberate the natural acids with which it was combined. The goods must gradually be moved into stronger liquors, but care must be taken throughout to keep the acid in excess of the tannin, so that the butts gradually plump up and remain plump, and it must be borne in mind that so far as swelling is concerned, acid and tannin are antagonistic. Putrid or stale liquors (which are often styled 'sour' but contain little or no acid) must be sedulously avoided in every sort of sole-leather tanning.

In the American treatment of 'acid' sweat-leather the sides are usually slightly coloured before plumping in a sweet and moderately strong hemlock liquor, and the acid used with water only, but if the colouring and plumping are done together, a sweet fresh hemlock liquor is used with the vitriol so as to tan the grain before it is much affected by the acid. The butts receive all their plumping in this acid vat, and are then tanned in liquors which contain no vitriol. Good results are not usually attained by adding vitriol in small quantities to the 'handler liquors.'

After the colour is fully set, and the butts by whatever method are fairly plumped in the suspenders, the rest of the process is very simple. The butts are laid flat in 'handler' pits, generally with liquor only, but sometimes with a little solid dusting material as the butts get forward. In these pits the goods are handled once a day or oftener, and the liquors are constantly changed and strengthened. This (or in the early layers) is the stage in which hemlock and other dark-coloured materials can be introduced with least injurious effect. When the butts are coloured quite through, they are placed in 'layers,' with stronger liquor and solid tanning material, such as mimosa bark, myrobalans, and valonia, strewed between them, and they are allowed to remain undisturbed for periods of from 1 to 6 weeks, according to the age and character of the goods and the practice of the tanner. This is repeated till the goods are fully tanned, when they are raised and drained, or sometimes washed from adhering 'dust' and strong liquor in a warm sumach or myrobalans liquor, or are 'vatted.' This process consists in suspension in a strong liquor made with bisulphited or 'bleaching' extract. They are then taken up into the drying lofts, where they customarily receive a slight oiling and are hung up until about half dry. They are then laid in a pile to soften and equalise the moisture ('sammed'), and the grain is struck out either by hand with the 'pin' (a two-handled knife with a triangular blade), or more generally by machine; again slightly oiled, somewhat further dried, and rolled twice and finally dried off in a warm loft. The exact dryness or 'temper' for the different operations is a matter of great importance, but is not easy to describe in writing, and it is besides somewhat influenced by the tannage. It is not uncommon to improve the colour of the grain by washing it with an aniline or other colour in the interval between striking and rolling 'off.'

Dressing leather. Hides intended for 'shaved' hides are generally light, not exceeding 60 lbs. in raw weight; those for 'dressing' or 'common' hides may be somewhat heavier. They are unhaired with lime and bated with hen or pigeon dung, and 'shaved' hides are shaved over the thick parts of the butt with a currier's knife, the edge of which is turned in a peculiar way with a slender steel. They are coloured by frequent handling, or better by the use of a vat agitated by a rotatory paddle wheel, in a sweet liquor sufficiently strong to colour and set the grain in a distended condition, so that, as the inner portions shrink under the further astringent action of the liquor, it becomes wrinkled up into a network of fine furrows. At this stage hides are often split with a reciprocating knife machine for 'grains,' which are finished in various ways, and 'fleshes,' which when good are usually 'waxed.' After this the tannage is conducted similarly to that of sole leather, but with much weaker liquors and tanning materials, selected to produce a soft and pliable leather. Acidity of the liquors which would swell the hide and produce a hard leather must be carefully avoided, while stale and so-called 'sour' liquors will soften and supplement the action of the bate, of course at the cost of a further loss of weight and firmness. In the shed, dressing hides are simply oiled and dried, but it is now more general to curry them wet out of the pits, an operation which is rather mechanical than chemical, but which consists in scouring out the bloom or deposit of ellagic acid which has formed in the surface, shaving down, and treating with oil and tallow. The 'stuffing' or impregnation with fats may be done by coating the moistened leather on one or both sides with 'dubbing,' a pasty mixture of tallow and oil of which the more liquid part is slowly absorbed; but it is now more usual to place the moistened leather in a warmed rotating drum, and run in the melted fats, which are absorbed in about 20 minutes. The mechanical processes are now almost entirely done by machines.

Enamelled, patent, or japanned leather. These names are applied to the various kinds of leather which are finished with a bright waterproof surface similar to the lacquered work of the Japanese, the first generally denoting leather so finished on the grain side, and with a grained surface. The colour is commonly, but not invariably, black. The leather may be tanned with a variety of materials, but must be well scoured and curried with but little oil or degras, and it is necessary that the hides should be well freed from grease by careful scudding before tanning, and frequently by the use of benzene or other solvents in a suitable apparatus. The skins are stretched on boards or frames, and coated with a linseed oil varnish boiled with Prussian blue, and sometimes lampblack, and other pigments. The colour of the japan is not blue, but a brown-black, and the iron of the Prussian blue acts not only as a colouring matter, but as a drier. The frames are then slid into grooves in a sort of closet heated by steam to 70°–80°, and when the coat is dry the process is repeated till the requisite thickness is obtained, each coat being smoothed with pumice before applying the next. In France and Germany the japan is frequently finally hardened in the sun. The American tanners are particularly skilful in treating large thin hides in this way. They are divided by the splitting machine into several thicknesses, and both the grain and flesh splits are frequently enamelled, the flesh split receiving a preliminary coating of thick boiled linseed oil and turpentine to form a sort of artificial grain.

Morocco, when genuine, is produced from goat-skins, but an article of equal quality is made from the rough-haired or 'blue-back' seal, and an inferior description, called 'French morocco,' from sheep-skins. The skins are unhaired by liming, puered with dog-dung, and passed through a bran drench, and are tanned with sumach, first in paddle-tumblers, and then in handlers. With sheep-skins the process is frequently much hastened by sewing them into bags, which are filled with sumach liquor and a little air, and are floated in a sumach bath and then laid on a shelf to drain and press. After a day's treatment they are again filled with a fresh sumach liquor, and this is usually sufficient to complete the tannage. When dried, these are called 'crust-roans.' The dyeing is done either by brushing on a table, or by folding down the back, or pairing, so as to protect the flesh-side as much as possible, and drawing through a dye-bath, which is generally of aniline colours or dye-woods. In more recent times the natural have been almost entirely superseded by artificial (coal-tar) colours, and the dyeing is frequently done in a paddle vat or in a drum. The grain receives a slight glaze of albumen and is polished by glazing machines by friction under agate, glass, or hard wood, and is sometimes impressed with an artificial grain by engraved or electrotyped rollers; the grain being afterwards raised or improved by the operation known as 'boarding.'

Russia leather is tanned with willow, birch, and probably other barks, and is dyed with Brazil wood grounded with stannic chloride. Its peculiar odour is due to the essential oil of birch-bark tar, which is applied during the finishing process. Many imitations made in England and on the Continent are scented by a small proportion applied, mixed with oil, to the flesh-side.

'**Chamois**' or **wash-leather** is a totally different product from those which have been already described. The ordinary article is made from the flesh-splits of sheep-skins, and is thoroughly limed so as to dissolve as much as possible of the cementing substance of the fibres, and so produce softness. The lime is then removed by a short bran-drench, and after the superfluous moisture has been pressed out, the skins are oiled on a table with fish or whale oil, folded in cushions, and worked under fulling stocks for 2 to 3 hours, and then shaken out and hung up for a short time to cool and partially dry. The process is repeated again and again until the water has been entirely replaced by oil, and they are then laid in a pile in a warm place, when a sort of fermentation takes place with a considerable production of heat caused by the oxidation of the oil, and the skins take a yellow colour. The surplus oil is now removed either by pressure ('degras'), or by washing with potash or soda lye, from which 'sod oil' is recovered by neutralisation with sulphuric acid. Though it is not known what chemical change takes place in the fibres, the leather is extraordinarily resistant both to boiling water, acids, and alkalis, and yields no gelatin to the former. It has been supposed that the fibres were merely coated with oxidised oil-products but this is negatived by the fact that the leather is unaffected by alkalis which readily dissolve oxidised oils, and it is more probable that the tannage is due to aldehydic products of the fatty acids and glycerol. Only oils of which the fatty acids have unsaturated double bonds will produce the result, and the most unsaturated are the most effective. Excellent leathers of a chamois type are produced by direct treatment with formaldehyde and some other aldehydes in a solution rendered alkaline by sodium carbonate (Payne and Pullmann's patent, 2872, 1898).

Crown leather (**Preller's**, or **Helvetia leather**). This leather, which is remarkable for its toughness, may be regarded chemically as intermediate between 'chamois' and kid, as it is produced by the action of oils and fats in conjunction with an albuminous 'filling' quite analogous to the egg-yolks and flour which are used in the kid manufacture. As the leather is employed for belting, picker straps, and other mechanical purposes, well flayed hides of medium substance are most suitable. They are unhaired by sulphides or sweating, or by a very short liming hastened by mechanical motion, so as to lessen injury to the fibre. For the sake of appearance they are often grained and coloured by working for 1–2 hours in a paddle tumbler in a moderately strong chestnut, hemlock, or other tanning liquor. They are then swollen (if not unhaired with lime), by paddling for a few hours with about 3½ oz. of sulphuric acid per hide, washed through clean water, and hung up until half dry. They are next spread on a table and covered on the flesh with a layer of tanning paste ¼ inch thick. This may be composed of 7 parts wheat flour, 7 parts horse grease, 1 part salt, and 1–2 parts tallow. (Originally ox-brains were used in the mixture, but are not necessary.) They are then folded in bundles and are placed in a large drum studded with pegs inside, and warmed by the injection of moist air to about 30° or 40°, according to the hardness of the fats employed, in which they are worked for 8–12 hours; at the end of this time they are again partially dried and coated with the fat-mixture, and the process repeated four or five times. The hides are then washed in water, and sometimes with a little soda, and are curried by setting out on both sides, and boarding to raise the grain. The yield is only about 30–40 p.c. of the raw weight of hide.

Calf- and glove-kid. As it is impossible within the limits of this article to give working details where the greatest nicety is required in every stage of manufacture, and as the general outlines are the same in both these products, it must suffice to take them together, briefly indicating how the different qualities of each are produced; especially as calf-kid has been almost entirely superseded for shoe purposes by chrome leathers. In calf-kid considerable firmness is required, together with great pliability, whilst in glove-kid, which is made from actual kid-skins, as well as to a large extent from fine lambskins, not only the greatest softness, but the property of stretching in every direction without tendency to spring back, is essential. This characteristic difference is due partly to the different character of the skins employed, and to the fact that in the latter case special care is taken in the beam-house so to dissolve the cementing matter of the tissue that the separate fibres can move over each other without adherence. Hence the calf-skins are usually unhaired simply by a rather thorough liming, whilst the kids are treated with limes which, in addition, contain realgar (red sulphide of arsenic), which is mixed with the hot slaked lime. In each case the skin is puered, first with a bate of dogs' dung, and then with a bran drench; and in both cases, but especially in the latter, the washing and working on the beam is very thorough, since unless the fat-glands and scud are very completely got rid of, it is impossible to dye the skins uniformly and properly. The tannage is effected in a drum containing a mixture of flour, alum, salt, and egg-yolks, with an addition of olive oil, being in principle a combination of mineral tannage with that of oil and albumen as described under 'crown leather.' After tanning, the goods, whether for shoe or glove purposes, are dried, softened by 'staking' or drawing over a blunt knife, and 'aged' by keeping at least a few weeks in a cool warehouse to fix the tan. Calf-kid is then damped and shaved on the flesh, and dyed black by grounding with a mixture of stale urine, or ammonia and potassium dichromate with logwood, sometimes by brushing, and sometimes by folding grain-side out, and passing through a bath of the dye-liquor, and darkened and fixed by a wash of ferrous sulphate. They are re-egged to restore the egg, &c., removed in washing and dyeing, partially dried, and then grounded with a moon-knife (a round knife with a central handle), rubbed over the grain with a mixture of wax, soap, and gum, and ironed to give them a gloss, hand labour being almost entirely superseded by machines.

In glove-kid the dyeing process is much more complicated, and most of the tannage is washed out with warm water, which necessitates a second feeding in the drum with egg-yolk and salt. The colours are produced by a great variety of dyes and mordants, among which the juices of a variety of berries may be mentioned. Aniline dyes are rarely used alone, but are frequently employed as a final wash to brighten the colour. After dyeing, the skins are wrung out or 'sleeked' out with a brass plate on a beam, dried, and again slightly damped and stretched by drawing over a blunt knife which is fixed on a post; an operation which is called 'staking.'

Mineral tanned leather. It has long been known that not only aluminium salts, but those of iron and chromium of corresponding type were capable of producing leather, and as early as 1858, Knapp described a method of chrome tanning, which is identical with one of the modern processes; but it is only within recent years that it has been realised that such leathers possess valuable properties, and especially as regards their resistance both to hot and cold water, which justify the much greater expense of chrome as compared with aluminium salts. It is quite possible to produce chrome leathers with chrome alum and salt, but practically Knapp's suggestion of forming a basic salt either by addition of sodium carbonate to the solution or in some other way is always employed in 'one-bath' tannage; while the 'two-bath' process of August Schultz, which curiously came into practical use before that of Knapp, actually produced a basic salt in the skin, by treatment with chromic acid and its subsequent reduction with acidified sodium thiosulphate. In either case the salt in the skin afterwards is rendered still more basic by 'neutralisation' with dilute solutions of borax or some other weak alkaline salt, and the leather is afterwards 'fat-liquored' with a thin emulsion of oil and soap, dyed, and subsequently dried out and softened by 'staking' by machine.

Iron leathers have never attained any commercial importance, although Knapp spent time and money in trying to develop them. Titanium and cerium salts have been shown to possess tanning properties, but are still in the experimental stage.

Investigations on chrome tannage have thrown much light on mineral tannages in general. It is now generally admitted that the salts are decomposed by hydrolysis, and the acid and the basic salt are absorbed simultaneously but separately by the skin. The function of common salt is maintained by a physical one, repressing acid swelling, and increasing the fixation of acid, whilst the colloidal basic salt is absorbed chemically or physically by the acidified fibre.

H. R. P.

LEATHER BROWN-YELLOW, CHRYSANILINE, *v.* Acridine dyestuffs.

LECANORIC ACID (*Diorsellinic acid*)

$$C_{16}H_{14}O_7,H_2O$$

was first described by Schunck under the name of 'lecanorin,' and was isolated by him from various species of the *Lecanora* and *Variolaria* lichens. It is also present in some quantity in the *Rocella canariensis*, *R. portentosa*, *R. sinensis*, and *Parmelia perlata*, and, according to Hesse (Annalen, 139, 24), is best isolated by the following method, which is a modification of that originally devised by Schunck. The finely divided lichen is extracted with ether, the extract evaporated, and the greenish-white crystalline residue treated with lime water. The solution, when neutralised with acid, gives a precipitate of lecanoric acid, which is collected and crystallised from alcohol. In case the product is not quite pure it is treated with ether, which dissolves the acid, but not the impurity.

Lecanoric acid crystallises in colourless needles, m.p. 166° (Hesse, Ber. 37, 4693), the solutions of which possess an acid reaction. With alcoholic ferric chloride it gives a dark purple colouration, and with dilute calcium hypochlorite a blood-red liquid, which, according to Hesse, is characteristic, and can be used to distinguish this substance from the known lichen acids.

Dibromolecanoric acid (Hesse, Annalen, 139, 28) $C_{16}H_{12}O_7Br_2$ consists of minute prisms, m.p. 179°, whereas *tetrabromolecanoric acid* $C_{16}H_{10}O_7Br_4$, prisms, melts at 157°.

Potassium lecanorate $C_{16}H_{13}O_7K,H_2O$; *barium lecanorate* $(C_{16}H_{13}O_7)_2Ba,5H_2O$; *calcium lecanorate* $(C_{16}H_{13}O_7)_2Ca,4H_2O$; *silver lecanorate* $C_{16}H_{13}O_7Ag$; *lead lecanorate*

$$(C_{16}H_{13}O_7)_2Pb+PbH_2O_2;$$

and *copper lecanorate* $(C_{16}H_{13}O_7)_2Cu,2H_2O$ have been obtained (J. pr. Chem. [ii.] 57, 264).

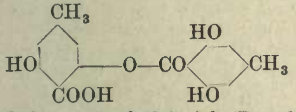
When boiled with water lecanoric acid yields orsellinic acid $C_{16}H_{14}O_7+H_2O=2C_8H_8O_4$; whereas by means of boiling acetic acid or baryta water, orcin, and carbon dioxide are simultaneously produced:

$$C_{16}H_{14}O_7+H_2O=C_8H_8O_4+CO_2+C_7H_8O_2.$$

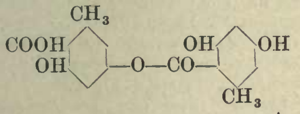
On the other hand, methyl alcohol at 85° gives, in addition to orcin and carbon dioxide, orsellinic acid methyl ester:

$$C_{16}H_{14}O_7+CH_3OH=C_7H_7O_2{\cdot}COOCH_3+C_7H_8O_2+CO_2.$$

The constitution originally assigned to lecanoric acid:



in view of the work of Heinrich (Ber. 37, 1406) on orsellinic acid, is more accurately expressed as follows:



A. G. P.

LECITHIN is a monaminophosphatide widely distributed in the animal and vegetable kingdoms. It is contained in the seeds of cereals, in many plants; in brain, bone-marrow, blood, and in most organs of the animal and human body; in foods, such as milk, butter, wine, in the sugar cane, in various oils and fats, and in the yolk of eggs, but its occurrence in the latter has been denied by Barbieri (Compt. rend. 1910, 151, 405). It is also said to occur in certain soils. It is sometimes spoken of in commerce as '*lecithol.*'

Preparation.—An animal or vegetable substance rich in lecithin may be extracted with volatile esters of fatty acids, the residue, which contains chiefly lecithins and albumins, is extracted with a fatty ester at a higher temperature or with boiling alcohol. The extract on cooling deposits lecithin (Fr. Pat. 390683, 1908); or the first extraction may be carried out with acetone or with acetone mixed with 10–30 p.c. of ether, benzene, chloroform, or similar substance (Fr. Pats. 371391, 1906; 406634, 1908; 333540, 1903).

Lupin or similar seeds freed from skins, may be dried and extracted with hot 96 p.c. alcohol. The extract is evaporated to $\frac{1}{5}$ its bulk and cooled rapidly. On allowing it to stand for a short time, the lecithin separates. It is then boiled with 96 p.c. alcohol until all the lecithin and part of the fat dissolves. On cooling, the fat separates and the solution is decanted and evaporated to obtain pure lecithin (Eng. Pat. 18540, 1909; D. R. PP. 210013, 200253).

Wheat germs are dried and extracted with a suitable solvent to remove oil. They are then extracted with alcohol. The latter is evaporated and the residue, consisting of lecithin, sugar, and albumen, taken up with 50–80 p.c. alcohol, after which the lecithin is precipitated by addition of mineral salts and purified in the ordinary way (Fr. Pat. 364896, 1906; *see* also Schulze, Zeitsch. physiol. Chem. 1908, 55, 338).

Lecithin may also be extracted from the yolk of eggs by means of 96 p.c. alcohol, or a mixture of alcohol and ether. The extract is then precipitated with cadmium chloride at 0°, and the lecithin cadmium chloride salt, suspended in alcohol, is decomposed with lead hydroxide or with moist silver oxide. The lecithin may then be purified by dissolving it in chloroform and reprecipitating with acetone (Ulpiani, Atti. Real. Accad. Lincei. 1901, [v.] 10, i. 368, 421; *see* also Nerking, Biochem. Zeitsch. 1909, 23, 262; Zuelzer, Zeitsch. physiol. Chem. 1899, 27, 254).

Constitution.—The formula usually given to lecithin is

$$RR'O_2:C_3H_5{:}O:P:O(OH)O{\cdot}C_2H_4{\cdot}NMe_3OH,$$

but its exact constitution is not known. It is the choline ester of the palmitic, stearic, or oleic ester of glycerylphosphoric acid, but since the lecithins from various sources, although yielding similar results on elementary analysis, differ in the quantity of choline they form on hydrolysis, it is possible that there is some difference in their constitution; it has therefore been proposed by Winterstein and Hiestand (Zeitsch. physiol. Chem. 1906, 47, 490) to call them by the more general name of *phosphatides.* Various lecithins exist which contain more than one acid radicle in the molecule (*see* also McLean, Bio-Chem. J. 1909, 4, 240; Hunderhagen, J. pr. Chem. [ii.] 28, 219; Gilson, Zeitsch. physiol. Chem. 12, 585; Schulze, *ibid.* 1907, 52, 54; Rollett, *ibid.* 1909, 61, 210; Wintgen and Keller, Arch. Pharm. 1905, 244, 3; Willstätter and Lüdecke, Ber. 1904, 37, 3753; Mayer, Biochem. Zeitsch. 1908, 8, 199; Dezani, Giorn. R. Accad. Med. Torino, 1909, 15; Gobley, Chem. Soc. Trans. 1874, 908; *ibid.* 1875, 92).

Properties.—Lecithin forms a crystalline, wax-like mass, readily soluble in most organic solvents, except acetone or methyl acetate, the solutions being precipitated by salt solutions lying within certain limits of concentration (Porges and Neubauer, Biochem. Zeitsch. 1907, 7, 152; Zeitsch. Chem. Ind. Kolloide, 1909, 5, 193). The alcoholic solution gives characteristic precipitates with cadmium or platinum chlorides (Riedel, Chem. Zentr. 1905, i. 772).

When pure, lecithin should not be transparent, and should form a colourless emulsion with water; to improve its appearance it is often adulterated with solvents and with phosphates and glycerophosphates (Morigi, Chem. Zentr. 1909, ii. 2135). The aqueous emulsion is but slightly affected by light and is very stable with respect to temperature. The emulsion has an acid reaction, but on precipitation with acetone the residue forms a neutral emulsion (Long, J. Amer. Chem. Soc. 1908, 30, 881, 895; *see* also Heubuer, Arch. Exp. Path. Pharm. 1908, 59, 420). When hydrolysed with alkali- or barium hydroxide or with dilute acids, lecithin yields chiefly choline together with palmitic, stearic, oleic, and, probably, linoleic acid (Schulze and Winterstein, Zeitsch. physiol. Chem. 1903, 40, 101; Moruzzi, *ibid.* 1908, 55, 352; McLean, *ibid.* 360; Cousin, Compt. rend. 1903, 137, 68; J. Pharm. Chim. 1906, [vi.] 23, 225; Cariat, Amer. J. Physiol. 1904, 12, 353; D. R. P. 193449; Eng. Pat. 342007, 1904). It is also decomposed readily by the steapsin of the gastric juice and by the pancreatic ferment (Bokay, Bied. Zentr. 1879, 112; Simanowski and Sieber, Zeitsch. physiol. Chem. 1906, 49, 50).

When, in the preparation of lecithin, heat is avoided, the product is dextrorotatory (Ulpiani, *l.c.*).

Ordinary *d*-lecithin when heated in a sealed tube with 10 times its weight of methyl alcohol for 5–6 hours at 90°–100° yields *i*-lecithin which is converted into *l*-lecithin, $[\alpha]_D - 8{\cdot}59°$, by the action of steapsin (Mayer, Chem. Zentr. 1906, ii. 493; Long and Gephart, J. Amer. Chem. Soc. 1908, 30, 1312; McLean, Zeitsch. physiol. Chem. 1908, 57, 296).

Physiological action of lecithin.—Lecithin is said to be a stimulating agent in normal growth (Hatai, Amer. J. Physiol. 1903, 10, 57), and to act favourably on the nutritive processes, being an easily assimilable form of a phosphorus compound (Stassano and Billon, Compt. rend. 1902, 134, 318; Desgrez and Zaky, *ibid.* 1166; Barnard, Chem. Zentr. 1902, i. 854), and it has been recommended as an adjunct to other means of treatment in tuberculosis (Claude and Zaky, Compt. rend. 1901, 133, 486). According to Renshaw and Atkins, lecithins cause a varying retardation in the development of bacteria, but their bactericidal properties are almost negligible for practical purposes (J. Amer. Chem. Soc. 1910, 32, 130).

A great deal of work has been done on the physiological and biological significance of lecithin (*v.* Stoklasa, Ber. 1896, 29, 2761; Zeitsch. physiol. Chem. 1898, 25, 398; Kyes, *ibid.* 1904, 41, 273; Küttner, *ibid.* 1907, 50, 472; Desgrez and Zaky, Compt. rend. 1901, 132, 1512; *ibid.* 1902, 134, 1522; Carrière, *ibid.* 1901, 133, 314; Maxwell, Amer. Chem. J. 15, 185; Slowtzoff, Beitr. Chem. Physiol. Path. 1906, 8, 370; Franchini, Biochem. Zeitsch. 1907, 6, 210; Glikin, *ibid.* 1907, 7, 286; *ibid.* 1909, 19, 270; *ibid.* 1909, 21, 348; Porges and Neubauer, *l.c.*; Usaki, Arch. Exp. Path. Pharm. 1910, 63, 270; Bied. Zentr. 1910, 39, 594).

Addition compounds of lecithin with the halogen hydrides are prepared by saturating an ice-cold solution of lecithin (1 part) in carbon tetrachloride (5 parts) with the required gaseous hydride. It is purified by treating the solution with calcined sodium carbonate, after which it is filtered and evaporated *in vacuô.* The product may then be crystallised from hot alcohol or acetone. The products are yellowish-brown, wax-like masses containing 32 p.c. of iodine or 21 p.c. of bromine. If the treatment with sodium carbonate is omitted, the content of halogen is much higher (Eng. Pat. 28011, 1908).

Bromolecithin is prepared by the action of a chloroform solution of bromine on lecithin, which is capable of combining with 50 p.c. of its weight of halogen (D. R. P. 156110).

An iodo derivative of lecithin has been prepared by shaking 5 kilos. of lecithin dissolved in 3 litres of alcohol, with 10 litres of Hübl's iodine solution at a temperature of 40°–50°. The solution is then cooled, filtered, and evaporated *in vacuô*, when a product containing 20 p.c. of iodine is obtained (D. R. P. 155629).

Lecithin albumin saline preparations may be obtained in the following way: 8 grams of lecithin are emulsified by an aqueous solution of 100 grams of casein and 2 of sodium hydroxide, and the emulsion is then treated successively with solutions of 5 grams sodium phosphate and 3 grams of calcium chloride. The precipitate is finally separated and dried *in vacuô* (D. R. P. 223876).

Lecithin dextrose is probably a solid solution or a molecular combination of the two substances. It readily reduces an alkaline solution of copper, is fermentable and forms an *osazone*, m.p. 205° (Mayer, Chem. Zentr. 1906, ii. 536).

Lecithin glucoses are of variable composition (Baskoff, Zeitsch. physiol. Chem. 1909, 61, 426). Lecithin molybdenum compounds are known (Ehrenfeld, *ibid.* 1908, 56, 89).

Lecithin may be estimated in a variety of ways, but usually the amount of phosphorus or phosphoric acid in the incinerated substance is determined (Nerking and Haensel, Biochem. Zeitsch. 1908, 13, 348; Otolski, *ibid.* 1907, 4, 124; Schulze, Zeitsch. physiol. Chem. 1894, 20, 225; Koch, *ibid.* 1906, 47, 327; Schulze, Chem. Zeit. 1897, 21, 374; *ibid.* 1904, 28, 751; *ibid.* 1908, 32, 186; Heckel and Schlagdenhauffen, Compt. rend. 1886, 103, 388; Bordas and Raczkowski, *ibid.* 1902, 134, 1592; Riedel, *l.c.*; Jäekle, Zeitsch. Nahr. Genussm. 1902, 5, 1062; Riegel, Pharm. Zeit. 1910, 55, 428).

(For further literature on the sources of lecithin, *see* Loew, Pflüger's Arch. Phys. 22, 62; Hoppe-Seyler, Ber. 1879, 12, 702; Schulze and Likiernik, *ibid.* 1891, 24, 71; Shorey, J. Amer. Chem. Soc. 1898, 20, 113; Schlagdenhauffen and Reeb, Compt. rend. 1902, 135, 205; Burow, Zeitsch. physiol. Chem. 1900, 30, 495; Koch, *ibid.* 1902, 36, 134; McLean, *ibid.* 1909, 59, 223; Funaro and Barboni, Chem. Zentr. 1905, i. 552; Rubow, *ibid.* 620; Manasse, *ibid.* 1906, ii. 805; Muraro, Gazz. chim. ital. 1905, 35, i. 314; Fornani, Boll. chim. Farm. 1909, 48, 520; Glikin, Biochem. Zeitsch. 1907, 4, 234; Bolle, *ibid.* 1910, 24, 179.)

LEDITANNIC ACID, LEDIXANTHIN, LEDUM CAMPHOR *v.* LEDUM PALUSTRE (Linn.).

LEDUM PALUSTRE (Linn.). *Marsh tea*; *Wild rosemary. Lédon* (Fr.); *Porsch, Sumpfporst* (Ger.). Marsh tea is a shrub, some 3 feet in height, belonging to the natural order *Ericaceæ*, which inhabits marshes, generally, throughout the northern hemisphere. Its inflorescence consists of umbels of white or pale rose-coloured flowers. The leaves possess acrid narcotic properties, and were formerly made use of in medicine. A strong decoction is now sometimes applied in veterinary practice to destroy cutaneous parasites, and it is also employed to kill vermin in furniture.

The most important constituents of the leaves are volatile oil, camphor, a glucoside and tannin. The *volatile oil* obtained by distilling the leaves with water was examined by Willigk (Sitzungsber. Wien. 9, 305) and Fröhde (J. 1861, 692). It contains a *terpene* $C_{10}H_{16}$, boiling at 160°, an *oxygenated oil* $C_{10}H_{16}O$, perhaps *ericinol*, boiling at 240°–242°, and camphor.

Ledum camphor $C_{15}H_{26}O$, a homologue of common camphor, was examined in 1796 by Rauchfuss (J. Pharm. 3, 1 and 189) and afterwards by Meissner (Berz. J. 13, 170), Grassmann (Rep. Pharm. 38, 53), Buchner (*ibid.* 38, 57; N. Rep. Pharm. 5, 1), Willigk (Sitzungsber. Wien. 9, 302), Rizza (J. Russ. Phys. Chem. Soc. 19, 319), Iwanow (J. 1879, 909), Trapp (Ber. 8, 542), Hjelt and Collan (*ibid.* 15, 2501). The camphor crystallises out abundantly when the volatile oil is placed in a freezing mixture, and may be separated and purified by recrystallisation from alcohol. It sublimes readily in needles, which melt at 104°–105°, and boil at 282°–283°. It is soluble in alcohol, ether, chloroform, and benzene. Heated with acetic anhydride at 150° a sesquiterpene *ledene* $C_{15}H_{24}$ is obtained, which boils at 255°, and at 0° has a sp.gr. 0·9349 (Hjelt, Ber. 28, 308) (*v.* CAMPHORS).

Marsh tea contains small quantities of the glucoside *ericolin* $C_{34}H_{56}O_{31}$ (?) (Rochleder and Schwarz, Sitzungsber. Wien. 9, 308; 11, 371) a compound which occurs generally in ericaceous plants (Kawalier, *ibid.* 9, 297; Thal, J. 1883, 1402). It is an intensely bitter, yellowish-brown, sticky resin (*v.* ERICOLIN). By the action of dilute acids it breaks up into glucose and *ericinol*, $C_{20}H_{26}O$ (?). The latter compound is also a product of the action of dilute acids on pinipicrin, a glucoside occurring in the needles of the Scotch fir (Kawalier, Sitzungsber. Wien. 11, 350; 13, 515). Ericinol is a colourless oil when first obtained, but it soon oxidises and turns brown when exposed to the air.

Leditannic acid $C_{15}H_{20}O_8$ (?) was examined by Willigk (Sitzungsber. Wien. 9, 302), Rochleder and Schwartz (*ibid.* 9, 307), Rochleder (*ibid.* 44, 493), and Thal (J. 1883, 1402). By treatment with dilute acid it is converted into *ledixanthin*, $C_{30}H_{34}O_{13}$ (?), but no sugar is formed. The tannin of the horse-chestnut appears to give the same compound when treated with dilute acids, and is perhaps identical with leditannic acid. Distilled alone leditannic acid yields an oil and *catechol* $C_6H_4(OH)_2$. A. S.

LEEK. *Allium Porrum* (Linn.). The Welsh national plant. The taste and odour are due to the presence of allyl sulphide $(C_3H_5)_2S$.

König gives the following analyses:—

	Water	Protein	Fat	Sugar	Other N-free subst.	Crude fibre	Ash	Organic sulphur
Root and bulb	87·6	2·8	0·3	0·4	6·1	1·5	1·2	0·06
Leaves . .	90·8	2·1	0·4	0·8	3·7	1·3	0·8	0·06

The following shows the composition of the ash:—

	Per cent. of ash in dry substance	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl

H. I.

LEGUMIN. *Vegetable caseïn.* The distinctive protein of the seeds of the *Leguminosæ*, found also in some other seeds; it closely resembles in composition and in some of its properties the casein of milk. It occurs mixed with other proteins in the seeds, and is with difficulty obtained in a pure state.

Different methods of extraction—especially the use of dilute alkalis—cause alterations in the proteins of plants, and hence a good deal of confusion has arisen both as regards the nature and the names of the various proteins.

Legumin was discovered by Einhof in 1805, and has been investigated by Proust, Vogel, Boullay, Braconnot, Liebig, Dumas, and Cahours, and others, and especially by Ritthausen, and later by T. B. Osborne and his fellow-workers.

Ritthausen divided plant caseïn into legumin, conglutin, and gluten-caseïn, which differ a little from each other in their composition and in a few of their properties. The first and third he considered albuminates, and the second a plant globulin.

These three forms of plant casein are, according to Ritthausen, only slightly soluble in water, but easily soluble in dilute alkaline solutions, in solutions of alkaline reacting salts, and in very dilute acids. They are precipitated from alkaline solutions by dilute acids and by rennet. Earlier investigators thought that phosphorus was an essential element. Sp.gr. 1·285–1·36 (Dittmar); specific rotation of legumin in 10 p.c. NaCl $[\alpha]_D$ −44·09° (Osborne and Harris).

Ritthausen obtained legumin from peas, haricots, beans, lentils, vetches, &c., by the following process. The seeds are finely powdered, macerated with about eight times their weight of cold water for 6 hours, the liquid decanted and strained, and the residue again macerated with water. In some cases, notably with beans and lupins, the solution is acid, and in such cases it is desirable to add to the water used in extracting the seed sufficient potassium hydroxide to render the mixture very feebly alkaline, otherwise much less proteïd will be extracted from the seed. The strained extract is allowed to settle for some time at a low temperature, 4°, and when clear, or nearly so, decanted and precipitated with dilute acetic acid (1 : 8), adding only just sufficient acid to complete the precipitation, and keeping the temperature low. The precipitate is collected on a filter washed with 50 p.c. alcohol, which causes it to shrink and separate easily from the filter; the precipitate is then further washed and extracted with dilute alcohol, strong alcohol, and with ether; then pressed, again washed with alcohol, and dried in a vacuum over oil of vitriol.

If the product is still impure it may be purified by dissolving it in the cold in a very dilute solution of potassium hydroxide (0·1–0·2 p.c.), and, after decanting from any insoluble matter, reprecipitating with dilute acetic acid.

Conglutin was obtained in a similar manner from sweet and bitter almonds and from lupins. It contains rather more nitrogen, is more glutinous, and more soluble in acetic acid than legumin, besides being completely soluble in dilute salt solution. Also, its compound with copper oxide differs a little from the legumin copper-oxide compound.

Gluten-caseïn was prepared from the seeds of *gramineæ* in a very similar way.

Ritthausen formed compounds of plant caseïn with copper oxide by dissolving the finely-powdered proteïd in water containing 0·2–0·3 p.c. of potassium hydroxide, largely diluting the solution with water, and adding a solution of blue vitriol and as much caustic potash as is necessary to dissolve the precipitate first formed and give the whole solution a violet colour. The clear solution is then neutralised with dilute sulphuric acid, and the precipitate collected and washed with water till it ceases to give a reaction for sulphates.

Legumin thus treated gives a precipitate containing from 13·5 to 15·5 p.c. of CuO, and the proteïn is unaltered by the treatment.

Conglutin is, to a slight extent, decomposed by the treatment, and yields a compound containing about 11·6 p.c. of CuO.

Gluten-caseïn is but slightly altered by this treatment; but its copper oxide compound is somewhat soluble in water, and contains about 14 p.c. CuO.

The legumin obtained from several sources by Ritthausen was found by him to be partially soluble in dilute solutions of salt; but there was little or no difference in composition between the soluble and insoluble portions. The composition of legumin and its allies, as given by Ritthausen, varies somewhat according to their source. There is no doubt that the use of alkalis in the extraction of the proteins, and also their subsequent precipitation by an acid, led to alterations in composition and properties in the proteins which has led to confusion and some erroneous results.

To T. B. Osborne of the Connecticut Agricultural Experiment Station and his fellow-workers, notably G. F. Campbell, S. H. Clapp, R. D. Gilbert, I. F. Harris, F. W. Heyl, and C. G. Voorhees, we are indebted for more exact knowledge of the composition and nature of legumin and other vegetable proteins. Osborne's researches began about the year 1891, and will be found, for the most part, recorded in the Journal of the American Chemical Society and the American Journal of Physiology from that date onwards. A summary of the results is given in The Vegetable Proteins, by Thos. B. Osborne, 1909, in which is a valuable bibliography of the subject.

Osborne has shown that legumin and its congeners are true globulins; he obtains legumin (and similar proteins) without the aid of alkalis. The finely ground material, peas or vetches, is extracted with petroleum naphtha to remove oil and treated with a strong solution (10–20 p.c.) of common salt. After filtering the liquid is treated with ammonium sulphate, the resulting precipitate redissolved in 10 p.c. sodium chloride solution, and the liquid dialysed free from chlorides when the protein separates in spheroids. It is washed with water and alcohol and dried over sulphuric acid.

Legumin thus prepared is insoluble in water; when freshly prepared and not dried it is readily soluble in a 10 p.c. solution of sodium chloride. After washing with alcohol and drying it becomes less soluble. A solution in 10 p.c. sodium chloride is not precipitated by saturating the solution with magnesium sulphate or with sodium chloride; nor by sodium sulphate at the ordinary temperature, but is precipitated at 34°. Saturation with ammonium sulphate at common temperatures completely precipitates it. In a salt solution, legumin is precipitated by picric, tannic, hydrochloric, nitric, sulphuric, or acetic acids, but not by mercuric chloride. It is readily soluble in dilute alkalis and alkaline carbonates.

The protein described under the name of conglutin by Ritthausen, obtained from almond and peach kernels, has been shown by Osborne to be different in some of its characters from legumin, and he has restored to it the name amandin, first given to it by Proust in 1802.

The name conglutin Osborne retains for the protein of lupins.

The percentage composition of some of the typical and purest preparations is as follows:—

—	Legumin from		Conglutin or amandin from almonds:		Conglutin from lupins.	
	peas and beans. Ritthausen	peas and vetches. Osborne	Ritthausen	Osborne	Ritthausen	Osborne
C .	51·5	52·1	50·4	51·3	50·8	51·0
H .	7·0	7·0	6·9	6·9	6·9	6·9
N .	17·1	18·0	18·1	19·3	18·4	18·0
S .	0·4	0·4	0·4	0·4	0·9	0·4
O .	24·0	22·5	23·7	22·0	23·0	23·7

Globulins have been found in walnuts, hazelnuts, candle-nuts (*Aleurites triloba* [Forst.]), para-nuts (*Bertholletia*), castor-oil beans, cherry kernels, plum and apricot kernels, earth nuts (*Arachis hypogæa* [Linn.]), hemp seed, cotton seed, coconuts, sunflower seeds, and several other seeds.

Ritthausen obtained the following percentages of legumin from different seeds:—French beans 11 p.c., peas 5·4–9·4 p.c., horse beans 10 p.c., Mazagan beans 18·7 p.c., and lentils 5·2 p.c. From sweet almonds he obtained 15 p.c. of conglutin, and from lupins 20 p.c.

The whole of the nitrogenous matter of these seeds is not in the form of legumin; other proteins are present. Thus field beans contain about 23 p.c., and lentils 25 p.c. of nitrogenous matter.

The products of the hydrolysis of legumin with acid and alkalis are those of the proteins generally, the nitrogen being found as ammonia, arginine, and other bases, glycine, alanine, leucine, tyrosine, phenylalanine, aspartic acid, glutamic acid, and other amino acids and tryptophan. Osborne and Harris found, on decomposing with strong hydrochloric acid, that of the total nitrogen 9·3 p.c. was obtained as ammonia, 28·4 p.c. as basic nitrogen, mainly in the forms of arginine, histidine, and lysine, and 61·4 p.c. as non-basic nitrogen.

In China and Japan a kind of vegetable cheese, known in the latter country as *tofu*, is made from the seed of the soy bean (*Glycine hispida* [Maxim.]). This leguminous seed contains about 37–40 p.c. of nitrogenous matter, and about 20 p.c. of fat, being a very concentrated food. Its globulin (glycinin) is very like legumin from peas, but contains rather more sulphur (0·8 p.c.) and rather less nitrogen (17·5 p.c.).

The cheese is made by soaking the beans in water, pounding them, and straining through a sieve, which removes most of the starch, boiling the residue with water, and straining the solution through cotton-cloth and pressing the residue. The strained liquor, containing the nitrogenous matter (legumin, &c.) and fat, is precipitated by the addition of the brine formed on the deliquescence of common sea salt; the precipitate pressed and cut into cakes is ordinary *tofu.* It contains about 89 p.c. of water, the dry matter being nearly two-thirds nitrogenous matter and one-third fat, with small quantities of carbohydrates and ash. A drier product is obtained by freezing these cakes of cheese, and then thawing by exposure to the sun. On thawing, a large quantity of water runs off, leaving a spongy, somewhat horny residue, known as *kori-dofu.*

Analyses of these products gave the following results:—

—	Fresh tofu	Frozen tofu or kori-dofu	Dry matter from frozen tofu
Water . .	89·0	18·8	—
Ash . .	0·5	1·6	2·0
Fat . .	3·2	28·8	35·4
Nitrogenous matter .	6·5	48·8	60·1
Carbohydrates	0·8	2·0	2·5
	100·0	100·0	100·0

E. K.

LEHRBACHITE *v.* SELENIUM.

LEIPSIC YELLOW. *Normal lead chromate* (*v.* CHROMIUM).

LEITHNER'S BLUE. *Cobalt blue* (*v.* PIGMENTS).

LEMNIAN EARTH, *Terra lemnia*, or *Sphragidite.* A red, yellow, or grey earthy substance, somewhat resembling fuller's-earth, and consisting of a hydrated aluminium silicate, with more or less iron. It takes its name from its occurrence at Lemnos, an island in the Grecian Archipelago, where, in consequence of its reputed medicinal virtues, it was formerly regarded as sacred. The earth was dug only once a year, with much ceremony, and, after mixture with goat's blood, was made into small cakes or balls, which were stamped with a seal by the priests, whence it was termed *terra sigillata.*

Lemnian reddle (*Rubrica lemnia*) was a red ochreous earth used as a colouring material.

F. W. R.

LEMON. The fruit of *Citrus medica* (Linn.) [*C. limonum*]. There are many varieties. König gives as the average of 33 analyses—

Mean weight of a fruit	The fruit consists of		
	Skin	Flesh	Seeds
153 grammes	38·5	59·2	2·3

The fruit contains—

Water	Invert sugar	Citric acic	Nitrogenous matter	Ash
82·6	0·4	5·4	0·7	0·6

The juice contains—

Total extract	Invert sugar	Cane sugar	Citric acid	Nitrogenous matter	Ash
10·44	1·42	0·52	5·83	0·32	0·20

The rind of Italian lemons contains—

Water	Nitrogen	Essential oil	Ash
76·38	0·23	1·01	0·52

The ash of lemons (whole fruit) contains—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	Mn_3O_4	P_2O_5	SO_3	SiO_2	Cl
43·2	2·7	30·2	5·1	0·6	0·4	13·6	3·1	0·7	0·5

Boric acid, to the extent of 6 milligrammes per litre, has been detected in lemon juice (Hebebrand, 1902). Lemons are largely used, both in the form of fruit and also for the preparation of citric acid (*q.v.*) and essence of lemon (*q.v.*). Lemon juice, both in its raw and concentrated (5 to 7 times) state, is also an important commercial product. According to the British Pharmacopœia lemon juice should have a sp.gr. of 1·039, and contain 32·5 grains of citric acid per oz., *i.e.* 6·77 grammes per 100 c.c. H. I.

LEMON-GRASS OIL *v. Verbena*, art. OILS, ESSENTIAL.

LEMON, OIL OF, *v.* OILS, ESSENTIAL.

LEMON YELLOW *v.* BARIUM CHROMATE and CHROMIUM.

LENTILS. The seeds of *Lens esculenta* (Moench.) [*Ervum lens*]. These are small in size and are largely used as human food. They are very nutritious, but unless thoroughly cooked are difficult of digestion.

There are many varieties, differing considerably in size and also in composition.

Balland (Compt. rend. 1897, 125, 119) found the following range of variation in composition:—

Weight of 100 seeds. grammes	Water	Protein	Fat	N-free extract	Crude fibre	Ash
2·5	11·7	20·3	0·6	56·1	3·0	2·0
to 6·6	13·5	24·2	1·5	62·4	3·6	2·7

Church (Food Grains of India, 1886 and 1891) gives analyses of husked and whole lentils—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Husked .	11·8	25·1	1·3	58·4	1·2	2·2
Unhusked .	11·7	24·9	1·5	56·0	3·6	2·3

König quotes as an analysis of the ash—

Per cent. of ash in dry substance	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	Cl
2·07	34·8	13·5	6·3	2·5	2·0	36·3	4·6

Lentils thrive in temperate climates, and best on a dry calcareous soil; their leaves and stems, when cut in the early stages of growth, furnish nutritious food for cattle and yield a hay which is excellent for dairy cows. H. I.

LENTISCUS or **LENTISK.** The leaves of *Pistacia lentiscus* (Linn.), a small shrub growing wild in Tunis. Contain from 10 to 12 p.c. of tannin and are used in admixture with sumach, the dried leaves of *Rhus coriaria* (Linn.), in tanning. For methods of detecting and estimating lentiscus in Sumach, *v.* Scarlata (J. Soc. Chem. Ind. 1900, 779).

LEPIDINE *v.* QUINOLINE.

LEPIDOLITE *v.* LITHIUM, also MICA.

LEPTANDRA. *Culver's Root.* The rhizome and rootlets of *Veronica* (*Leptandra*) *virginica* (Linn.) contain a resin leptandrin. It is used as a cathartic in biliousness or constipation.

LETHAL *see Spermaceti*, art. WAXES.

LETTUCE. *Lactuca scariola* (Linn.) and other species. Several varieties are known. The leaves are eaten as a salad.

König gives as the average composition of the usual species—

Water	Nitrogenous substances	Fat	N-free extract	Crude fibre	Ash	Organic sulphur
94·3	1·4	0·3	2·2	0·7	1·0	0·01

The ash contains—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
37·6	7·5	14·7	6·2	5·3	9·2	3·8	8·1	7·6

The juice contains potassium hydrogen citrate.

All lettuces possess slight narcotic properties, and the milky juice of certain species, especially *L. viroŝa* (Linn.), when evaporated, yields a brown, viscid residue which has been used in medicine under the name "lactucarium" (*q.v.*). H. I.

LETTUCE OPIUM *v.* LACTUCARIUM.

LEUCANILINE *v.* TRIPHENYLMETHANE COLOURING MATTERS.

LEUCINE. The name *leucine*, suitably prefixed, is given to the four following monoaminocaproic acids:—

1. *l-Leucine* (*α-amino-γ-methylvaleric acid*)
$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$.
2. *d-iso-Leucine* (*α-amino-β-methylvaleric acid*)
$CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H$.
3. *n-Leucine* (*α-amino-n-hexoic acid*)
$CH_3[CH_2]_3CH(NH_2)CO_2H$.
4. *ϵ-Leucine* (*ϵ-amino-n-hexoic acid*)
$H_2N{\cdot}CH_2[CH_2]_4CO_2H$.

With the exception of the last they all occur among the degradation products of a great many of the proteins.

***l*-Leucine,** *α-amino-γ-methylvaleric acid*

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$$

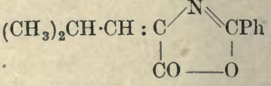
is, next to arginine, the most widespread of the amino acids that occur in proteins. It was discovered by Proust (Ann. Chim. Phys. 1818, [ii.] 10, 40) in decaying cheese and called "oxide-caséux"; Braconnot (*ibid.* 1820 [ii.]. 13, 19) isolated it from the products of the acid hydrolysis of meat, and named it leucine (λευχος) because of the glistening white crystals it forms. Mulder (J. pr. Chem. 1839, 16, 290) established the identity of the two substances and also obtained it by boiling meat with alkali and by the putrefaction of casein.

Leucine occurs in the free state in many of the organs of the animal body, in the tissues of the lung (Cloetta, Annalen, 1854, 92, 289), in the thymoid and thyroid glands and the pancreas (Gorup-Besanez, Annalen, 1856, 98, 7; Radziewsky, Zeitsch. Chem. 1866, 416), in the brain (Müller, Annalen, 1857, 103, 131); it is found in the liver and urine under certain pathological conditions (Frerich and Städeler, J. 1854, 678; 1856, 702; 1858, 550; Salkowsky, J. Thierchem. 1880, 457; Valentiner, J. 1854, 675; Sotnitschwski, Zeitsch. physiol. Chem. 1879, 3, 391). Among the lower animals leucine occurs in the pupæ of butterflies (Schwarzenbach, J. 1857, 538), in spiders and in crayfish. In the vegetable kingdom leucine has been found in the juice of etiolated vetch seedlings (Gorup-Besanez, Ber. 1874, 7, 146; Cossa, Gazz. chim. ital. 1876, 6, 314), also in the young green plants (Schulze, Landw. Versuchs. Stat. 1895, 46, 383); in potatos (Schulze and Barbieri, *ibid.* 24, 167); in young pumpkin plants (Schulze and Barbieri, Ber. 1878, 11, 1233); in fungi (Winterstein, Zeitsch. physiol. Chem. 1899, 26, 438); in the pod of the broad bean (Bourquelot and Hérissey, J. Pharm. Chim. 1898, [vi.] 8, 385); and in beet juice (Erlich, Zeit. Ver. deut. Zuckerind. 1903, 571, 809).

l-Leucine crystallises in glistening white leaves, melts at 280° when rapidly heated (Trans. Guinness Res. Lab. 1903, i. 57), and has sp.gr. 1·293 in absolute alcohol at 18° (Engel and Vilmain, Bull. Soc. chim. 1874, [ii.] 22, 279). It dissolves in 46 parts of water at 18° (Schulze, Zeitsch. physiol. Chem. 1884, 9, 254); in 1040 parts of cold alcohol (96 p.c.) or in 800 parts of hot alcohol (98 p.c.) (Zollikoffer, Annalen, 1852, 82, 176); in 10·9 parts of glacial acetic acid at 16° or 29·23 parts at 117° (Habermann and Ehrenfeld, Zeitsch. physiol. Chem. 1902, 37, 18). The molecular heat of combustion is 854·9 Cal., and the heat of formation 158·4 Cal. (Berthelot and André, Compt. rend. 1890, 110, 884). Natural leucine or *l*-leucine is lævorotatory in aqueous and dextrorotatory in acid or alkali solution (Lewkowitsch, Ber. 1884, 17, 1439), and has $[\alpha]_D+15{\cdot}6°$ in hydrochloric acid solution (Ehrlich and Wendel, Biochem. Zeitsch. 1908, 8, 399); when heated with barium hydroxide solution at 150°–160° for three days it is racemised, and the inactive leucine can be resolved by the action of *Penicillium glaucum*, yielding *d*-leucine, the rotation of which is equal in magnitude and opposite in direction to that of the lævo isomeride (Schulze and Bosshard, Zeitsch. physiol. Chem. 1886, 10, 140).

The constitution of leucine as *α*-amino-*γ*-methylvaleric acid was first established by Schulze and Likiernik (Ber. 1891, 24, 669), who showed that the synthetic *α*-amino*iso*butylacetic acid (*α*-amino-*γ*-methylvaleric acid) prepared by Hüfner (J. pr. Chem. 1870, [ii.] 1, 6) by the action of ammonia and hydrogen cyanide on *iso*valeraldehyde, was identical with the inactive leucine obtained by heating natural *l*-leucine with barium hydroxide. The two compounds have the same solubility in water, 1 part in 105 at 13°; yield the same *d*-leucine when used as a culture medium for *Penicillium glaucum*, and give the same leucic acid (hydroxycaproic acid), m.p. 54·5° on treatment with nitrous acid.

Further syntheses of *r*-leucine are described by (1) Erlenmeyer and Kunlin (Annalen, 1901, 316, 145), who obtained the anhydride



of *α*-benzoylamino-*β*-*iso*propylacrylic acid by condensing hippuric acid and *iso*butyraldehyde in the presence of acetic anhydride; the corresponding acid $(CH_3)_2CH{\cdot}CH{:}C(NH{\cdot}COPh)CO_2H$ when heated with excess of ammonia solution at 150°–170° is hydrolysed, yielding *r*-leucine, *iso*valeric, and benzoic acids. (2) Bouveault and Locquin (Bull. Soc. chim. 1904, [iii.] 31, 1180) from ethyl *α*-oximino*iso*hexoate

$$(CH_3)_2CH{\cdot}CH_2{\cdot}C(NOH)CO_2Et$$

obtained by the action of nitrosyl sulphate on ethyl *iso*butylacetoacetate; this on reduction yielded ethyl α-amino*iso*hexoate

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2Et,$$

from which by hydrolysis *r*-leucine was obtained. (3) Fischer and Schmitz (Ber. 1906, 39, 351) who obtained *r*-leucine from ethyl *iso*butylmalonate $(CH_3)_2CH{\cdot}CH_2{\cdot}CH(CO_2Et)_2$ by converting into the bromo derivative

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CBr(CO_2Et)_2,$$

hydrolysing this ester, and converting the *iso*butylbromomalonic acid thus obtained into *iso*butylbromoacetic acid

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CHBr{\cdot}CO_2H$$

by distillation under reduced pressure; this on treatment with ammonia yielded *r*-leucine $(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$.

r-Leucine has been resolved into *d*- and *l*-leucine by the fractional crystallisation of certain alkaloid salts of the benzoyl and formyl derivatives (*q.v.*) (Fischer, Ber. 1900, 33, 2370; Fischer and Warburg, *ibid.* 1905, 38, 3997).

Derivatives. *Salts.—Mercury salt*

$$(C_6H_{12}O_2N)_2Hg$$

formed by dissolving mercuric oxide in a solution of leucine (Gössmann, Annalen, 1854, 91, 134); *lead salt* $(C_6H_{12}O_2N)_2Pb,H_2O$ crystallises in leaves (Strecker, Annalen, 1849, 72, 90); *copper salt* $(C_6H_{12}O_2N)_2Cu$, small light blue crystals, soluble in 3045 parts of cold or 1460 parts of boiling water (Hofmeister, Annalen, 1877, 189, 16). The salts with acids are readily soluble; the two *hydrochlorides* $C_6H_{12}O_2N,HCl$ and $(C_6H_{12}O_2N)_2,HCl$ are described (Laurent and Gerhardt, Ann. Chim. Phys. [iii.] 34, 321; Schwanert, Annalen, 1857, 102, 222); the *nitrate* $C_6H_{12}O_2N,HNO_3$ (Laurent and Gerhardt); the *platinichloride* $(C_6H_{12}O_2N)_2,H_2PtCl_6$ forms a yellow crystalline precipitate.

Anhydride $(C_6H_{12}ON)_2O$ obtained together with its *dibenzoyl* derivative $(C_6H_{11}ON{\cdot}C_7H_5O)_2O$, m.p. 80°, by the action of benzoyl chloride on leucine at 100° (Destrem, Compt. rend. 1878, 86, 484). *The potassium salt of trimethylleucine iodide*

$$C_5H_{10}(NMe_3I)CO_2K$$

hygroscopic slender needles obtained by the action of methyl iodide and potassium hydroxide on leucine; the corresponding *chloro* compound forms a yellow *aurichloride*

$$C_6H_{11}O_2NMe_3Cl{\cdot}AuCl_3,$$

m.p. 163°, and an orange-yellow *platinichloride* $(C_6H_{11}O_2NMe_3Cl)_2PtCl_4$ (Koener and Menozzi Gazz. chim. ital. 1883, 13, 351).

Leucinimide (3:6-di*iso*butyl-2:5-diketopiperazine)

$$NH{<}\genfrac{}{}{0pt}{}{CH(C_4H_9)CO}{CO{\cdot}(C_4H_9)HC}{>}NH,$$

m.p. 271° (corr.), yields *leucyl-leucine*

$$NH_2{\cdot}CH(C_4H_9)CO{\cdot}NH{\cdot}CH(C_4H_9)CO_2H$$

on hydrolysis, this crystallises with $1\frac{1}{2}H_2O$, and melts slightly above 270° (Cohn, Zeitsch. physiol. Chem. 1900, 29, 283; Fischer, Ber. 1900, 33, 2370; 1902, 35, 1095; Salaskin, Zeitsch. physiol. Chem. 1901, 32, 592). *Ethyl ester* of *r-leucine* has b.p. 83·5°/12 mm., sp.gr. 0·929 at 17°; the *picrate* has m.p. 136° (corr.), and the *d-tartarte*, m.p. 145° (corr.); the *ethyl ester* of *l-leucine* has $[\alpha]_D^{20°} + 13{\cdot}1°$, and is not racemised on hydrolysis; it forms a *picrate*, m.p. 129·5° (corr.) (Fischer, Ber. 1901, 34, 433; *cf.* Röhmann, *ibid.* 1897, 30, 1978). When the ethyl ester of *r*-leucine is left in contact with water and crude pancreatin, it undergoes asymmetric hydrolysis, that is, the *l*-ester is hydrolysed, whilst the *d*-ester is not (Warburg, Ber. 1905, 38, 187). *n-Propyl ester* of *leucine* has b.p. 95°–96°/12 mm. (Warburg, Zeitsch. physiol. Chem. 1906, 48, 205).

r-Leucinamide $C_6H_{14}ON_2$, m.p. 106°–107° (corr.), is prepared by the action of liquid ammonia on the ethyl ester; the *β-naphthalene sulphonyl derivative* has m.p. 176°–178° (corr.); and *carbethoxy-dl-leucinamide* $C_9H_{18}O_3N_2$, m.p. 108°, readily yields *β-iso*butylhydantoin by shaking with sodium hydroxide (Koenigs and Mylo, Ber. 1908, 41, 4427).

The *ethyl ester* of *l-leucinecarbimide*

$$CO : N{\cdot}CH(CO_2Et)CH_2{\cdot}CHMe_2,$$

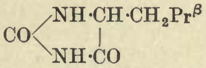
b.p. 120°–130°/18 mm. is formed together with *diethyl leucinecarbimide*

$$CO[NH{\cdot}CH(CO_2Et)CH_2{\cdot}CHMe_2]),$$

b.p. 180°–190°/18 mm. by the action of carbonyl chloride on the ethyl ester of leucine; *isobutylhydantoic acid*

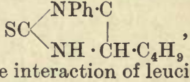
$$NH_2{\cdot}CO{\cdot}NH{\cdot}CH(CH_2Pr^\beta)CO_2H,$$

m.p. 200°–210° (with decomposition) is obtained by dissolving leucine in excess of carbamide at 130°–135°, and yields *isobutylhydantoin*



$$CO{<}\genfrac{}{}{0pt}{}{NH{\cdot}CH{\cdot}CH_2Pr^\beta}{NH{\cdot}CO}$$

m.p. 200°–210°, when heated at 150°; the *ethyl ester* of *isobutylhydantoic acid* is obtained by the action of ammonia on the ethyl ester of *l*-leucinecarbimide, and this on hydrolysis yields the free acid identical with the substance obtained by the action of carbamide on leucine; when aniline is substituted for ammonia the *acid* $NHPh{\cdot}CO{\cdot}NH{\cdot}CH(CH_2Pr^\beta)CO_2H$ is obtained, m.p. 115° (Hugounenq and Morel, Compt. rend. 1905, 140, 150, 505, 859). *Leucine phenylthiohydantoin*



$$SC{<}\genfrac{}{}{0pt}{}{NPh{\cdot}C}{NH{\cdot}CH{\cdot}C_4H_9},$$

m.p. 178°, is formed by the interaction of leucine and phenyl mustard oil in the presence of potassium hydroxide, and its formation affords a convenient method of isolating leucine from the crude material obtained by hydrolysing proteids (Röhman, Ber. 1898, 31, 2188).

Phthalylaminocaproic acid $C_{14}H_{15}O_4N$, prepared by fusing a mixture of phthalic anhydride and leucine, has m.p. 115°–116°; it is lævorotatory, and is converted into the racemic isomeride on dry distillation; the *platodiammonium salt* $Pt(NH_3{\cdot}NH_3C_{14}H_{15}ON)_2$ of the active acid contains $3H_2O$, that of the inactive acid $3\frac{1}{2}H_2O$. *Leucinephthaloic acid*

$$CO_2H{\cdot}C_6H_4{\cdot}CO{\cdot}NH{\cdot}CH(CO_2H)CH_2{\cdot}CHMe_2$$

is obtained by the partial hydrolysis of the preceding compound, the active acid melts and decomposes at 130°–137°, forming phthalylaminocaproic acid; the *potassium salt*

$$K_2C_{14}H_{15}O_5N$$

is crystalline and readily soluble; the *sodium salt* is amorphous; the *barium salt* is crystalline and sparingly soluble; the *platodiammonium salt* forms soluble rhombic plates; the amorphous *copper salt* is soluble in alcohol; the inactive *leucinephthaloic acid* has m.p. 152°–153°, and forms a crystalline *potassium* and an amorphous *silver salt* (Reese, Annalen, 1887, 242, 1; Ber. 1888, 21, 277). The *benzene sulphonic* derivative

$$SO_2Ph{\cdot}HN{\cdot}C_5H_{10}{\cdot}CO_2H$$

of *r*-leucine sinters at 140°, melts at 146° (corr.), and forms soluble crystalline alkali salts, and sparingly soluble lead and silver salts; the corresponding derivative of *d*-leucine crystallises in needles, m.p. 119°–120° (corr.), and has $[\alpha]_D^{20}-39°$ (Fischer, Ber. 1900, 33, 2370; 1901, 34, 449).

Benzoyl-r-leucine

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH{\cdot}COPh)CO_2H,$$

m.p. 137°–141° (corr.), can be resolved by means of its alkaloid salts, the cinchonine salt of the *d*- and the quinidine salt of the *l*-isomeride being sparingly soluble. *Benzoyl-d-leucine* melts at 105°–107° (corr.), dissolves in 120 parts of boiling water and has $[\alpha]_D^{20}$ $-6{\cdot}39$ in sodium hydroxide solution. *Benzoyl-l-leucine* melts at 105°–107° (corr.), has $[\alpha]_D^{20}+6{\cdot}59$ (Fischer, Ber. 1900, 33, 2370).

Formyl-r-leucine

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH{\cdot}CHO)CO_2H$$

forms octahedra, m.p. 115°–116° (corr.); *formyl leucylchloride* $C_4H_9{\cdot}CH(NH{\cdot}CHO)COCl$ is a crystalline powder. The *brucine* salt of formyl-*d*-leucine is sparingly soluble, and yields on decomposition *formyl-d-leucine*, crystallising in long thin prisms, m.p. 141°–144° (corr.), $[\alpha]_D^{20}$ $+18{\cdot}8°$ in 10 p.c. alcoholic solution. *Formyl-l-leucine* obtained from the more soluble leucine salt has the same melting-point as the *d*- compound and $[\alpha]_D^{20}-18{\cdot}5°$. For a description of the numerous *polypeptides* containing the leucyl radicle, *see* Fischer and Bargell, Ber. 1903, 36, 2592; Fischer and Brunner, Annalen, 1905, 340, 142; Fischer and Warburg, *ibid.* 152; Fischer and Koelker, *ibid.* 172; Fischer, Ber. 1905, 38, 2914; 1906, 39, 2893; Fischer and Steingroever, Annalen, 1909, 365, 167; Fischer and Gerngross, Ber. 1909, 42, 1485; Fischer and Gluud, Annalen, 1909, 369, 247; Fischer and Fielder, *ibid.* 1910, 375, 181; Abderhalden and Hirszowski, Ber. 1908, 41, 2840; Abderhalden, *ibid.* 1909, 42, 2331; Abderhalden, Hirsch, and Schuler, *ibid.* 1909, 42, 3394; 1910, 43, 907; Abderhalden and Weber, *ibid.* 1910, 43, 2429; Hans Fischer, *ibid.* 1909, 42, 4320; Krause, Monatsh. 1908, 29, 1119; Hopwood and Weizmann, Chem. Soc. Trans. 1911, 99, 574, 1579).

Decomposition.—Experiments conducted on dogs show that leucine, like other amino acids, can replace ammonium salts in the formation of urea (Salaskin, Zeitsch. physiol. Chem. 1898, 25, 128). Leucine as well as tyrosine is assimilated by certain plants such as *Algæ* (Loew and Bokorny, J. pr. Chem. 1887 [ii.] 36, 279; Schulze, Landw. Versuchs. Stat. 1901, 56, 97), *Cucumis* species *Aspergillus niger*, *A. repens*, *Penicillium glaucum* (Lutz, Compt. rend. 1905, 140, 380). Yeast poor in nitrogen develops rapidly in a sugar solution containing leucine; when racemic leucine is employed the fermentation proceeds at the expense of both optical isomerides, but the natural *l*-leucine is destroyed much more rapidly than the *d*-leucine, which can thus be recovered to the extent of 76 p.c. of the theoretical quantity at the end of the reaction (Ehrlich, Zeit. Ver. deut. Zuckerind, 1906, 608, 840). The degradation of amino acids in the plant and animal economy appears to be deamidisation and oxidation of the terminal carbon atom (Sachs, Biochem. Zeitsch. 1910, 27, 27), this would lead in the case of leucine to the formation of ammonia and amyl alcohol; and Ehrlich (Ber. 1906, 40, 1027) is of opinion that the occurrence of fusel oil during alcoholic fermentation is due to the hydrolysis of *l*-leucine and *d*-*iso*leucine according to the equations:

$$CHMe_2{\cdot}CH_2{\cdot}CH(NH_2)CO_2H+H_2O$$
$$=CHMe_2{\cdot}CH_2{\cdot}CH_2{\cdot}OH+CO_2+NH_3$$
$$CHMeEt{\cdot}CH(NH_2)CO_2H+H_2O$$
$$=CHMeEt{\cdot}CH_2{\cdot}OH+CO_2+NH_3$$

On oxidation with hydrogen peroxide leucine yields *iso*valeraldehyde, *iso*valeric acid, ammonia and carbon dioxide; on further oxidation acetone is formed from *iso*valeric acid, the reaction closely resembling several biochemical reactions in which leucine takes part (Dakin, J. Biol. Chem. 1908, 4, 63).

By the action of nitrous acid leucine is converted into leucic acid (α-hydroxycaproic acid) (Strecker, Annalen, 1848, 68, 55); and on reduction with hydriodic acid yields caproic acid and ammonia (Hüfner, Zeitsch. Chem. 1868, 391).

Separation and *detection.*—A mixture of leucine and tyrosine is readily separated by the aid of boiling glacial acetic acid in which the leucine is fairly (29·23 at 117°) and the tyrosine very sparingly soluble (0·18 at 117°) (Habermann and Ehrenfeld, Zeitsch. physiol. Chem. 1902, 37, 18). To separate tyrosine, leucine, and valine, Levene and Jacobs (Biochem. Zeitsch. 1908, 9, 231) recommend the following method. The mixture is treated with bromine, and the bromo derivative of the tyrosine removed by means of amyl alcohol; the valine and leucine are crystallised from the mother liquor, redissolved, and the leucine precipitated by lead acetate and ammonia. On decomposing the lead precipitate with sulphuretted hydrogen, leucine and *iso*leucine are obtained and can be separated by extracting the copper salts with methyl alcohol in which the copper derivative of *iso*leucine is soluble. Glutamic acid and leucine can be separated by saturating the solution with hydrogen chloride when the insoluble hydrochloride of glutamic acid is precipitated (Étard, Compt. rend. 1901, 133, 1231).

*d-iso***Leucine,** *α-amino-β-methylvaleric acid* $CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H$ was discovered by Ehrlich (Zeit. Ver. deut. Zuckerind. 1903, 571, 809; Ber. 1904, 37, 1809) in the mother liquor of the beet sugar manufacture to which the strontia desaccharification process had been applied; it is separated from the *r*- and *l*-leucine that occur with it by the aid of its copper salt which dissolves freely in methyl alcohol, the corresponding salt of leucine being only sparingly soluble. *iso*Leucine has also been isolated from the products of hydrolysis obtained by digesting blood fibrin with pancreatic juice, from the hydrolytic products of ovalbumin, from the crude leucine obtained by the putrefaction of beef (Ehrlich, *l.c.*); and from the products of hydrolysis of casein (Weitzenböck, Monatsh. 1906, 27, 831). It is probable indeed that *d-iso*leucine occurs invariably along with *l*-leucine as a primary product of proteid hydrolysis (Ehrlich, *l.c.*; Ehrlich and Wendell, Biochem. Zeitsch. 1908, 8, 399).

*d-iso*Leucine crystallises in shining rods or leaflets, which melt and decompose at 280° when heated in a closed tube; it has $[\alpha]^{20}_{D}+9{\cdot}74$ in aqueous, $+36{\cdot}80$ in 20 p.c. hydrochloric acid, or $+11{\cdot}1°$ in alkaline solution, and dissolves in 25·84 parts of water at 15·5°, the solution having a bitter taste. It is completely racemised and partially converted into *alloisoleucine* after heating for 20 hours at 180° with barium hydroxide solution (Ehrlich, Ber. 1904, 37, 1809).

Locquin (Bull. Soc. chim. 1907, [iv.] 1, 595, 601) finds slightly different physical constants for the synthetic *d*- and *l-iso*leucine; both compounds crystallise from water in brilliant spangles, and have m.p. 280°–290°; *l-iso*leucine has $[\alpha]^{20}_{D}-10{\cdot}55$ in aqueous, $-31{\cdot}37°$ in dilute or $-40{\cdot}86°$ in concentrated hydrochloric acid solution, and *d-iso*leucine has $[\alpha]^{20}_{D}+11{\cdot}29$ in aqueous or $+40{\cdot}61°$ in concentrated hydrochloric acid solution.

When *d-iso*leucine is subjected to dry distillation it yields partially racemised *d*-amylamine $CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH_2{\cdot}NH_2$, together with *iso*leucinimide; and it is decomposed by yeast growing in a sugar solution to form *d*-amylalcohol

$$CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H+H_2O$$
$$=CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH_2{\cdot}OH+NH_3+CO_2$$

It follows, therefore, that *iso*leucine is α-amino-β-methylvaleric acid, and this view of its constitution is confirmed by various synthetic preparations. (1) Bouveault and Locquin (Compt. rend. 1905, 141, 115) prepared an inactive leucine from ethyl *sec*butylacetoacetate

$$CHMeEt{\cdot}CHAc{\cdot}CO_2Et,$$

this yields ethyl α-oximino-*sec*butylacetate (α-oximino-β-methylvalerate)

$$CHMeEt{\cdot}C(NOH){\cdot}CO_2Et$$

by the action of nitrosylsulphate, which on reduction is converted into the inactive leucine $CHMeEt{\cdot}CH(NH_2)CO_2H$. On resolving this compound by the fractional crystallisation of the leucine salt of its formyl derivative, *d-iso*leucine was obtained, identical with Ehrlich's natural product (Locquin, Bull. Soc. chim. 1907, [iv.] 1, 595, 601). (2) Ehrlich (Ber. 1907, 40, 2538) synthesised *iso*leucine from *d*-amylalcohol $CHMeEt{\cdot}CH_2{\cdot}OH$, by the following series of reactions, the *d*-amylalcohol was oxidised to *d*-valeraldehyde $CHMeEt{\cdot}CHO$, which was converted by the action of ammonia and hydrogen cyanide into aminovaleronitrile $CHMeEt{\cdot}CH(NH_2)CN$, and this, on hydrolysis, gave a mixture of *d-iso*leucine and *alloisoleucine* $CHMeEt{\cdot}CH(NH_2)CO_2H$. Allo*iso*leucine is a stereoisomide of *iso*leucine, which contains two asymmetric carbon atoms; it closely resembles *iso*leucine in its external appearance, and in the properties of its derivatives; it has, however, a sweet taste, is lævorotatory, $[\alpha]^{20}_{D}-14{\cdot}4$ in aqueous and $-36{\cdot}95$ in hydrochloric acid solution; and it dissolves in 34·2 parts of water at 20°. (3) Using Fischer's method (Ber. 1906, 39, 351), Ehrlich (*ibid.* 1908, 41, 1453) has synthesised racemic *iso*leucine from secondary butyl iodide and ethyl malonate; on hydrolysing the condensation product of these two compounds, Rombурgh's *sec*butylmalonic acid is obtained; this on bromination yields bromo-*sec*butylmalonic acid $CHMeEt{\cdot}CBr(CO_2H)_2$, which decomposes when distilled under reduced pressure yielding α-bromo-β-methylvaleric acid

$$CHMeEt{\cdot}CBr{\cdot}CO_2H,$$

on treating this compound with ammonium hydroxide it is converted into racemic *iso*leucine, m.p. 275° in a closed tube. The same synthesis was made by Brasch and Friedmann (Beitr. Chem. Physiol. Path. 1908, 11, 376).

Derivatives. *Salts.*—*d*-iso*Leucine-hydrochloride* forms stellate needles; the *copper salt* $C_{12}H_{22}O_4N_2Cu$ is deep blue and crystalline, dissolves in 278 parts of water at 17°, in 476 parts of 99 p.c. alcohol, and in 55 parts of methyl alcohol at 17°; the *silver salt* is white flocculent and crystalline; the *lead salt* is strongly lævorotatory.

Acyl derivatives of (1) *r-iso*leucine, the *formyl* derivative has m.p. 121°–122°; the *benzoyl* derivative has m.p. 79°, and b.p. 211°/15 mm.; the *benzenesulphonyl* derivative has m.p. 169°; and the *p-toluenesulphonyl* derivative has m.p. 139°. (2) *d-iso*Leucine, *formyl* derivative forms fine translucent crystals from water, m.p. 156°–157°, $[\alpha]^{20}_{D}+28{\cdot}26$; *benzoyl* derivative, m.p. 116°–117°, $[\alpha]^{20}_{D}+26{\cdot}36°$ in alkaline solution; *benzenesulphonyl* derivative, m.p. 149°–150°, $[\alpha]^{20}_{D}-12{\cdot}04°$ in alkaline solution; the *phenylisocyanate*, m.p. 119°–120°, $[\alpha]^{20}_{D}+14{\cdot}92$ in alkaline solution; the *phenylhydantoin* has m.p. 78°–79°; *leucinimide* (*iso*-2 : 5-*diketo*-3 : 6-*diisobutylpiperazine*)

$$CHMeEtCH\left\langle\begin{matrix}CO{\cdot}NH\\NH{\cdot}CO\end{matrix}\right\rangle CH{\cdot}CHMeEt$$

forms slender needles, m.p. 280°–281°, and is slightly dextrorotatory in alcoholic solution. (3) *l-iso*Leucine, *formyl* derivative has m.p. 156°–157°, and has $[\alpha]^{20}_{D}-27{\cdot}76°$ in alcoholic solution; the *benzoyl* derivative has m.p. 118° and $[\alpha]^{20}_{D}-26{\cdot}03$ in *N*/2 sodium hydroxide. For the description of *polypeptides* containing the *iso*leucine radicle, *see* Abderhalden, Hirsch, and Schuler, Ber. 1909, 42, 3394; 1910, 43, 907.

n-**Leucine**, *α-amino-n-hexoic acid*

$$CH_3[CH_2]_3CH(NH_2)CO_2H$$

has not been isolated from the products of hydrolysis of proteins, but *n*-valeric acid is formed when casein is oxidised by bromine (Skraup and Witt, Monatsh. 1906, 27, 663), and this suggests the presence of *n*-leucine in casein. Further evidence in favour of this suggestion was obtained by Heckel (Monatsh. 1908, 29, 15), who found that by oxidising with potassium permanganate that fraction of the leucine esters from casein least soluble in hydrochloric acid, a mixture of acids was obtained about one half of which was *n*-valeric acid. Samee (Monatsh. 1908, 29, 55) also obtained a similar result, using the leucine obtained from the neck band of the ox. Kudielka (Monatsh. 1908, 29, 351) has prepared *n*-leucine by Fischer's method (Ber. 1900, 33, 2320) from both natural and synthetic *n*-hexoic acid, using Kahlbaum's preparation; 100 parts of the former gave 37 parts of *n*-leucine, whilst 100 parts of the latter gave only 6 parts. Racemic *n*-leucine melts at 290° (corr.) in a closed tube. The *copper* salt forms pale blue leaflets, the *nickel* salt is greenish-blue, the *cobalt* salt crystallises in red leaflets; the methylated base yields a yellow *aurichloride* $C_9H_{19}O_2N,HAuCl_4$, m.p. 142°.

The resolution of racemic *n*-leucine has been effected by Fischer and Hagenbach (Ber. 1901, 34, 3764) by the fractional crystallisation of the cinchonine salt of the benzoyl derivative. The *benzoyl* derivative of racemic *n*-leucine has m.p. 134° (corr.); l-*benzoyl*-n-*leucine* crystallises with $\frac{1}{2}H_2O$, has m.p. 53° (corr.), and $[\alpha]_D^{20°}-21{\cdot}9$ in aqueous solution; lævo n-*leucine* prepared from this has $[\alpha]_D-22{\cdot}4$; *d-benzoyl*-n-*leucine* has $[\alpha]_D+21{\cdot}4°$, and dextro n-*leucine* has $[\alpha]_D+21{\cdot}3°$.

Marko (Annalen, 1908, 362, 333) has similarly separated *d*- and *l*- *n*-leucine from the racemic compound by crystallising the brucine salt of the formyl derivative of the racemic compound. *r-Formyl*-n-*leucine* has m.p. 113°–115° (corr.); *l-formyl*-n-*leucine* has m.p. 115°–118·5° (corr.), and $[\alpha]_D^{20}-17{\cdot}56°$; *lævo* n-*leucine* has $[\alpha]_D^{20}-22{\cdot}99°$, *d-formyl*-n-*leucine* has $[\alpha]_D^{20}+17{\cdot}63$, and yields *dextro* n-*leucine* $[\alpha]_D^{20}+23{\cdot}14°$. M. A. W.

LEUCITE. A volcanic mineral consisting of potassium aluminium silicate $KAl(SiO_3)_2$, found as grey crystals with the external form of the cubic icositetrahedron (211). Optical examination of the crystals in thin sections shows them to be birefringent and to consist of a complex intergrowth of twin-lamellæ. At a temperature of 714° the material is optically isotropic and truly cubic, and in the red-hot lavas it, no doubt, grew as a cubic crystal. Sp.gr. 2·47; H. 5½. The mineral occurs abundantly as embedded crystals in the alkali-rich lavas of certain districts, *e.g.* Vesuvius, Rome, and the Eifel. It is decomposed by hydrochloric acid, and is readily affected by weathering processes. Containing a considerable amount of potash (K_2O, 21·5 p.c.), attempts have been made to employ this mineral as a source of potassium salts and as a fertiliser. L. J. S.

LEUCOMAÏNES *v.* PTOMAÏNES.

LEVANT SAPOTOXIN *v.* GLUCOSIDES.

LEVIGATION. Levigation is the mechanical process by which hard substances are reduced to a very fine powder by grinding them with water. The process is used principally in the preparation of pigments. On a small scale the substance is ground with a 'muller.' The muller is a piece of hard stone, convenient in shape and size to hold in the hand, and carefully flattened and polished on one side. The pigment to be ground is mixed with water on a large square slab of stone, preferably marble, and then ground with the muller. The finest artists' colours are ground in this way. On the large scale the pigment is first thoroughly mixed with water in a pug-mill. It is then ground between millstones similar to those used for flour, or under edge runners. Sometimes the millstones are replaced by three horizontal granite rollers, between which the pigment is ground. A mill with stones 2 feet in diameter will grind 15 cwt. of paint in 11 hours.

LEVULIN *v.* DANDELION ROOT.

LEVULOSE, LÆVULOSE *v.* CARBOHYDRATES.

LEVURETIN, LEVURINOSE *v.* SYNTHETIC DRUGS.

LIBAVIUS, FUMING LIQUOR OF. *Stannic chloride* $SnCl_4$ (*v.* TIN).

LICHENIN *v.* GUMS.

LICHENS. According to modern ideas these curious and interesting plants are of a compound character, and are considered to be algæ upon which fungi are supported. Many species have been employed from the earliest times in medicine, dyeing, and as foodstuffs (Mémoires sur l'utilité des lichens, par Hoffmann, Amoreux et Willemet, Lyon, 1787). From about the year 1300 certain species have been employed for the production of the purple dyestuff 'archil' or 'orchil,' since, as shown by modern researches, they contain colourless principles, derivatives of orcin, which under the influence of ammonia and atmospheric oxygen yield the purple colouring matters known as orcein (*v.* ARCHIL). Under the name of *Crottle* or *Crotal*, with various descriptive prefixes, several species have been, and still are to a very limited extent, directly applied in dyeing buff and brown colours on homespun yarn in the Highlands of Scotland, Wales, &c. Those lichens, *e.g.* Iceland moss (*Cetraria islandica*, Ach.), which serve as foodstuffs, contain a starch-like substance termed *lichenin*, which is capable of conversion into glucose.

Our earlier chemical knowledge of the constituents of many of these lichens is mainly due to the work of Knop, Rochleder, Heldt, Schunck, Schmidt, Stenhouse, Stenhouse and Groves, and Weppen, whereas for the later very numerous investigations we are chiefly indebted to the chemists Oswald Hesse and Wilhelm Zopf. As a result, a very large number of new compounds have been isolated and described, the constitutions of which in most cases, however, are as yet undecided. On the other hand, considerable advance has been made as regards the exact structure of some of the more common constituents, viz. atranorin (atranoric acid), barbatic acid, evernic acid, erythrin (erythric acid), lecanoric acid, and ramalic acid, and the chemistry of these substances is dealt with under their special headings.

As the work of Hesse (H.) is mainly to be found in the Journal für praktische Chemie, and that of Zopf (Z.) in the Annalen, to avoid frequent repetition the year only of the papers published in the journals is noted below.

Trachylia tigillaris, Fr. (*Acolium tigillare*; *Calicium tigillare*, *Cyphelium tigillare*), rhizocarpic acid $C_{28}H_{20}O_7$ (H.), m.p. 177°–178°, and acolic acid (H. 1900).

Acarospora chlorophana, rhizocarpic acid, pleosidic acid $C_{17}H_{28}O_4$, m.p. 131°–132° (Z. 1903).

Alectoria implexa, Nyl. (*A. cana*), zeorin, salazinic acid (Z. 1898). *A. ochroleuca*, usnic acid $C_{18}H_{16}O_7$, and barbatic acid (Z. 1899). *A. sarmentosa*, usnic acid (Z. 1900). *A. jubata*, var. *implexa*, salazinic acid, alectoric acid $C_{28}H_{24}O_{15}$, m.p. 186°. *A. articulata*, *d*-usnic acid, usnaric acid

$C_{30}H_{22}O_{15}$, m.p. 240°–260°. *A. canariensis*, *d*-usnic acid, usnaric acid (H. 1902). *A. implexa*, atranorin (H. 1906).

Anaptychia ciliaris, atranoric acid (atranorin). *A. speciosa*, atranorin, zeorin $C_{52}H_{88}O_{4}$ (Z. 1895–1897).

Aspicilia calcarea, erythric acid, oxalic acid, aspicilin, m.p. 178·5° (H. 1900). *A. gibbosa*, aspicilic acid, m.p. 150° (H. 1904).

Baeomyces roseus, an acid, m.p. 180° (H. 1898).

Biatora lucida, rhizocarpic acid $C_{28}H_{20}O_7$, atranorin (Z. 1897; H. 1907); no usnic acid (*cp.* Knop, 1843). *B. mollis*, diffusic acid (Z. 1905). *B. Lightfootii*, *l*-usnic acid (Z. 1906). *B. grandulosa*, gyrophoric acid $C_{16}H_{14}O_7$ (Z. 1906).

Blastenia arenaria (*Callopisma erythrocarpa*), phytosterol, blasterin, m.p. 170° (H. 1898). *B. arenaria*, atranorin, gyrophoric acid $C_{16}H_{14}O_7$ (H. 1898). *B. Jungermanniæ*, parietin (Z. 1906).

Calycium crysocephalum, vulpic acid (H. 1898; Z. 1895). *C. chlorinum* or *chlorellum*, vulpic acid (Z. 1895); pulvic acid and traces of leprarin $C_{19}H_8O_9$ (Kassner, Arch. Pharm. 239, 44; H. 1900). *C. flavum*, chyrsocetraric acid $C_{19}H_{14}O_6$ (H. 1900). *C. Stenhammari*, calycin $C_{18}H_{12}O_5$ (Z. 1895).

Callopisma flavovirescens, chrysophanic acid, physcion $C_{16}H_{12}O_5$ (H. 1902). *C. vitellinum*, calycin (Z. 1895); callopismic acid and mannitol (Z. 1897).

Rhizocarpon oreïtes, A. Zahlbr. (*Catocarpus oreïtes*), rhizocarpic acid $C_{28}H_{20}O_7$, psoromic (parellic) acid, $C_{21}H_{16}O_9$ (Z. 1905).

Cetraria cucullata (*Platysma cucullatum*), protolichesteric acid $C_{18}H_{32}O_5$ (Z. 1902). *C. chlorphylla*, protolichesteric acid and atranorin (Z. 1902). *C. complicata*, protocetraric acid $C_{30}H_{22}O_{15}$, *l*-usnic acid, and atranorin.

Cetraria islandica contains starch not deposited in granules, but uniformly distributed among the cells (lichenin). The lichenin, which is convertible into sugar, is present in such large quantity that this lichen can be used for food (Schmidt, Annalen, 51, 29). There is also said to be present cetraric acid, lichenstearic acid (Knop and Schaedermann, Annalen, 55, 114), protocetraric acid, and proto-*a*-lichesteric acid Z. 1902; H. 1903 and 1904), *a*-lichenostearic acid $C_{18}H_{30}O_5$ (m.p. 122°–123°), *β*-lichenostearic acid $C_{18}H_{20}O_5$ (m.p. 121°), *γ*-lichenostearic acid $C_{18}H_{30}O_5$ or $C_{19}H_{32}O_5$ (m.p. 121°–122°), paralichenostearic acid $C_{20}H_{34}O_5$, dilichenostearic acid $C_{36}H_{60}O_{10}$, and cetraric acid $C_{26}H_{20}O_{12}$ (H. 1898).
