Portfolio Assessment in the Classroom

Muchun Yin

Indiana Wesleyan University, USA

Perhaps the greatest theoretical and practical strength of a portfolio, used as an assessment instrument, is the way it reveals and informs teaching and learning. (Hamp-Lyons & Condon, 2000, p. 4)

Introduction

The assessment of portfolios—collections of student work—has increasingly been seen as an important means of optimizing and strengthening the connection between teaching, learning, and assessment. Portfolio assessment (PA) is not one specific method of assessment, but rather a general assessment strategy or approach that affords a great deal of flexibility in implementation (Hamp-Lyons & Condon, 2000). In fact, any examination of PA beyond a cursory one reveals a vast diversity in what comprises portfolios, how they are implemented, and how they are assessed, even in language classrooms. It can be said that this diversity results from different permutations of a myriad of decisions made (in this case) by language teachers in the process of conducting PA. This chapter takes as a central premise the view that teachers are “agents of assessment” (Rea-Dickins, 2004) who, while obviously working within the constraints of given educational programs, institutions, and systems, still wield much decision-making power over what and how they assess in their classrooms.

This chapter begins with common characteristics of PA and a brief history, from PA’s earlier identity as an “alternative assessment” to its significant role in current assessment regimes in both general and language education. This is followed by a review of research on the effectiveness of PA for improving language learning and on students’ and teachers’ views of portfolio use in language classrooms. A conceptual distinction is made between the portfolio “product” on the one hand and

the portfolio implementation “process” on the other, with the latter being the determinant of usefulness. Developing the central premise of teachers as assessment agents, the chapter then considers both macro- and micro-level decisions involved in the implementation process, and outlines challenges and future directions.

Basic Characteristics

In order to help readers better understand the rest of this chapter, an example of PA in a language classroom is described below:

Brenda teaches an academic writing course in a university-affiliated English language center in the USA. By the end of the course, it is hoped that students will be able to execute common types of expository writing required in undergraduate coursework—in this case, cause–effect, compare–contrast, classification, problem solution, and extended definition. Brenda spends about 2–3 weeks on each type of writing. During each unit, she has students write a first draft, which receives comments from peers and the teacher, then has them revise and turn in a second draft. She gives comments on the second drafts and returns them to students. At the beginning and end of each unit, Brenda reminds her students to keep together and *collect* their first and second drafts. Several weeks before the end of the term, Brenda tells her students to *select* what they think are their three best essays, put them in a folder, and turn them in for grading. She adds that these three essays can be revised once more before they are turned in. Brenda also requires her students to write an essay, also graded, in which they *reflect* upon why they chose those three essays, what they have learned during the term, and what they believe are their strengths and weaknesses in writing.

The above example describes only one of the many ways of implementing PA, but it does feature the three general characteristics that define it: collection, selection, and reflection (Hamp-Lyons & Condon, 2000; Cummins & Davesne, 2009; Duong, Cuc, & Griffin, 2011). At a basic level, PA refers to the assessment of a *collection* of multiple pieces (also known as artifacts) of student work (such as essays, book reports, poems, or recorded speech) that the student has *selected* and has provided *reflection* on in terms of what he or she has learned or achieved. While it is conceivable to have assessment of a portfolio with only the first two characteristics, many writers consider the third to be the *sine qua non* of PA; O’Malley and Valdez Pierce (1996) go so far as to state that “without self-assessment and reflection on the part of the student, a portfolio is not a portfolio” (p. 35).

Hamp-Lyons and Condon (2000) expand these three characteristics into a list of nine related ones. While the authors are referring to writing portfolios, the list of characteristics is applicable to portfolios of other abilities as well.

1. Portfolios consist of a *collection* of more than one performance.
2. Collection allows a *range* of performances, rather than only the single performance of a traditional exam.
3. The range of performances, which have been completed under different constraints over a period of time, thus displays *context richness*. That is, the context in which learning takes place is represented by the portfolio.

4. Because collection, selection, and reflection take time, portfolios often involve *delayed (summative) evaluation*. This gives students the opportunity to revisit and improve earlier work, and teachers the opportunity to focus on formative feedback rather than solely summative grades or scores.
5. Range, context richness, and delayed evaluation allow *selection* of the learner's works that best represent his or her achievement.
6. When teachers delay summative evaluation and give students a degree of latitude over selection, *student-centered control* results. Such control over their portfolio process and content can enable students to see the value of effort and time on task in affecting their summative outcomes.
7. It is hoped that as their control and decision making over their portfolios increase, learners will become more explicitly aware of their learning. This *reflection and self-assessment* can lead to further learning.
8. The selected works can display *growth along specific parameters*—in assessment terms, the construct(s) to be evaluated. These are usually articulated in grading criteria that the learner can self-assess on.
9. Given the characteristics above, portfolios also show a learner's *development over time*. This development can be across assignments, within one assignment, or both; multiple assignments in the collection can be seen as snapshots taken over the duration of the class, while the inclusion of revisions (e.g., multiple drafts of one essay) can show change within one assignment.

While not usually seen as an inherent one, *scale* is an important characteristic of PA that influences if not absolutely determines many of the other characteristics. Portfolios can be used at the scale, or level, of the classroom, up through the program, the school or institution, or beyond (e.g., district, state, nation) (O'Malley & Valdez Pierce, 1996; Hamp-Lyons & Condon, 2000; Klenowski, 2002). This chapter focuses on the classroom level, thus emphasizing decisions that need to be made by the classroom teacher. At each progressively larger scale, the decisions multiply, becoming a process that is increasingly complex and political as the number of stakeholders grows. This can be negative, frustrating teachers and twisting the original intentions of PA (Klenowski, 2002), although not necessarily so. For instance, Hamp-Lyons and Condon (2000) give examples of how implementing PA offered writing program teachers the opportunity, as part of the decision-making process, to discuss a variety of views and experiences about aspects of their work, leading to professional growth and a stronger sense of community. PA beyond the classroom is beyond the scope of this chapter, but large-scale PA has drawn much attention in recent years (see history below), so interested readers are encouraged to read the cited works and explore the growing literature on this topic.

A Brief History of PA

The origins of PA in education have been attributed to various sources, such as John Dewey's (1933) *How We Think: A Restatement of the Relation of Reflective Thinking to the Educative Process* (cited in Cummins & Davesne, 2009, p. 849), and Pat

Belanoff and Peter Elbow's (1986) report of writing portfolio implementation at the State University of New York at Stony Brook (cited in Hamp-Lyons & Condon, 2000). Interest in PA started in the assessment of English language arts and writing and was later taken up by researchers and practitioners in language teaching. Two books focused on language classroom assessment that were published in the same year—O'Malley and Valdez Pierce (1996) and Genesee and Upshur (1996)—both discuss PA at some length; their publication indicates a kind of solidification of early efforts to apply PA in language teaching.

While PA can conceptually align with a variety of pedagogical approaches or views (see below), it aligns especially well with a cluster of several significant educational trends, leading to PA's growth and popularity. These trends include:

- the increase of process-oriented approaches to writing pedagogy (Hamp-Lyons, 2006; Romova & Andrew, 2011). Process approaches to writing emphasize formative feedback on multiple revisions, and portfolios act as a forum within which such feedback and revisions can occur.
- the move from fixed response testing toward performance assessment, as concerns have grown about washback and the (mis)alignment between curriculum and assessment. As noted in the previous section, the characteristics of a portfolio are such that a range of student performances across the duration of a course can be represented.
- specifically relevant for this chapter, the spread of communicative language-teaching methodologies. These methodologies emphasize the socially appropriate use of language (i.e., for "real life"), and PA affords the collection of students' linguistic performances over a range of social contexts for a variety of purposes (Cummins & Davesne, 2009).
- the widening influence of sociocultural or social constructionist theories of learning (Gipps, 2002; Klenowski, 2002). In these views, learning is a process of development and construction of understanding, usually through the interaction of others such as peers and teachers. In PA, learners have the opportunity to reflect on and review their progress, and to receive significant feedback from others that can help further growth.

Like the above trends, PA has been typically portrayed as an innovation, with the benefits and challenges that that entails. For example, in their account of PA for writing classes at the University of Michigan, Willard-Traub, Decker, Reed, and Johnston (1999) tell of their development of PA over a six-year period that brought benefits to students and teachers but ultimately ended due to administrative decisions to cut budgets and reorganize the writing program. Song and August (2002) describe in their study how PA was introduced into one course within a sequence of courses for developmental English writers at a New York community college, and how school trustees only allowed PA for course exit, requiring scores from the ACT (a standardized exam used primarily for decisions on admission to many American universities) for exit from the sequence. Where PA has been accepted at the systemic level (e.g., the US states of Kentucky and Vermont), it has been seen as having to struggle against tendencies to return to traditional forms of assessment, such as standardized tests. In English as a foreign

language (EFL) contexts, too, the literature on PA suggests that it has been introduced at classroom and program level, not at institutional or systemic level, and not without difficulty (Aydin, 2010; Lo, 2010; Duong et al., 2011).

With the rise of digital and online technologies, the use of electronic portfolios, or e-portfolios, has also increased in educational contexts. E-portfolios have been characterized as using “electronic technologies as the container, allowing students/teachers to collect and organize portfolio artifacts in many media types (audio, video, graphics, text) and using hypertext links to organize the material, connecting evidence to appropriate outcomes, goals, or standards” (Barrett, 2005, cited in Cheng, 2008, p. 100). There has also been an increasing number of projects involving the development of e-portfolios for large-scale formative and low stakes summative assessment of language; most prominent are the European Language Portfolio and its American counterparts *LinguaFolio* and the *Global Language Portfolio* (see Cummins & Davesne, 2009, for an overview of these three projects).

In very broad terms, the current state of PA can be described in this way: it is used by teachers individually, in programs with varying degrees of cooperation across teachers (i.e., on one end, some programs have specific PA requirements for all teachers, with unified grading, while on the other end, some programs require teachers to use PA but with much freedom in implementation, without unified grading), and in some systems, such as in specific states in the USA (e.g., Kentucky and Vermont) or administrative areas like Hong Kong. A phenomenon to be seen is that the larger the scale of implementation, the greater the emphasis on summative uses and reporting, and the less the emphasis on formative uses. In addition, in situations where PA serves summative purposes, it is typical for PA results to go alongside results of external exams as evidence of student achievement (Klenowski, 2002).

Effectiveness of PA in Language Classrooms

Many claims about the benefits of PA have been made, usually related to the educational trends outlined earlier. However, as Duong et al. (2011) point out, the claims are often taken for granted without empirical evidence. Therefore, some of the main claims are set out below, with supporting evidence drawn from empirical studies conducted in language classrooms.

Benefits of PA: Empirical Evidence

Probably the most outstanding claim about PA’s effectiveness is that it enables the matching of the means of assessment with the goals of a curriculum, especially as opposed to external or one-shot exams that do not match what teachers have taught. Song and August (2002) report that as teachers in their developmental writing program (including English as a second language [ESL] writers) shifted toward process-oriented pedagogy, they wanted to replace a timed essay exam with a more appropriate method of assessment; when PA was introduced, both teachers and students stated that it seemed to be more suitable and fairer than the timed exam. In Lam and Lee’s (2010) study involving an academic English writing

course that implemented PA in a Hong Kong university, among the benefits of PA expressed by students and teachers were that it promoted more critical thinking and allowed more time for research. In addition, Romova and Andrew (2011) collected focus group and reflective writing data from an academic writing course for English as an additional language (EAL) students at a New Zealand university, and it is clear that many of the benefits expressed by students matched the course's process- and genre-oriented curriculum goals.

Another claim is that PA improves language abilities. Foremost are writing-related abilities (since most PA has been in relation to writing courses). At the very least, Song and August (2002) found that ESL students taking a writing course implementing PA fared no worse in the next course of the sequence than students who had taken the equivalent course but without PA. Hong Kong students in Lam and Lee's (2010) study stated that through the portfolio process, their linguistic accuracy and their ability to generate more ideas improved. According to Romova and Andrew's (2011) EAL participants, PA helped them improve their planning and editing of writing. In addition, in a study using PA with six first-year students in an advanced English reading and writing course at a Turkish university, Yayli (2011) had participants collect their writing in several genres—e-mail, recipe, vita, complaint letter, and essays. Students stated that they were able to transfer learning from one genre to another, evidence of increased "cross-genre awareness" (p. 127). Some evidence exists for the effectiveness of PA in improving language skills more generally as well. In Aydin's (2010) study of English language teaching department students at a Turkish university, participants reported that keeping portfolios in their writing course helped their vocabulary, grammar, reading, research, and rhetorical skills. Using a quasi-experimental design, which is rarely found in PA research, Barootchi and Keshavarz (2002) compared two English classes of 30 Iranian high school students each, with the teachers—who taught both classes—implementing PA in one and not the other. Both classes had equivalent proficiency at the beginning and were given an achievement test at the end measuring spelling, vocabulary, grammar, pronunciation, language function, and reading comprehension; the researchers found that the PA class had a statistically significant higher average than the other class on the achievement test, and that students' portfolio scores given by raters had a high correlation with their achievement test scores.

A prominent claim for PA is that it increases students' self-reflection, autonomy, and metacognition. In terms of evidence for this claim, Lam and Lee (2010) found that their Hong Kong students felt that PA gave them more autonomy to choose their best work to be graded. Similarly, the 75 Taiwanese junior high school students in Chen's (2006) study felt that "compiling portfolios helped immensely in self-reflection; they examined their growth by reviewing what they experienced in learning and became aware of their strengths and weaknesses" (p. 80). Nunes (2004), in a study of tenth-grade students taking an EFL class in a Portuguese high school, found that they expressed reflections in four main areas—about the syllabus, about instruction, about their learning, and about assessment—and that "the students' reflections revealed different levels of complexity, from a more elementary level of thought to a higher level of metacognition" (p. 333). Students in Romova and Andrew's (2011) study also made statements exhibiting reflectiv-

ity, such as “For me . . . the reflection stage was special as it was new . . . You need to think about why you repeat a mistake,” and “Because of reflection . . . I come to know myself” (pp. 118–19).

In line with sociocultural theories of learning, it is claimed that PA increases communication between students and teachers. Lam and Lee (2010) did find that students felt their portfolio-based writing classroom provided a supportive learning environment through means such as ongoing teacher feedback. Also, one of the main themes arising from the data in Romova and Andrew (2011) was students’ appreciation of teacher feedback on a variety of aspects of their writing.

It is also claimed that PA can increase students’ motivation. Teacher feedback in the process of PA is one primary motivator, as Romova and Andrew (2011) found; one student stated “I always look forward to getting the teacher’s feedback to see if it is the same with what I thought about my text. It gives me confidence when I am able to find flaws myself and I quite like redrafting” (p. 119). Lam and Lee (2010) found that increased autonomy, teacher feedback (including in conferencing), and a supportive learning atmosphere all contributed to students’ motivation.

Benefits of PA: Caveats and Counterevidence

While the claims for PA’s effectiveness have support, they need to be tempered or balanced with some caveats and counterevidence. First, there are methodological issues. While the reliability of instruments used to collect quantitative data and of procedures used to collect and analyze qualitative data in these studies usually are reported and acceptable, the validity question remains of what exactly is being measured or examined. Most of the studies investigating the effectiveness of PA in language classrooms have used forms of self-report (e.g., interviews, surveys, focus groups) about *perceived* learning, rather than objective evaluations (e.g., comparison of language used in or scores given on learners’ linguistic production) of *actual* learning. This tendency is not negative per se. Positive perceptions can be accurate, not to mention beneficial in terms of encouraging student motivation and attitudes. Additionally, researchers using experimental designs (e.g., with pretests and post-tests) to evaluate PA effectiveness would be hard pressed to separate out which effects are attributable to teaching and which to PA, since they are intertwined in practice. For example, in Barootchi and Keshavarz (2002), “typical portfolio activities included students’ reading aloud the passages on tapes, and their showing creativity by relating what they had learnt to their everyday life” (p. 284). But it is unclear what kinds of (nonportfolio) activities the non-PA students were required to do or how they were taught. Regardless of how one views the results of experimental designs with PA, the preponderance of findings about perceived learning compared to findings about actual learning is clearly a limitation of the research base.

Second, there is empirical evidence (also based on self-report) that the positive claims for PA are not a given. Hirvela and Sweetland (2005) conducted a detailed qualitative study of two students taking ESL writing courses implementing PA at an American university, and found that the two students did not derive any of the touted benefits of PA:

What was significant was that they never saw the assigned portfolios as accomplishing missions they had assigned to portfolios on their own or that the course co-ordinators had in mind in adding the portfolio assignment to each course. For them the . . . portfolios became burdens to some extent, and the participants seemed to chafe at the restrictions imposed on them. In the end, it was dutifully completing the assignment and receiving a good grade, not reflecting meaningfully on their writing and writing development that mattered most to [the two students]. And so the assigned portfolios became one more compulsory component of the landscape of the two writing courses rather than opportunities to consider their progress as writers. (p. 208)

In Aydin (2010), students complained that, among other difficulties, “portfolio keeping is boring, tiring, and takes too much time” (p. 199). In addition, Lo (2010) writes that while studies have shown Asian EFL students gaining the benefits of PA reported in Western research, studies also indicate that students may find it difficult to reflect on their work, lack experience producing portfolios, and tend to be product rather than process focused.

Finally, because the teaching approach and the means of assessment are so closely intertwined in PA (see above and below), it is difficult to distinguish between what is a result of a particular pedagogy employing PA and what is a result of PA per se (for example, nearly all the studies cited above related to writing involved a process approach combined with PA). Perhaps attempting to make such a distinction is meaningless, but the question remains of whether the purported benefits of PA would hold true under different pedagogical approaches.

A key point underlying the preceding discussion is that when PA is deployed in a classroom, its effectiveness will not be automatic but will ultimately depend upon how it is implemented. At any given point in time during a course with PA, a student’s portfolio will be a kind of static material “product” that both results from and contributes to a dynamic human “process” of implementation and engagement between the teacher and the learners. The benefits claimed for PA will accrue to the extent that the teacher plans for, prepares students for, and maintains throughout the course an ongoing emphasis upon PA. Tellingly, Hirvela and Sweetland (2005) ascribe their participants’ “lukewarm reaction” to PA as possibly due in part to what they call a “minimalist approach” by the course coordinators and teachers, who seemingly

failed to recognize the need to nurture an ongoing portfolio culture that would enable students to better understand what the portfolio pedagogies were meant to achieve and how they were expected to operate within them. This point raises an important concern about L2 [second language] writing teachers underestimating the kind of sustained focus on and commitment to portfolios necessary to successfully implement a learning-centered portfolio culture. (p. 209)

It is to some of the key decisions that a teacher will need to make during the implementation process that will embed PA into a course and avoid a “minimalist approach” that this chapter now turns.

Decisions in PA Implementation

In this section, decisions related to the implementation of PA in a language classroom will be divided into macro-level and micro-level decisions. This distinction is admittedly loose and somewhat arbitrary, but is made here for the purpose of explanation; generally speaking, the former are strategic decisions that have wide-ranging implications, and the latter are tactical decisions that are determined in large part by (and within the context of) the former.

To expand the point about teacher agency made at the beginning of this chapter, however, undergirding and influencing all of these decisions will be the teacher's personal teaching beliefs and pedagogical approach. A teacher's personal teaching beliefs and pedagogical approach contribute a great deal to "setting the table"—setting the parameters or constraints—for classroom assessment decision making (Yin, 2010), including PA implementation. A simple example would be that a language teacher who believes that learning autonomy and a learner-centered teaching methodology are vital for language learning would subsequently place a high value on the reflection aspect of PA and give students much freedom in selecting artifacts for the portfolio.

This connection between teaching beliefs and approach on one hand and PA implementation on the other can be illustrated in more detail by the analysis of Hamp-Lyons and Condon (2000). In their second chapter, the authors show how the nine PA characteristics (see above) are variously available, emphasized, or ignored depending on the theory of writing pedagogy taken. For example, in the approach the authors term "formalism"—characterized by the study of traditional rhetorical modes such as description, classification, and comparison and contrast, by authority primarily being invested in the teacher, and by an emphasis on a written product's correctness in terms of genre, grammar, and style—the characteristics of collection and selection are prominent, and the characteristics of range, context richness, and delayed evaluation are also available; meanwhile, student-centered control, reflection and self-assessment, growth along specific parameters, and development over time are likely to be ignored because they do not fit well with formalism's teacher-centeredness and product orientation. In contrast, in an "expressivist" writing pedagogy—in which students are encouraged to communicate their internal meanings and write about their responses or feelings towards a topic, and authority is invested in the student—the nine characteristics are all available, but range, student-centered control, reflection and self-assessment, and development over time are likely to be emphasized, while characteristics like selection or growth along specific parameters would be less central because criteria would be determined more by learners' reactions than by teacher authority.

Ultimately, PA implementation will depend on the teacher's desire and perseverance. Besides deciding whether he or she has the time and energy to devote to PA, the teacher also needs to take stock of whether his or her program, institution, and especially students will support PA efforts (i.e., is there a "learning culture" that is open to PA?). Chen (2006), who worked with two Taiwanese junior high school teachers to implement PA in their English classrooms, found that its

confrontation with traditional testing was the greatest obstacle the teachers faced. One teacher said:

The students took the second term exam [required for all the classes] this Tuesday and Wednesday. Last week, their homeroom teacher reminded me that our average score had to be the highest this time. He told me that he was afraid that the students' English score would let him down because there were fewer tests or quizzes than he expected. He asked me to test them more often. But it was too late for me to quiz them more. I was worried that the homeroom teacher's nightmare would come true. Right after the exam, the homeroom teachers of the other two . . . classes asked me how well my students did on the English exam. I was not only worried but also nervous about my students' average score because of their concern. Fortunately, it turned out that my students won this English battle. But strange to say, I was not happy. (p. 86)

Since PA is an innovation in many contexts, especially where summative testing systems strongly impinge upon the classroom, the teacher will be an agent of change and thus need to consider the possibly long road ahead of working with administrators, colleagues, parents, and students on successfully implementing PA.

Now, as the discussion turns to macro- and micro-level decisions, it should be noted that there are good how-to guides available for practitioners wishing to implement PA, such as O'Malley and Valdez Pierce (1996) in language education and Shaklee, Barbour, Ambrose, and Hansford (1997) in general education (which also emphasizes teacher decision making in PA). The sections below attempt to review, reformulate, or problematize several of the decisions commonly discussed in the PA literature.

Macro-Level Decisions

Will the Portfolio Be Used for Formative or Summative Purposes? PA lends itself to formative purposes in that the portfolio materials provide a medium through which the teacher can gain information about student development so as to guide future instruction, and through which learners can gain feedback about their work so as to guide their future learning. However, as (language) education often occurs in a system that requires reporting of student achievement and formal decisions on student advancement or failure based upon such reporting (i.e., summative purposes), PA for formative purposes alone runs up against the likely disparity between time and effort spent on it in the classroom versus the high stakes of summative assessments like exams.

The typical solution to this problem is to make portfolios serve both formative and summative purposes. In the example class at the start of this chapter, the teacher gave formative feedback on all work during the term and then gave summative grades at the end on the pieces the students selected. Combining purposes allows the benefits of formative assessment while satisfying the demand for summative results. However, this solution also has its own issues.

First is the tendency for the summative purpose to overshadow the formative purpose (e.g., see Hirvela & Sweetland, 2005, above). Lam and Lee (2010) found that students preferred interim drafts to be graded (in this case, only the final

portfolio collection was graded by the teacher, but a portfolio can also be graded at a midpoint of the course, as Hamp-Lyons and Condon, 2000, point out), and students seemed to believe that grades could motivate them to improve. One participant stated, "I think a grade can serve as a performance indicator. If I usually get grade B and suddenly got a D, then I know I have to work harder," and another student stated, "If I get a D and my classmates get a B, then I will have strong motivation to work harder" (p. 61). This phenomenon seems double-edged. On the one hand, it is probably positive that students derive formative information on their progress from their summative results. On the other hand, a summative result is intrinsically reductive and the information thus derived would be limited in nature.

Another issue with the dual-purpose portfolio lies in how teachers cognitively approach assessment differently for each purpose. Hamp-Lyons and Condon (1993) collected data from open-ended questionnaires that readers of portfolios from introductory writing courses at an American university filled out as they graded a set of portfolios; these authors report that their findings raise questions about common assumptions in PA. First, because a portfolio contains several texts and texts of more than one genre, it is assumed that there is a broader basis for judgments, making decisions easier. However, the data indicated that readers' grading decisions were in fact more difficult to make because the portfolio presents a more complex picture of student performance; perhaps more disconcerting is that while it is also assumed that graders will attend to all the texts in the portfolio,

we have found again and again in portfolios of different kinds, at different times, from different readers, a clear suggestion that readers do not attend equally to the entire portfolio. Although the portfolios in our study contain four texts from a course of instruction, each of which has the potential to offer conflicting evidence to the other three, readers' self-reports indicate that readers arrived at a score during their reading of the first paper. A few readers reached a tentative score after the first or second paragraph of the first piece of text. Some readers postponed any decision until the second piece, but moved to a score rather soon within it. Readers seemed to go through a process of seeking a "center of gravity" and then read for confirmation or contradiction of that sense. (pp. 320-1)

Another assumption is that PA allows viewing of students' revision ability and rewarding of positive evidence of revision. The authors in fact found that portfolio graders who saw both an impromptu writing sample and revised texts often were suspicious, on the basis of their awareness of the role they as teachers played in improving their own students' texts, of revision work and thus discounted their appraisals of abilities of the student whose portfolio was being graded.

Considering these two issues, then, if a dual-purpose portfolio is chosen, the teacher needs to think of ways to balance the purposes, such as by including evidence of uptake of formative feedback as part of the summative grade (Klenowski, 2002), or by making nonbinding or estimated grades a part of the formative feedback. The teacher also needs to be prepared to "switch" between different mind-sets when assessing portfolio work for the two different purposes.

What Abilities or Knowledge Will Be Assessed Through the Portfolio? As the example class illustrated, the predominant general answer to this question in language classrooms has been those abilities related to writing. However, speaking abilities and reading abilities (usually assessed through students' written comments on reading texts, like book reports) are often assessed by portfolio as well (O'Malley & Valdez Pierce, 1996; Ikeda & Takeuchi, 2006). The literature thus far does not have any report of portfolios being used to assess listening ability, but it is conceivable. Intercultural knowledge or knowledge of the L2 culture has also been assessed by portfolio (e.g., Cummins & Davesne, 2009; Su, 2011).

As part of this question, the teacher also needs to clarify the subconstructs under the skill(s) being assessed. In a sense, teachers using PA are faced with the positive challenge of thinking clearly and deeply about the aspects they want to assess, because PA affords a wider range of possibilities than a single fixed response or performance assessment. For example, writing teachers can assess through the portfolio not only traditional aspects of writing like vocabulary, grammar, and organization, but also abilities like revising and researching. As another example, a speaking portfolio can allow teachers to assess subconstructs like pronunciation, accuracy, the ability to conversationally interact with a variety of interlocutors, the ability to give an extended spoken discourse or speech, or all of these.

The use of PA also offers other possible "PA-intrinsic" constructs to be assessed. One such construct is the ability to organize the portfolio. This can be a judgment of simply whether a student is careful and neat, or of whether the student is able to bring a cohesive order to a disparate collection of artifacts. This construct can also be seen as part of a more common and arguably more important PA-intrinsic construct, namely the ability to reflect upon and self-assess one's own learning as evidenced in the portfolio. Reflection is usually expressed in a written commentary accompanying the portfolio. Duong et al. (2011), on the basis of their efforts to develop formal writing PA criteria at a university in Vietnam, state that reflection can be represented as three capabilities. The first is whether students can justify the organization of their portfolios. The second is whether students express process-oriented writing knowledge and other course objectives. The third is whether students can assess themselves according to the grading criteria and make statements about their overall portfolio performance.

Having students reflect on their portfolio does not necessarily entail summatively assessing the resulting reflections; there are in fact at least two reasons for clearly *not* doing so. First is the vagueness of the construct. One of the stated reasons why Duong et al. (2011) offered the above description of the reflection construct was because little work has been done in formulating reflection more precisely. While their three capabilities above help specify the construct, evidence of reflection, unlike evidence of, for example, linguistic constructs like vocabulary or grammar, is still arguably high inference—that is, generalizations about a student's reflection are based on only a single piece of evidence—and is potentially too subjective. Another reason for not assessing reflections summatively is that the reflective pieces themselves can become a genre that students learn to leverage for a higher summative grade; students may "fake it" by giving

seemingly thoughtful responses they think the teacher wants to hear (Sunstein, 2000).

The above discussion demonstrates that PA offers many possible answers to the question of what to assess, but in the final analysis, teachers must find their answers directly in their curriculum and their pedagogical goals. Careful thought about this question, plus clear communication of the answers—in the form of rubrics or grading criteria for students—can do much in bringing curriculum and assessment into alignment and producing the results of PA that teachers desire.

What Degree of Freedom Will Students Have in Portfolio Collection, Selection, and Reflection? In the classroom, the teacher retains final authority for portfolio collection, selection, and reflection, but can offer students choices and freedom under his or her benevolent regime. For example, in her class, Brenda assigned five essays and then allowed students to choose any three of them for the graded portfolio. As this chapter has, it is hoped, made clear, decisions about the degree of latitude given to students depend much upon the teacher's personal beliefs and pedagogical approach. As with the formative/summative purpose issue, there is also an inherent tension here; less student freedom will more likely give the portfolios more uniformity and give the teacher the artifacts that will provide evidence of performance on the assessed construct, but will also reduce the extent of student self-assessment and reflection, while more student freedom may have the opposite effect.

In a vivid portrayal of her attempt to use informal PA with her 8-year-old son Xiao-di, who was studying in an American elementary school, Fu (1992) describes how she collected a variety of Xiao-di's creations and then asked her son, his regular classroom teacher, and his ESL teacher to select what best represented him as a reader and writer. She writes:

There was a big difference in what Xiao-di and his teachers selected. The pieces chosen by the teachers were invariably those done at school, and they were mainly connected with verbal skills. The work chosen by Xiao-di covers a much wider range. He selected thirteen pieces of work: bilingual writings, a letter to a friend, a birthday card to his mom, a picture, two published [in-class] books, some reading-response writings, and several stories. It represented work done at school and at home, finished and unfinished, and teacher-assigned and self-assigned. (p. 172)

Also, the classroom teacher chose pieces that showed how Xiao-di had developed words into sentences and ideas into stories, the ESL teacher chose pieces that reflected the boy's improvement of language aspects like grammar and of cultural understanding, and Xiao-di chose pieces that had deeply personal meanings only understandable within the context of his own views about his development (pp. 173–4). This illustration highlights the dilemma that greater teacher control over PA collection, selection, and reflection may give teachers what they want at the cost of a meaningful assessment experience for students, while the reverse may also be true. To resolve this dilemma, as with others, the PA-implementing teacher needs to strike a careful balance.

Micro-Level Decisions

What Artifacts Will Be Collected, Selected, and Reflected Upon? While the nature of the materials in the portfolio will essentially be determined by the macro-level questions, there is still a wide array of possibilities within the language classroom. Almost any production by the student can potentially serve as portfolio material, such as a written story, a recording of a conversation inside or outside the classroom, a research report, comments on a reading text, or a text written in the target language but for another course (e.g., an English lab report by an ESL student for a chemistry class). The materials may also be determined by the medium (see below).

What Medium Will Be Used for the Portfolio? As mentioned earlier in this chapter, the use of e-portfolios has increased dramatically with the development of virtual learning environments and both students' and teachers' growing technical proficiency. E-portfolios have become a much more viable option to the traditional paper-based portfolio than in the past, providing advantages such as convenient storage of the (digital) artifacts, easy sharing of portfolio materials, and the potential for future use of portfolio materials beyond the classroom (Cheng, 2008; Cummins & Davesne, 2009). However, prerequisite for using e-portfolios are sufficient technical infrastructure (e.g., computer resources, staffing) and appropriate training for both teachers and students in e-portfolio use (Cummins & Davesne, 2009).

How Will Self-Assessment and Peer Assessment Be Incorporated Into the Portfolio? As stated earlier, PA emphasizes self-assessment and reflection. Its structure also allows assessment of a student's work by peers. Successful incorporation of these two elements into a PA-implementing classroom requires the teacher to prepare specific *processes* and *products*. *Processes* here refer to the following procedures, which are now widely seen as good practice in terms of making performance assessments serve learning purposes (O'Malley & Valdez Pierce, 1996; Black, Harrison, Lee, Marshall, & Wiliam, 2003):

- Provide students with clearly stated grading criteria reflecting the abilities that are to be assessed.
- Give students exemplars of student work at each level of quality.
- Have students identify the characteristics of each exemplar that make it fit its grade.
- Have students assess work in groups or pairs before letting them assess their own work individually.

These procedures train students in looking at their own and peers' work from the perspective of the teacher. The last procedure in fact suggests a progression from teacher-guided peer assessment toward individual self-assessment, as a student may need to practice assessment with others before assessing on his or her own.

Products here refer to teacher-made checklists, sets of open-ended questions, or other items that students will use in the process of their peer assessment, self-assessment, and reflection. O'Malley and Valdez Pierce (1996) give a wealth of examples of such products. When making questions in these products for students

to answer, it is important to make them specific. For example, according to Sunstein (2000), when guiding student reflection a specific question like “why did you choose these pieces for the portfolio?” is better than a general one like “please reflect on your learning in this portfolio”; better still, she adds, are questions directly related to the grading criteria, like “look at the list of can-do statements and explain which works show that you can do them.”

How Will Feedback Be Incorporated into the Portfolio? While this question is last on this list of micro-level decisions and is constrained by macro-level decisions, it is this author’s view that the answer to this question will greatly determine the success or failure of a PA implementation. As with self-assessment, feedback needs to be carefully designed into processes and products during implementation. In terms of processes, the teacher needs to set aside time and so order the class schedule as to build opportunities for students to turn in their work, for the teacher to prepare feedback, and for the teacher to communicate that feedback to students. In terms of products, the teacher can provide feedback using products similar to those used for self-assessment (e.g., checklists and question forms). When giving comments, it is recommended that language teachers try their best to make their feedback clear, not only in terms of legibility but also in terms of pragmatic purpose. That is, if a teacher wants to direct a student toward making a specific change, wording the comment as an imperative or declarative like “you should add more details here” will likely be clearer than wording it as a question, like “can you add more details here?”; an L2 learner may be confused by the intention of the latter, leading to possible lack of uptake of the feedback in future revision. In addition, not only does the feedback need to be actionable—for example, the comment “awkward” written above a sentence is not as helpful as “break up this sentence into 2–3 simpler ones”—but the PA process also needs to be designed so as to give students the opportunity to take action. It does no good to give students formative feedback after a summative grade has been given. Here, PA’s characteristic of delayed evaluation can come into play, giving both students and teachers the time to interact and communicate about student work.

Challenges and Future Directions

Portfolios for assessment in language classrooms have increased in popularity, but challenges (with inherent opportunities) remain. One such challenge is defining and theorizing the concepts of validity and reliability as applied to PA. Some scholars have argued that PA should fit definitions of validity and reliability similar to those for other forms of educational measurement, while others have argued that different conceptualizations of validity and reliability are needed because the concerns of PA significantly differ from those of traditional educational measurement, especially the latter’s concern for standardization (Broad, 1994; Klenowski, 2002). With so much debate and discussion, much work obviously remains on developing and resolving these issues, both theoretically and practically.

Another challenge, alluded to earlier, is the implementation of PA as an innovation in educational contexts where exams and other summative assessments are

the entrenched norm. PA-using teachers will need to bring change in such situations, but research on such change agency is also needed; what lessons can be learned from innovators about the problems of using PA on a regular basis in PA-resistant systems and about the solutions to those problems?

Another PA-related innovation that presents challenges and opportunities is the development of large-scale e-portfolio systems like the European Language Portfolio, LinguaFolio, and Global Language Portfolio (see history of PA above). These e-portfolios are designed primarily for self-assessment and for allowing learners to demonstrate their language proficiency to employers and educational institutions. While they are independent of language classrooms (and thus have not been explored in this chapter), they can be used in conjunction with the classroom (e.g., Little, 2009, gives examples with the European Language Portfolio). Evidence so far that such e-portfolios can benefit language classrooms is positive, but more research is needed. It is encouraging to note that teacher decision making and ownership have been seen in such research as central to successful implementation.

Conclusion

This chapter has highlighted the importance of teacher decision making in PA, especially in language classrooms. It has been argued here that the way PA is enacted in practice depends a great deal on a teacher's personal beliefs about teaching and pedagogical approach. In writing about harnessing the power of assessment for learning purposes, Black et al. (2003) make the point that doing so will require teachers to see assessment and pedagogy as mutually permeating; that is, teachers will need to see that teaching can be done through the processes of assessment, and assessment can be done through the processes of teaching. This idea is perhaps illustrated most clearly in PA. For example, in PA, teachers can communicate portfolio grading criteria and indicators of quality to students and give feedback on portfolio materials (teaching through assessment), and teachers can include the results of instructional activities among the portfolio artifacts to be assessed (assessment through teaching). If PA is thus successfully implemented in the classroom, then, revisiting the epigraph from Hamp-Lyons and Condon (2000), it can be said that PA can not only reveal and inform but also advance teaching and learning.

Dynamic Assessment in the Classroom

Matthew E. Poehner

Pennsylvania State University, USA

Introduction

Although dynamic assessment (DA) has only recently become known in the field of second language (L2) studies (Lantolf & Poehner, 2004), it has quickly gained attention from assessment researchers, teachers, and those interested in processes of L2 development. The appeal of DA derives in no small part from its basis in Vygotskian theory, whose popularity among L2 researchers has been growing steadily since the late 1980s (see, for instance, Lantolf, 2000). In addition, DA offers a systematic framework for relating assessment practices to teaching and learning, a matter that has preoccupied many in the field (Bachman & Cohen, 1998). Indeed, a central tenet in DA is that to fully diagnose learners' abilities requires taking account of their responsiveness when support is offered to help them address difficulties, and, likewise, it is precisely such interaction that allows instruction to promote learner development. In other words, assessment and teaching together form a unified, development-oriented activity (Poehner & Lantolf, 2010).

To be sure, this conceptualization of assessment diverges in important ways from much current thinking in the field, where assessment is typically viewed as a means of gathering information for understanding the results of previous instruction and experience and not as an intervention in developmental processes. This may explain why L2 DA has most frequently been linked to classroom formative assessment (e.g., Rea-Dickins & Poehner, 2011), as the latter is clearly committed to situating assessment as part of a broader educational activity. This comparison is not without merit. However, in this chapter I argue that the hallmark of DA is the theoretical orientation to development that guides interactions with learners and interpretations of performance. For this reason, while DA may overlap with formative assessment and has much to offer classroom contexts, this

does not exhaust its relevance to the L2 field. As I will attempt to show, classroom-based DA demonstrates theoretical principles that may be recontextualized in the service of more formal assessments. To help the reader appreciate this argument, the following section offers additional remarks on the origins of DA in Vygotskian theory.

Previous Views or Conceptualization

Central to Vygotsky's (1987) theory of mind is the understanding that humans do not relate to the world in a direct manner like other animals. Instead our relation to the world is mediated by artifacts available to us in our culture, as well as our social interactions with others (see also van der Veer & Valsiner, 1991). Following Wertsch (2007), mediation may be understood as the affordances with which we act that render our activity possible and that also result from our activity. Just as humans act on and shape our environment in a manner mediated by physical tools (hammers, saws, bulldozers, etc.), our psychological functioning is similarly tool-mediated. Dialogic mediation, as occurs when individuals jointly engage in activities that are beyond an individual's capabilities, is a driving force of development. In fact, Vygotsky (1978) insisted that such cooperation is not a precursor to mental activity but rather is mental activity carried out in the dialogic space created during interaction. It is here, on what Vygotsky termed the *intermental plane*, that new cognitive functions first appear. Later, these functions re-emerge on the *intramental plane* as individuals rely increasingly on internalized forms of mediation to regulate their thinking and actions, that is, to *self-regulate*.

In experiments undertaken with children, Vygotsky and colleagues traced the genesis of new cognitive functions through sessions of joint activity with an adult or expert in which children were mediated to exceed their current or actual level of development. During these experiments, mediator and learner functioned cooperatively, creating what Vygotsky (1987) termed the *zone of proximal development (ZPD)*. In other words, mediator-learner intermental activity indicates the next or proximal level of development the learner will reach intramentally. It is in this regard that the ZPD is of such crucial importance to diagnoses of learner functioning. In his critique of conventional assessments, Vygotsky argued that observations of learner independent performance reveal only a part of their capabilities, namely, their intramental functioning as they rely on internalized forms of mediation to self-regulate. These observations, however, reveal nothing of those abilities that are still emerging and have not fully developed. It is through joint activity that one comes to understand how learners are able to contribute to the completion of difficult tasks, the extent to which mediation is required, and how responsive they are to mediator support. Taking account of the ZPD allows for a greatly expanded range of insights into learner abilities (Vygotsky, 1998).

Vygotsky (1998) further explained that the provision of mediation, including prompts, feedback, leading questions, models, and examples, is crucial to supporting learners to perform beyond their current capabilities. The aim of ZPD activity, however, is not merely to help learners carry out tasks but to identify the appropriate focus of instruction: the set of learner abilities that are emergent and

most amenable to targeted intervention. Through continually calibrating mediation so that it is sufficiently explicit to be of value to learners but not so explicit that the mediator simply completes the task, learner abilities are both tracked and promoted.

To summarize, DA follows Vygotsky's argument that conventional assessment models requiring only dispassionate observation of learner functioning be broadened to include interaction and intentional mediation. Assessment then encompasses the products of past development, determined by observation of learner independent functioning, as occurs in most assessments, but it also requires cooperation when learners encounter difficulties, with the level of functioning that learners realize taken as an indication of abilities that are currently forming. In addition, the instructional quality of this interaction, which may include hints, prompts, leading questions, and models, helps to guide learner development. As Vygotsky (1978) explained, what an individual can do today in cooperation with others, she or he will be able to do tomorrow independently. As explained in the next section, however, very different conceptualizations of DA have emerged since Vygotsky's time and are currently being explored.

Current Views or Conceptualization

As should be clear, DA is distinguished from other approaches to assessment by its insistence on mediating the relation between learner and task, a position motivated by an understanding of abilities that sees such interaction as crucial to diagnosis as well as the basis for development-oriented instruction. Lantolf and Poehner (2004) propose that current models of DA may be grouped according to whether they approach mediation as prescribed treatment, designed in advance of interaction and administered to learners in a standardized manner, or see mediation as a negotiated property of interaction that unfolds through mediator-learner dialoguing. The former orientation to DA, which Lantolf and Poehner term *interventionist*, typically organizes mediation as scripted prompts or hints that are arranged from least explicit to most explicit, often culminating in the solution to a task or problem and an explanation of the underlying principles involved. Prompts are offered one at a time until either the learner responds correctly or the final prompt is reached. An advantage of this approach is that the number of prompts a learner required for particular tasks can simply be recorded and the results of the procedure easily reported. The open-ended orientation to DA, which Lantolf and Poehner describe as *interactionist*, conceives of mediation as a process that involves mediator probing of learner understanding, and leading questions and feedback as learners work through difficulties. No two interactionist sessions are likely to involve precisely the same mediator moves in precisely the same order, although the mediator does follow principles to orient to the interaction, as explained below.

The decision to follow either an interventionist or an interactionist approach should be informed by the purpose behind employing DA. The matter may be framed by asking to what extent DA is intended to both diagnose and promote learner development. From a Vygotskian perspective, the strength of ZPD activity

is that these purposes are integrated; that is, assessment involves instruction and appropriate instruction takes account of assessment, with both contingent upon mediated interaction. Yet, while DA encompasses assessment and instruction, it is certainly possible to foreground one or the other of these purposes. For example, in many formal assessment contexts, such as when decisions need to be made regarding learner entry into a program of study, placement of learners at appropriate levels, or certification of learner competencies, guiding learners toward more autonomous functioning is likely less important than procuring as much information as possible about their abilities, including how they respond when offered support during interaction.

Outside of the L2 field, there is a strong tradition of pursuing DA as an alternative measure to traditional tests of cognitive abilities. Not surprisingly, the favored orientation to DA is interventionist. Moreover, Haywood and Lidz (2007) explain that DA is most frequently conceived as a three-stage process that mirrors the classic experimental research design of situating a treatment phase between a pre- and a post-test. This test-intervene-retest organization, which Sternberg and Grigorenko (2002) have dubbed the *sandwich* format of DA, begins with a traditional assessment, without mediator-learner interaction, to establish a baseline of learner performance. This is followed by an intervention program designed to teach principles essential to carrying out test tasks. Finally, the same or a parallel version of the original test is administered, again without interaction between mediator and learner. The two sets of scores that are produced for each learner are then compared to ascertain the degree of change, which is interpreted as an indication of latent potential and included in recommendations to teachers and other school personnel (for full discussion see Tzuriel, 2011).

As Holzman (2009) explains, such conceptualizations of DA understand the ZPD itself not as an activity but as a construct that learners possess, much like intelligence quotient. Indeed, the general DA research literature is replete with references to *learning potential* and *cognitive modifiability*, both of which stand in contradistinction to more conventional definitions of intelligence and cognition and are interpreted according to gains made as a result of intervention. Following Holzman (2009), a narrow view is taken of mediation itself, which is seen simply as treatment administered to learners in discrete amounts in order to evoke a response.

This strong measurement orientation to DA has unquestionably proved important to psychologists and educators concerned with meeting the needs of special needs learners, immigrants, learners from diverse cultural backgrounds, minority children, and others who struggle to succeed in mainstream schooling. In these situations, DA results have provided nuanced insights into learner abilities as well as challenges learners face and how these may be overcome through enrichment programs and individualized instruction. In sharp contrast, L2 DA work has fallen primarily within the scope of classroom-based assessment, although current work intends to build on insights gleaned from the classroom to design DA procedures for more formal assessment purposes. Rather than emphasizing the ZPD as a potential that remains untapped by other assessments, L2 DA conceives of it as activity undertaken with learners in which mediator and learner participation are both crucial but contributions are in flux as learners draw new insights and make

new connections, as well as encounter new questions and difficulties. The lion's share of L2 DA work has followed an interactionist approach, and in many ways has similarities to formative assessment. While it is true that both recognize the value of interaction and feedback in understanding learner abilities, this is explicitly theorized and systematized in DA. Indeed, a major challenge faced by L2 DA researchers has been to remain flexible in adapting mediation, during the course of interaction, to meet learner needs while holding to the theoretical principle behind the ZPD of supporting learners but also allowing the struggle necessary to guide development (Poehner, 2008).

One of the earliest and most important L2 studies concerned with determining appropriate forms of mediation was conducted by Aljaafreh and Lantolf (1994). These authors employed the concept of the ZPD to organize one-to-one tutoring sessions designed to help English as a second language (ESL) learners with difficulties in academic writing. While interactions between tutor and learner were open-ended, the tutor endeavored to attune mediation according to tutee responsiveness. That is, the tutor first made relatively implicit moves, such as pauses or prompts to reread a draft and look for errors. If these did not lead learners to identify errors, the tutor became more explicit, drawing learner attention to particular paragraphs, then particular sentences, and finally particular constructions within sentences that contained errors. After an error was identified, if the learner was not able to correct it, the mediator provided support here as well, employing metalinguistic terms to cue learners to the nature of the problem, and if necessary even providing the correction and offering an explanation.

Following a grounded analysis of the sessions, Aljaafreh and Lantolf (1994) proposed three properties of effective mediation: It should be graduated, dialogic, and contingent. Two of these, namely the principles that mediation be graduated from implicit to explicit and that it unfold dialogically to allow for maximal attunement to learner needs at any given moment, are characteristic of interactionist DA and have already been discussed. Contingent mediation refers to the principle that mediation "should be offered only when it is needed, and withdrawn as soon as the novice [learner] shows signs of self-control and ability to function independently" (Aljaafreh & Lantolf, 1994, p. 468). Providing mediation when it is not necessary or offering support that is more explicit than actually needed obscures the view of learner abilities and also robs the learner of the struggle needed to stretch beyond his or her current capabilities. Taken together, these three principles are essential to rendering DA interactions highly systematic, a property that both enhances the effectiveness of interactions in appropriately diagnosing and promoting development and also aids in generating profiles of learner development during the course of a session and across sessions.

It is with regard to systematicity that Poehner and Lantolf (2005) have argued that DA stands to contribute to formative assessment practices. Citing the work of Torrance and Pryor (1998) in the general education field and Rea-Dickins and Gardner (2000) in the L2 field, Poehner and Lantolf identify a lack of systematicity as a major challenge in developing formative assessment models. The authors point to anecdotal observations of student performance and the often hit-or-miss nature of feedback provided to learners during interaction that are reported in the formative assessment research literature. The DA principle of offering mediation

that is as implicit as possible and becoming gradually explicit in response to learner needs provides a framework that may guide teacher interactions with learners. The potential here is that a theoretically motivated approach to offering support to learners minimizes the chance that the support is far more explicit than necessary. This allows for a more fine-grained diagnosis of learner abilities, as the precise level of support learners require while working through tasks can be determined, and it also creates the possibility to more closely track changes over time in the level of support that individual learners or groups of learners require (see Poehner, 2009, for discussion).

Current Research

An emerging strand of L2 DA research is concerned with addressing assessment issues outside the classroom. However, in contrast to DA approaches in psychology and special education, which as explained have been heavily influenced by “treatment” designs in experimental research, L2 researchers are seeking to adapt insights gained through classroom-based interactionist DA for use in procedures where the assessment function of DA is brought to the foreground. In essence, this represents an assessment design that proceeds from classroom contexts to more formal ones. To my knowledge, two such L2 DA projects have been developed. Initial results from the first of these projects have been reported by Antón (2009). Owing to the constraints of the present chapter, I will only briefly comment on that project and will refer interested readers to Antón’s publication for full details. I address more fully the second project, which is currently underway (see Poehner & Lantolf, in press).

Antón (2009) describes a series of assessments conducted to place advanced university undergraduate learners of L2 Spanish at appropriate levels of study. Students underwent a five-part assessment targeting different communicative abilities and knowledge of the language. Two of these assessments, namely the writing and speaking assessments, have been formatted to reflect DA principles. The writing assessment consists of four phases. Students are first given a prompt and allowed 20 minutes to prepare their essay. They are then directed to revise their writing independently. Once they have finished, they move to the third phase of the assessment during which they are free to ask questions and discuss the essay with a mediator. Students then prepare and submit a final revision. The number of revisions students make to their work is counted and each is marked according to the following categories: a correction or improvement; a revision that either maintains an error or creates a new one; a revision that yields a change to the original text but not a correction.

During the speaking assessment, students are asked first to complete a personal oral narrative on their own. They are then encouraged to repeat the narrative, but this time the mediator interjects suggestions, feedback, and prompts to help learners identify and correct errors. It is this interactive renarration that is scored by the mediator, taking account of pronunciation, fluency, content, comprehensibility, vocabulary, and grammar as well as the extent of support offered and learner responsiveness. At the time of writing, Antón (2009) has only reported results from

a small-scale pilot of the dynamic writing and speaking assessments. She notes, however, that both assessments in their dynamic version yielded insights into learner abilities that would not have likely emerged otherwise. In some instances, she explains, the revelation during the dynamic procedures that learners were either close to or far from successful independent performance led to different placement. While she advocates continued use of DA for placement purposes, Antón also acknowledges that the dynamic procedures rendered the overall assessment of new students more labor intensive, an issue she suggests merits further attention if more programs are to adopt similar uses of DA.

The feasibility of conducting DA on a large scale was foremost in the design of the second project, which involves the development of computerized dynamic assessments (C-DAs) of reading and listening comprehension for L2 learners of Chinese, French, and Russian (Poehner & Lantolf, in press). The project¹ is unique in that mediation is delivered via a computer program rather than a human teacher or examiner. To be sure, this approach requires compromise with the commitment to dialogic mediation that has characterized other L2 DA studies. The computerized mediation follows an interventionist approach wherein prompts are scripted and arranged from least to most explicit and programmed as part of the computerized tests. However, unlike other interventionist DA approaches, mediation in this project is derived from one-to-one interactionist administrations of the test. That is, every item on every test was first piloted individually with four to eight learners, each of whom was mediated in a dialogic format. These sessions were recorded and transcribed, and a subsequent grounded analysis led to the generation of the sets of mediating prompts programmed for use in the computerized version of the tests. This process is illustrated below with a sample item and extract from an interactive DA session.

The tests, modeled after other standardized measures of L2 comprehension, ask learners to respond to multiple choice questions based on short reading and listening texts. Four mediating prompts were prepared for each test question. If a learner's first attempt to respond to a question is correct, full credit (four points) is recorded for that item and the learner is offered the chance to access an explanation as to why that answer is correct. The purpose in offering the explanation is that learners will still have an opportunity to learn something even if they have simply succeeded in guessing the correct answer. Whether a learner chooses to view the explanation is recorded but does not affect the number of points earned for that item. The learner can then proceed to the next item. In the event that a learner's first response is incorrect, the least explicit prompt is offered and the learner is directed to reattempt the item. This involves highlighting the portion of the text, typically of paragraph length, where the answer may be found and directing the learner to "try again." If the second attempt is correct, then the explanation is offered and the learner is free to move on; in this case, three points are awarded for that item. If the second attempt is incorrect, the next mediating prompt is given: A shorter excerpt from the passage is highlighted and the learner is offered a prompt such as "try again and this time consider what the author says about life in the country." This process continues until either the learner selects the correct answer or the fourth and final prompt is given, which is in fact a display of the correct answer. Learners to whom the correct answer has been revealed may

choose to access the explanation or they may simply move to the next question. In this way, the number of points earned for each item (ranging from zero to four) is recorded, as is whether the learner opted to view the explanation. With regard to the assessment function of DA, then, the tests reflect much more nuanced information about learner performance than simply how many items they answered correctly.

In terms of the other aim of DA, namely promoting learner development, the availability of explanations allows for instruction even after learners have answered correctly, or if they have answered incorrectly and received all the prompts. As mentioned, this would seem particularly important in cases where learners might select the correct answer either by guessing or through other test-taking strategies. Working around texts rather than engaging in comprehension is an issue, of course, in all comprehension assessments. In an interactionist approach to DA, a mediator would be able to help learners maintain a comprehension rather than test-taking or problem-solving focus. While the C-DA tests do not offer such flexible mediation, delimiting the search space in the text and providing prompts pertinent to the content of the passage are intended precisely to keep learner attention on the passage and the task as one of comprehension. In addition, current research is examining the extent to which changes in learner performance during the administration of the test itself may provide additional insights into how learners are engaging with test items (Poehner & Lantolf, in press).

At the end of each test, the program automatically generates a profile for each learner. The profile includes an *actual score* as well as a *mediated score*. The actual score reflects only learners' independent performance, that is, the learner's initial attempt, before any prompts are offered. Thus, a learner's actual score for an item is either four points (for a correct response) or none at all, indicating an incorrect response. The actual score, then, is akin to a nondynamic version of the test. The mediated score reflects the process described above in which learners earn points according to the number of prompts they received. A mediated score may range from zero to four and is intended to capture what learners are able to do with mediation. In addition, the profile groups test items according to the primary construct the item tests. In the case of reading, constructs include knowledge of the lexicon, grammar, discourse-level grammar, pragmatics, and cultural or topical knowledge; for the listening test, phonology is also included. Grouping the items by construct allows one to see at a glance the areas where a learner requires more extensive mediation. Finally, in cases where an entire class of learners takes one of the tests, teachers may aggregate the performance of each class member for a display of how the class as a whole performed on the test overall, on individual items, and on items grouped by construct. It is anticipated that information reported in learner profiles may be useful to language teachers and program directors in tracking learner progress over time, placing students in a program of study, and planning future instruction to meet learner needs.

At present, initial piloting of the computerized tests is underway, and data are not yet available. However, to help the reader better understand how the tests function and the process through which mediation was designed, I will present one item from the French reading comprehension test and will describe a fragment of one of the mediator–learner interactions around this item that occurred during

- (7) what does Bolotny think about the role of business in soccer?
- a. Soccer is a business like any other.
 - b. Soccer should be deregulated.
 - c. Soccer players should be professionals for over ten years.
 - d. To maximize both the sporting and financial side of soccer, it must be regulated.
 - e. In the past, soccer was wrongly considered as a business.

the one-to-one dynamic administrations. The item, presented in Figure 41.1, is the seventh question on the test and pertains to a relatively lengthy reading on the topic of national and international regulation of soccer. The text is in fact a transcript from an interview with the former French minister of sports, François Bolotny, who describes the potential benefits of greater international regulation over the sport.

In the interview, Bolotny points to the long-term trend that soccer teams that receive more financial support have more successful seasons. He further explains that regulating the business side of the sport on a country-by-country basis results in additional complications, and for this reason international regulation is required. The correct answer, then, is option (d).

Poehner and van Compernelle (2011) report an interaction between a mediator and a learner, Nicole (a pseudonym), as they attempt to respond to this item. The authors explain that while Nicole, a third-semester undergraduate student of French, had read the entire passage on her own, she had not adequately comprehended the main points to be able to make informed choices. Instead, Nicole first selected option (a). When prompted by the mediator to reflect on her choice, she instead switched to option (e). As Poehner and van Compernelle point out, this change in fact represents two fully oppositional readings of the text. The first simply states that the sport is a business without implying any judgment as to the merits of this view, while the second denotes that the sport is no longer considered a business and that it would be wrong to see it as such. It appears that while Nicole understood that Bolotny was discussing the question of whether soccer should be viewed as a business, she failed to grasp his opinion on the matter and how the additional statements made in the interview are intended to support his point of view.

We pick up the interaction where the mediator attempts to insert himself into the comprehension process to determine the support Nicole needs to construct meaning from the text that will be relevant to choosing from among the three remaining options. The mediator begins by physically pointing to the options on the test paper and reading them aloud:²

1. MEDIATOR: so + we have these three. ((pointing to response options)) soccer should be deregulated? soccer players should be professionals for ten years? and to maximize both the sporting and financial side of soccer it must be regulated.
2. NICOLE: okay.
3. MEDIATOR: so. it is + in this + second paragraph. ((indicating paragraph in text with both hands)) okay? um and ++ what I want you to concentrate on? is starting here, ((pointing to text)) *mais l'erreur + serait de le considerer*. (('but the mistake would be to consider it')) okay? and see if you can't figure it out from that.
4. (19.0) ((re-reading text and response options))
5. NICOLE: oh. ++ I think it's D? it must be regulated + because
6. MEDIATOR: mhm, right,
7. NICOLE: + it + needs to be regulated for the maximization of the () of sports? ((pointing to text with pencil and translating sentence))
8. MEDIATOR: yep that's it.

After the mediator reads the responses to Nicole, she still does not make an immediate selection, and so the mediator proceeds to draw her attention to a particular segment of the text in which Bolotny's view is specified (turn 3). This move effectively reduces the amount of text to which Nicole must attend and allows her to narrow her focus to only those portions that are immediately relevant to the item at hand. It is worth noting that the mediator actually offers two levels of specification at this point: He first refers the learner to the second paragraph and then to a particular line in that paragraph. It may be the case that simply cuing Nicole to examine the second paragraph would have proven adequate in helping her to understand the text. Because both mediating moves were employed simultaneously, it is impossible to know whether the more specific prompt was needed. This point was noted during analysis of the session as the scripted prompts for use in the computerized version of the test were prepared. At any rate, Nicole selects the correct response (turn 5), although her questioning intonation suggests that she still may not be certain of her choice. She does, however, explain her reasoning (turn 7) by appropriately rendering the relevant lines in English.

In this particular instance, the one-to-one DA interaction underscored the value of narrowing learner focus to relevant portions of the text and doing so in a phased manner (i.e., increasingly smaller selections of text) as one approach to mediating learners' efforts to respond to test items based on their comprehension of the texts rather than simple guessing. After completing this process for every test item and with multiple learners, prompts were prepared for the computerized versions of the tests. In the case of this particular item, if a learner's first response is incorrect, she or he is prompted to try again and directed to pay attention to a portion of the text whose colour changes from black to green. The green text is the second paragraph the mediator referred to in the above interaction. If a learner's second attempt is also unsuccessful, a smaller portion of the text turns to orange and the learner is directed to "think about what Bolotny says about soccer (football) in relation to other types of business." This prompt thus further narrows the selection of text and also alerts learners to Bolotny's discussion of the sport as a business, albeit one that differs from other businesses. If this level of mediation is

still not sufficient, the learner is told that in Bolotny's view soccer is not like other businesses, and she or he is asked what Bolotny believes is needed. Simultaneously, one line from the text turns to red, "C'est un business qui a besoin d'être régulé." At this point, learners may still receive one point for recognizing that Bolotny is stating that soccer is a business that must be regulated. In the event that they are unable to do so, the correct answer is revealed. After the answer has been revealed (or as soon as a learner selects the correct answer on his or her own), the option to view an explanation is presented. For this item, the explanation includes key phrases from the text (in French but also rendered in English), such as his statement that the sporting value of the game as well as its economic value could be boosted by additional international regulation.

As should be clear, this project draws upon the strengths of both classroom-based L2 DA and the more formal, measurement-focused approaches to DA in psychology. It goes without saying that a dialogic, interactionist format would offer far greater potential to adapt mediation to the emerging needs of individual learners. The computerized format, however, enables the tests to be dynamically administered to large numbers of learners simultaneously, and automatically generates learner profiles to capture performance. Of course, the relevance of C-DA to L2 education will ultimately be determined by language educators.

Challenges

Given the infancy of L2 DA relative to other models of assessment, it is clear that much work remains to be done and that there are pressing issues to be considered. This is the case even in psychology, where DA has enjoyed a far longer history, and discussions in that field may also help to orient L2 DA researchers. In a recent review of the state of DA research, Karpov and Tzurriel (2009) draw attention to two challenges in particular that are also relevant to L2 contexts: the need for better training opportunities for those who administer DA procedures, and additional arguments to establish the viability of DA.

With regard to preparation for conducting DA, Karpov and Tzurriel conceive of training sessions to teach school psychologists how to include scripted prompts in their administration of standardized tests of abilities and how the resulting scores should be interpreted. In the L2 field, similar preparation might be appropriate for individuals preparing to apply DA principles in formal assessment contexts, such as placement and achievement testing, where a strict interventionist DA format might be desired. Equally important for the careful design of such procedures, however, is an understanding of the theoretical basis of DA. Through engaging with the conceptual writings of Vygotsky and his colleagues that explicate ideas such as the ZPD, mediation, and internalization, one can develop the expertise necessary to make thoughtful choices regarding the focus of assessment and intervention, the forms of mediation that will be made available, how interactions will be approached, and the ways in which development may manifest. In other words, the preparation that is needed is not merely technical in nature but also conceptual.

This point is equally relevant to classroom contexts, where practitioners are frequently responsible for designing both instructional and assessment tasks and

for determining appropriate curricular objectives. As explained, classroom-based DA presents a theoretically motivated framework for organizing learners' participation in the activity of their own development. Without a theory of development to guide decision making, it is difficult to imagine how teachers can systematically create the conditions necessary for ZPD activity or how they would respond in appropriate ways to learner needs. Indeed, this echoes the conclusion reached by Torrance and Pryor (1998) that classroom formative assessment frequently misses opportunities to understand and guide learners' development because teacher feedback during assessment is not sensitive to their emerging abilities and instead tends to be more affectively oriented. Understanding that mediation need not be always implicit or explicit but should be attuned to learner responsiveness and contingent upon learner needs optimizes the possibility that instruction will be neither too far beyond learner abilities nor trailing behind them, but will instead, as Vygotsky envisioned it, lead development.

Of course, the goal of rendering assessment and instruction a development-oriented activity is very much linked with the viability of DA. While the lion's share of ZPD research has privileged teacher–student or adult–child dyads, Vygotsky (1998) also referred to the possibility of promoting the development of groups through ZPD activity. This proposal holds much potential for the future of DA in L2 classrooms.

To date, the only study of L2 group dynamic assessment (G-DA) is Poehner (2009). Poehner distinguishes two formats for offering mediation to support groups of learners to stretch beyond their current capabilities. In *concurrent G-DA* the focus of mediation is the activity of a group of learners rather than an individual. A particular prompt or hint may be addressed to one member of the group, but it is in the context of contributing to the group's efforts to complete a task. In concurrent G-DA, a mediator may offer several forms of support and each may be directed toward different group members, so long as the entire group is engaged in the activity at hand. *Cumulative G-DA* differs in that an entire mediation sequence is pursued with one learner at a time but in the context of group activity. Cumulative G-DA then appears quite similar to the one-to-one format except that the rest of the group, because they witness the interaction, are able to benefit from their peer's struggles and the mediation offered. When one exchange finishes, another member of the group is invited to engage directly with the mediator. Importantly, that learner begins at a different point because she or he has already participated, at least as an observer, in the earlier interaction. An additional advantage of cumulative G-DA is that it allows for the possibility of tracking the performance of individuals over time as well as the group as a whole, an issue discussed in detail in Poehner (2009). However, much more work is needed to better understand how teachers might apply either of these formats in their own classroom contexts.

Future Directions

Each of the topics discussed in this chapter, namely integration of DA principles with classroom teaching and assessing, computerized administrations of DA, and

DA in group settings, has only just begun to be explored and they therefore represent directions for future research. Having said that, I will briefly mention two additional areas that may provide fertile ground for research.

As noted, most L2 DA has followed an interactionist approach and has therefore been marked by dialogic negotiation between mediator and learner. Careful attention to the content of these exchanges as well as to overt behaviors, such as requests for support or the posing of questions, has provided considerable insight into processes of effective mediation. At the same time, advances in discourse and conversation analytic methods call attention to subtle, nuanced features of interaction, which some researchers have begun to interpret according to a Vygotskian theoretical perspective on development (e.g., Mondada & Pekarek Doehler, 2000). Most recently, van Compernelle (2010) has offered compelling evidence of ways in which practices from conversation analysis may be useful for examining L2 development as it unfolds during ZPD activity. In particular, he argues that mediation itself may be construed as jointly achieved in interaction between mediator and learner rather than something that is made available for learners to accept or reject. It remains to be seen to what extent processes of mediation, struggle, and development during DA may be better understood through the highly detailed system of transcription and notation advanced by conversation analysts.

In addition to the processes through which DA interactions unfold, it is also worthwhile to consider the L2 knowledge or abilities that are the focus of interaction. In the L2 field, where debates persist over form-focused and meaning-focused instruction, DA might be employed to explore, for example, learners' control over a discrete feature of the language (e.g., Poehner, 2009), but it might also be used to support learners' interpretation and construction of meaning in the L2. With regard to the latter, Negueruela (2003), taking a Vygotskian perspective, has argued in favor of organizing curricula around linguistic concepts rather than rules on the basis that learners may internalize concepts and rely upon them to regulate their functioning in the language. Lantolf and Thorne (2006) elaborate that such an approach understands concepts such as tense, mood, aspect, and voice, among others, to bring form and meaning together as learners are able to understand how the meanings they wish to express may be formed and tailored by conscious selection from among a number of linguistic options. Such an approach, these authors argue, is in stark contrast to conventional pedagogies that position learners to memorize and apply grammar rules in order to produce "correct" constructions. The authors point to the growing field of applied cognitive linguistics as a rich source of language research that may be leveraged for the design of concept-based pedagogies. DA principles for structuring interaction, married with a conceptual approach that focuses mediation on supporting learners' internalization of tools for self-regulation, would offer a particularly powerful framework for L2 education.

Notes

- 1 This project was funded by a grant from the United States Department of Education (Grant Award P017A080071). However, the contents of this chapter do not necessarily represent the policy of the Department of Education, and one should not assume endorsement by the Federal Government.
- 2 Transcription conventions are as follows:

+	short pause
++	long pause
.	full stop marks falling intonation
,	comma marks slightly rising intonation
?	question mark indicates raised intonation (not necessarily a question)
(word)	single parentheses indicate uncertain hearing
(xxx)	unable to transcribe
((comment))	double parentheses contain transcriber's comments or descriptions
<u>underline</u>	underlining indicates stress through pitch or amplitude
=	latched utterances

Diagnostic Feedback in the Classroom

Eunice Eunhee Jang

University of Toronto, Canada

Maryam Wagner

University of Toronto, Canada

Introduction

Although diagnostic assessment is widely used in clinical psychology and medicine, it has garnered little attention in second language (L2) assessment and education, where the stronger focus has been on proficiency and achievement testing. At its core, diagnostic assessment in education is intended to determine a learner's strengths and areas of improvement in the skills and processes being targeted in assessment and instruction, and to use that information to subsequently improve the student's learning and guide further instruction (Davies, 1968; Jang, 2010). Alderson (2005) provides a working definition of diagnostic assessment that summarizes its purposes and use in L2 or foreign language assessment:

Diagnostic tests are designed to identify both strengths and weaknesses in a learner's knowledge and use of language. Focusing on strengths will enable the identification of the level a learner has reached, and focusing on weaknesses or possible areas for improvement should lead to remediation or further instruction. Moreover, diagnostic tests should enable a detailed analysis and report of responses to tasks, and must give detailed feedback which can be acted upon. Test results and feedback should be provided as soon as possible after the test . . . The content of diagnostic tests may be based on material which has been covered in instruction or which will be covered shortly. Alternatively, it may be based on a detailed theory of language proficiency. (pp. 256–7)

This definition highlights the importance of the feedback generated from diagnostic assessment. Diagnostic feedback provides learners with information that can help them reflect on their learning in order to take remedial action. Although feedback has been widely researched in L2 education in general, and especially in L2 writing (e.g., Shohamy, 1992; Hedgcock & Lefkowitz, 1996; Lyster & Ranta,

1997; Ferris & Roberts, 2001; Ferris, 2003; Lee, 2003; Hyland & Hyland, 2006a), the research has tended to focus on the types and delivery modes of feedback to evaluate its effectiveness. Effective feedback, regardless of its type and delivery mode, needs to be grounded in a knowledge base about how learning takes place in the first place, which is one of the key ingredients of diagnosis. That is, a theoretical foundation must exist to explain the learning processes.

In this chapter, we examine the centrality of diagnostic feedback to advancing students' cognitive skill and strategy development. We begin by discussing previous research on feedback in general, and further conceptualize cognitively grounded diagnostic feedback in terms of its role in advancing student learning. Additionally, we take into account individual learner differences and contextual conditions that enable or inhibit the maximal *use* of feedback.

Research on Different Types and Modes of Feedback

Feedback, in general, is conceptualized as information provided for learners following an assessment task regarding positive aspects and areas for improvement in their performance or understanding (Hattie & Timperley, 2007). The learner may use this information to "confirm, add to, overwrite, tune, or restructure information in memory, whether that information is domain knowledge, meta-cognitive knowledge, beliefs about self and tasks, or cognitive tactics and strategies" (Butler & Winne, 1995, p. 275).

There are various types and delivery modes of feedback. For example, teachers may provide students with oral feedback during instruction or through student-teacher conferences. Oral feedback that encourages students' participation, drawing from a student's idea, is shown to be associated with effective teaching (Berliner, 1985; Richards, 1990). Teachers also spend a considerable amount of time providing written feedback. Teachers' feedback on students' writing can be distinguished in terms of whether an error is explicitly identified alongside its corrected form (direct or corrective feedback) or errors are identified, but without the provision of the correct form (indirect or facilitative feedback) (Bitchener, Young, & Cameron, 2005). Indirect forms of feedback may be further categorized according to whether or not the teacher uses a set of linguistic error codes. Teachers often use error codes to indicate linguistic errors in student writing, hoping that their comments will help their students to pay attention to recurring error types and correct them on their own. However, Ferris (2003) cautions that if a teacher's feedback is too cryptic or too indirect (e.g., in question form) without a clear suggestion for revision (e.g., "Tense?" "Agreement?"), it fails to lead to the desired result.

Then, how much direction should feedback provide to the learner? There is no clear research evidence indicating whether direct or indirect feedback leads to greater accuracy over time, although some studies point to greater benefits of indirect types of feedback in L2 writing (e.g., Lalande, 1982; Ferris, Chaney, Komura, Roberts, & McKee, 2000; Ferris & Helt, 2000). Bitchener et al.'s study (2005) reports that different types and conditions of feedback (i.e., oral, direct written, and no feedback) do not have statistically significant effects on accuracy

in the use of targeted linguistic forms when the target linguistic error categories are not differentiated. Bitchner et al. suggest that the effect of feedback may differ by linguistic features because they represent independent domains of knowledge and learners acquire each linguistic feature through different processes. Another noteworthy aspect of this study is the suggestion that individual learner differences (e.g., motivation, attention span) and learning tasks may explain why learners show differences in responding to feedback on different linguistic features.

In addition, feedback can be evaluative or descriptive in nature (Tunstall & Gipps, 1996). As its name implies, descriptive feedback provides learners with detailed information about processes and strategies used for solving problems, with the aim of informing subsequent learning goals. In contrast, evaluative feedback is summative in nature and tends to rely on qualifiers, such as "good," "nice job," or "excellent." Feedback using tangible objects as a reward (e.g., gold star stickers or smiley faces) commonly found in kindergarten and elementary school classrooms is essentially evaluative. Research suggests that both evaluative and tangible feedback types may be detrimental to student learning, as they tend to rely on students' extrinsic motivation (Tunstall & Gips, 1996; Black & Wiliam, 1998; Chappuis & Stiggins, 2002).

Research shows that verbal and symbolic feedback is more effective than tangible feedback because the former has potential to redirect children's attention to relevant cues in learning materials (Barringer & Gholson, 1979). Furthermore, tangible feedback presented only to correct responses results in the poorest learner performance because it tends to distract students' attention from the learning materials. Further, there is a less facilitative effect of giving only positive feedback rather than providing only negative feedback, probably because the former does not provide learners with an opportunity to confirm or disconfirm their approach to solving a problem. Students tend to show the greatest resistance when their teachers stop providing negative feedback. Due to various confounding factors, the effects of feedback can have facilitative or detrimental effects on students' learning. Consequently, understanding the nature and uses of feedback is pivotal to advancing student learning.

Evaluative and corrective types of feedback tend to focus on learning outcomes rather than cognitive processes and strategies. Outcome feedback contains mainly binary information about whether a student's response is correct or incorrect, and provides minimal guidance to a learner about how to improve (Butler & Winne, 1995). In contrast, cognitive feedback (Balzer, Doherty, & O'Connor, 1989; Butler & Winne, 1995) provides descriptive information that links students' perceptions about cues they take from a task to their performance on the tasks. It is important that the tasks used for cognitive feedback be designed to elicit and collect the traces of learners' cognitive processes, and that students' self-perceptions about cues be assessed alongside their cognitive processes (Butler & Winne, 1995). Therefore, it is not only the content of the feedback that contributes to advancing students' learning; the tasks on which the feedback is based play an equally pivotal role.

Cognitive feedback can target either learners' beliefs or their processing skills (Butler & Winne, 1995). In addressing a learner's errors in conceptual knowledge and beliefs, feedback should be tuned to each conceptual misunderstanding.

Cognitive feedback can (a) *confirm* a learner's understanding that is consistent with instructional objectives, (b) *add* missing information to the student's prior knowledge, (c) *replace* misconceptions, (d) *tune* the learner's understandings by specifying conditions and classifying concepts, and (e) even *restructure* prior knowledge incompatible with new learning. In addition to targeting knowledge and beliefs, cognitive feedback can focus on strategies that enhance students' approaches to tasks and facilitate their cognitive processing.

Cognitive feedback may be generated internally (i.e., by the self) or provided externally. Self-generated cognitive feedback is the result of learners' monitoring of their own learning progress. This internal feedback may also reflect a learner's beliefs and perceptions about a task's cues. Externally provided feedback includes feedback provided by peers participating in collaborative group work or by teachers, or may be generated by computer software. Though external feedback is a main source of feedback in education, feedback generated by the learner can play a crucial role by illuminating gaps between learners' perceptions about their learning (e.g., progress, rates, effectiveness) and achievement, which will help self-regulate learning. Butler and Winne (1995) note:

For all self-regulated activities, feedback is an inherent catalyst. As learners monitor their engagement with tasks, internal feedback is generated by the monitoring process. That feedback describes the nature of outcomes and the qualities of the cognitive processing that led to those states. We hypothesize that more effective learners develop idiosyncratic cognitive routines for creating internal feedback while they are engaged with academic tasks. For example, by setting a plan for engaging in a task, a learner generates criteria against which successive states of engagement can be monitored. In some cases, when a discrepancy exists between current and desired performance, self-regulated learners seek feedback from external sources such as peers' contributions in collaborative groups, teachers' remarks on work done in class, and answer sections of textbooks. (p. 246)

Cognitive feedback that provides descriptive information by making specific reference to students' actual cognitive processes has potential to facilitate self-regulated learning. This potential is what distinguishes cognitive from evaluative feedback, which mainly judges the quality of learning outcomes. Table 42.1 summarizes various types of feedback we have reviewed in this section.

Limitations of Previous Research on Feedback

As noted, previous research on feedback has been predominantly focused on students' final product without considering their cognitive processing and strategies. Various types and delivery modes of feedback are widely researched; however, research on its effects remains inconclusive (Cohen, 1985; Hattie & Timperley, 2007; Shute, 2008) because research has failed to address the cognitive bases of feedback; that is, how a learner's cognitive processing "unfolds as a function of regulative feedback" and in turn "how feedback is generated or accessed within cognitive processing" (Butler & Winne, 1995, p. 246). Research on feedback in L2 education and language assessment is far more limited to corrective feedback in L2 writing. The pedagogical potential of feedback that ranges along a full

modes of feedback limited to their learning outcomes. The role of diagnostic feedback is not simply to provide learners with error corrections, but rather to address a cognitive gap between a current level of performance and some desired level of performance or goal. Resolving this gap can motivate students to attain higher levels of effort. To address a cognitive gap for diagnosis, the level of feedback specificity should be considered. Feedback may be general, providing non-specific, normative information (Shute, 2008), or course information following a placement test (Bachman & Palmer, 2010). Alternatively, feedback may be more specific, targeting a cognitive skill or language process. Specific feedback in classrooms may facilitate remedial action for improvement in areas that have been diagnosed as weak. As Shohamy (1992) articulates it: “for assessment information to be used effectively it needs to be detailed, innovative, relevant and diagnostic, and to address a variety of dimensions rather than being collapsed into one general score” (p. 515). Additionally, more specific feedback permits learners to gain an understanding of how close to or far from a targeted performance criterion that ultimately leads to improved performance they are (Goodman & Wood, 2004; Goodman, Wood, & Hendrickx, 2004).

Specificity, a measure of granularity, however, should not be confused with quantity. That is, the amount of feedback that is provided to a student is not equivalent to its specificity. For example, students’ L2 writing development is positively impacted by the provision of judicious error feedback, not feedback that addresses *all* errors (Goldstein, 2001; Ferris, 2002, 2003). It is the specificity of feedback (or lack thereof) that is a primary distinguishing feature between the various types of feedback addressed in previous research and *diagnostic* feedback.

To reiterate, diagnostic feedback is intended to signal a gap between the learner’s current level of performance and a desired level of performance or goal. Then, how do we determine the learner’s current level of understanding, knowledge, or proficiency? How do we set the desired level of performance? How specific should be the feedback that we provide to the learner? When is the best time to deliver the feedback and how? Keeping these questions in mind, in the following section, we discuss some current developments of diagnostic assessment-based feedback and research on its effectiveness.

Proficiency Descriptor-Based Feedback

One common source of diagnostic feedback is information derived from an observed or measured discrepancy in performance between a current proficiency level and an expected mastery level. Language proficiency scales that are widely used around the world are based on the conceptualization of learners’ language proficiency according to distinct reference levels. For example, the Common European Framework of Reference (CEFR) for languages (Council of Europe, 2001) includes six reference levels, such as Basic (Breakthrough, Waystage), Independent (Threshold, Vantage), and Proficient (Effective Operational Proficiency, Mastery). Performance-level descriptors are used to illustrate a learner’s knowledge and skills, progressing toward the mastery level, and to facilitate teachers’ professional judgments about the individual learner’s progress. It is these detailed performance-level descriptors that are diagnostically useful, rather than the per-

formance category labels. We review the feedback systems of DIALANG and Steps to English Proficiency (STEP) as examples of language proficiency descriptor scales.

DIALANG

DIALANG is a computer-based diagnostic test of language ability designed to assess learners' ability across reading, writing, listening, vocabulary, and grammar structures (Alderson, 2000, 2005; Alderson & Huhta, 2005). The test is based on the scales of the CEFR (Council of Europe, 2001) and offers test takers the opportunity to assess their language skills in 14 different languages. One of the many strengths of the DIALANG system is its computer interface, which delivers the feedback; the feedback is not being provided by an authority in the classroom. If users choose to take the initial vocabulary placement test, they receive immediate results across a six-band continuum where their skill may range from "very low" to "indistinguishable from a native speaker." Learners may also complete a self-assessment component of DIALANG comprising a series of can-do statements targeted at determining test takers' perception of their language ability across listening, reading, and writing skills (not vocabulary and grammar).

Following the DIALANG assessment, users are offered two types of feedback. The first allows test takers to immediately realize the outcome of their response to each question. This immediate feedback is optional and test takers may choose to discontinue receiving the information at any time during the test. The second type of feedback is delivered to test takers upon completion of the test. This feedback is detailed and diagnostic, comprising (a) the level that test takers achieved in terms of one of six levels of the CEFR, alongside a description of the level; (b) an itemized table of responses to each test item, grouped by skill level (each item is "clickable," allowing the test taker to revisit the question); (c) a placement test score (not aligned with the CEFR) that places the learner's score along a 1–1,000 scale; (d) self-assessment feedback that tells test takers whether their assessment of language ability matches their test results or not; and (e) advice on their test results that includes information about the adjacent CEFR levels (above and below), as well as suggestions for improvement. This detailed feedback is provided for each type of skill and language in which the test takers choose to be assessed.

Chapelle's (2006) review of DIALANG offers an overall positive evaluation of the test, but raises some concerns about the validity of its claims. This concern is also discussed in the use of DIALANG as a self-assessment tool in portfolio-based assessments to raise students' awareness of their own ability (González, 2009). Because the system is freely open to users, it appears to be difficult to collect controlled student data, which is essential for seeking empirical validity evidence.

STEP

Steps to English Proficiency (STEP) is an example of a language assessment framework developed in Canada to assist teachers in the process of evaluating students' English language proficiency in K-12 schools. STEP is a set of descriptor-based continua that provide descriptions of observable language behaviors across three

skill sets for each of four grade clusters: reading, responding, writing, and oral communication. Currently, Ontario school teachers use STEP to assess their students' language development. The descriptors in the STEP assessment framework are aligned with curricula implemented in Ontario K-12 schools.

Research on STEP (Cummins et al., 2009; Jang, Stille, Wagner, Lui, & Cummins, 2010) shows that the proficiency descriptors help teachers understand English language learners' (ELLs') language development, an understanding they use for guiding instruction. Having separate scales for three modalities helps teachers understand the complex nature of English language development among school-aged ELLs. Teachers report that they look to the adjacent level to identify subsequent learning goals for skill development. Because STEP is aligned with the curriculum, it provides teachers with the opportunity to align their instruction and assessment with STEP in order to provide students with formative feedback to promote their English language development. The research of Jang et al. (2011) on STEP examined a range of learner characteristics including language history, language goal orientations, and language learning activities as well as teachers' assessment beliefs and competence in evaluating its validity.

The most immediate effect of STEP is on teachers, as they use it to identify students' immediate language-learning strengths, and identify subsequent areas on which they need to focus. Specifically, teachers reported that STEP helped to clarify students' specific needs by identifying gaps in their language learning, and by drawing their attention to each student's individual needs (Cummins et al., 2009). These comments illustrate how STEP can help teachers to strengthen their assessment competency and integrate a systematic feedback loop in teaching.

The following case of a grade nine ELL, Nadia (a pseudonym), based on research from Jang et al. (2011), illustrates how students may benefit from STEP. Nadia speaks Urdu as her first language. She arrived in Canada 17 months prior to the initial STEP assessment. She is a highly motivated student who studies English daily by reading, watching television news broadcasts, and spending multiple hours a week volunteering in the community in an effort to practice her English. She does not think that learning English is a fun activity, nor is it her favorite activity, because she believes that if an individual is having fun, then she is not learning. Nadia identifies her primary goal to be to "get perfect [*sic*] in English" (Nadia, personal communication, June 13, 2011).

In an interview with Nadia, she explains that she receives both positive and negative feedback from her teacher, and that she greatly values both. For example, her teacher identifies Nadia's strengths and areas for improvement using the STEP descriptors. Nadia is currently working on STEP 4 of the oral communication modality of STEP; she has consistently demonstrated the observable language behaviors included in the previous STEP (STEP 3) oral descriptors, but not all of those in STEP 4. Using the descriptors in the STEP assessment framework, Nadia's teacher is able to tell her that she is able to successfully "rehearse and make a presentation which includes significant points and supporting details" (STEP 4 descriptor), but she has not yet mastered the ability to "use vocabulary to clarify/enhance meaning by incorporating low frequency words" (STEP 4 descriptor).

In addition, an observation of Nadia's classroom shows how feedback is used in daily interactions in classrooms. Nadia's teacher provides oral, whole group feedback during which she identifies areas that require further development. The teacher addresses multiple aspects of Nadia's oral communication skills including pronunciation, voice, grammar, and content. Nadia cited one specific example where the teacher suggested that the students make eye contact with a minimum of three people during an oral presentation.

While STEP provides opportunities for teachers to increase their understanding of English language development and assessment competencies as well as the quality and content of their feedback to students, the impact of the *use* of the feedback by students has not been investigated. Further research is needed to understand how STEP-based diagnostic feedback facilitates positive learning environments.

Cognitive Diagnostic Assessment

Cognitive diagnostic assessment (CDA) provides detailed accounts of the underlying cognitive profile of a learner's performance (Nichols, Chipman, & Brennan, 1995; Jang, 2005, 2008; DiBello, Roussos, & Stout, 2007; Leighton & Gierl, 2007). CDA bases its inferences on the classification of learners according to the probabilistic mastery level of each tested skill. The cognitive base comprises skills that learners use to process knowledge required for tasks. CDA begins by specifying a set of core skills, processes, or strategies guided by the relevant theory, followed by a careful design of tasks that elicit the skills. Using multidimensional latent class models, CDA estimates individual learners' mastery standing for each skill and provides detailed feedback for both learners and teachers.

Jang (2005) developed cognitive skill profiles for students enrolled in Test of English as a Foreign Language (TOEFL) preparation courses in the USA and examined the users' perspectives about the validity of skills profiling and feedback. Students' responses to the question of how well the diagnostic feedback identifies strengths and areas for improvement in tested skills are insightful. Students note that the accuracy of skills diagnosis depends on various factors, including (a) the number of questions (more questions provide more convincing feedback and are illustrative of the ratio between skills and tasks) and (b) the number of skills a task assesses as skills cannot be divided accurately when questions assess multiple skills demonstrating cognitively complex multidimensionality. Students also noted that skills diagnosis is irrelevant when an entire reading passage is understood (unitary view of reading proficiency). These issues are at the heart of CDA.

Students' views of diagnostic feedback also reveal some important motivational factors, which we discuss later in this chapter. While most students appreciated diagnostic feedback, students with low proficiency responded to their skill profiles with embarrassment and disappointment. Conversely, a high proficiency student questioned what it meant to have all the skills mastered, indicating that his skill mastery profile confused him because there was no further direction for future action. When asked about the use of the diagnostic feedback after the instructional term ended, 78 percent of the students found it "a little bit" to "always" useful.

Those who reported that the feedback was of little use were the students who had “flat” skill profiles (mastery of either none or all of the skills), suggesting that the usefulness of feedback depends on whether it provides information about what future action needs to be taken. From interviews with teachers, Jang (2005, 2008) notes that while they agree that diagnostic feedback could help students raise their metacognitive awareness of the target skills and further help teachers to understand the areas for improvement and plan instruction to help students to improve them, the usefulness of cognitive diagnostic feedback depends on the context of learning and the heavy curriculum load.

Kim (2010) developed proficiency descriptor-based assessment checklists for L2 writing teachers and learners, and constructed individual students’ writing skill profiles using CDA. Her study demonstrated that teachers found the detailed, diagnostic writing information beneficial as it contributed to their understanding of the domains in which all students required help as well as those that necessitated further instruction for individual students. Her study also highlighted that some teachers believed that provision of excessive diagnostic information (e.g., identification of all grammatical errors) could be “demotivating” and create contexts of “disempowerment” for students. Additionally, teachers suggested that the diagnostic information should be offered incrementally for students at different proficiency levels because they perceived that motivated students would benefit more from the detailed feedback than more proficient students. Similar to the STEP study that we discussed earlier, Kim’s investigation also focused on the impact of the diagnostic information on teachers’ practice, not on students’ use of feedback to improve their writing.

Despite the benefits and promise of CDA modeling, there rest a few challenges to its implementation on a large scale. These issues include the fact that CDA models require careful design of diagnostic tasks, involving a sound theoretical understanding of the nature of language processes (Jang, 2008).

Criterion

The Educational Testing Service’s (ETS) Criterion® Online Writing Evaluation Service is another example of a feedback system. In this Web-based service, a learner’s text is analyzed and rated electronically to provide almost instantaneous diagnostic feedback on the written product. Criterion provides two types of information: a holistic score and a trait feedback analysis. The latter comprises feedback on three broad areas: grammar, which is further delineated into usage and mechanics; style; and organization and development. These categories are identical to those of the analytical trait-scoring approach, as in the 6-trait or 6+1-trait scoring methods (Quinlan, Higgins, & Wolff, 2009). Within each category, more detailed feedback is provided about each of the traits. The feedback screen is interactive, allowing learners to roll over highlighted parts of their text to generate a comment box that offers additional feedback on each micro-feature of the writing. It should be noted that while the feedback is descriptive and detailed, it is not corrective; that is, it does not provide any corrections to identified errors. Teachers may also insert additional comments for students to view. All of the feedback is available in English or in the dual languages of English and Spanish for language learners who would benefit from the translations.

The Criterion Online Writing system may be incorporated into an elementary or secondary school classroom in which teachers may use the system as part of their instruction. Although development of ideas and planning of writing are incorporated into the system, Criterion's e-rater is designed to evaluate the final text or product (Quinlan et al., 2009). The writer is not provided with feedback on each step of the process, but rather on the outcome, which aligns the system with a product approach to writing. The Criterion Online Writing system is also able to aggregate students' results for instructors (i.e., feedback for teachers) so that they are able to gain a holistic understanding of their students' strengths and weaknesses.

Empirical research on the effects of Criterion on students' writing is inconclusive. While Shermis, Burstein, and Bliss (2004) report no statistically significant difference in gains attributable to the use of Criterion for secondary school students, Attali (2004) reports that students in grades 6 and 7 who implemented feedback for revision showed improvement in their subscores in development, grammar, usage, mechanics, and style. Warschauer and Ware (2006) raise concerns about the use of Criterion and other automated writing evaluation software programs to support the writing development of, especially, beginner language learners, and call for more empirical evidence to support the effectiveness of Criterion for low proficiency language learners in the development of their writing. As noted above, Criterion only provides feedback on students' final writing, and not on any previous drafts. This aspect of the e-rater may pose a serious limitation to maximizing the positive impacts of feedback on writing. Research indicates that students benefit from feedback on multiple drafts of their work during process-oriented writing practices (Fathman & Whalley, 1990; Ferris, 2003). Criterion's 6+1-trait scoring method does not address the content or ideas that students have developed in their writing; rather, the focus is more on the structural features (e.g., grammar, mechanics, style) of writing. As Criterion acknowledges, it is a system that supports teachers in their instruction of students' writing; it is not meant to replace teachers.

Dynamic Assessment

As noted, what distinguishes diagnostic assessment from other general tests is its focus on assessing the gap between a student's existent (actual) ability and cognitive functions, and short- and long-term potential (future) development. Dynamic assessment is an interactive approach to determining students' potential learning ability by providing them with mediation to develop cognitive functions that are emergent in the zone of proximal development (Vygotsky, 1986; Minick, 1987). These emergent cognitive functions become internalized through interpersonal, collaborative interaction (Kozulin & Garb, 2004). This feature is the main characteristic of dynamic assessment (Lantolf & Poehner, 2004). Dynamic assessment typically involves pretesting of a student's current cognitive ability, a mediated intervention, which is indispensable for the student's future development, and post-testing of the student's actualization of emergent cognitive functions. Lantolf and Poehner (2004) point out that "assessing without mediation is problematic because it leaves out part of the picture—the future—and it is difficult to imagine an assessment context that is *not* interested in the future" (p. 251, emphasis in text).

In dynamic assessment, feedback can reduce the learner's cognitive load through facilitative feedback that scaffolds language tasks. Such mediated and immediate feedback is especially pivotal for low ability learners faced with complex language-learning tasks. For example, teachers can mediate through scaffolding by questioning the learners to reorient their attention when they face difficulty, and by demonstrating how to accomplish the task.

Kletzien and Bednar's study (1990) demonstrates how the dynamic assessment procedure can be used to determine at-risk students' cognitive strategy use and attitude to reading instruction. A strategy analysis of a grade 10 student, Suzana, indicated her over-reliance on background knowledge in understanding the text. As she became more frustrated with her lack of reading ability, which was lower than her grade level, she tended to avoid making an effort and attributed her difficulty to inability (i.e., she considered herself to be "really stupid," and "not good at this"). The teacher provided her with a subsequent mediated intervention by discussing both her strengths and limitations when interacting with the text. Identifying visualization as her strength, the teacher used a think-aloud procedure to model how the student could use the strategy with an expository paragraph. Suzana was asked to visualize her mental images while reading a new paragraph, and the teacher continued to provide oral feedback for clarification and reinforcement. A post-assessment indicated that the student could understand materials at a much higher level using visualization. This research demonstrates that orally mediated feedback from dynamic assessment can be valuable for at-risk readers and that it helps them to gain a greater sense of control and confidence in learning.

While dynamic assessment can be easily integrated into instruction, it is not clear how an assessor or mediator determines a learner's current proficiency level. Mediation also requires a developmental theory that articulates how the learner makes progress. Research on the potential of dynamic assessment can offer insights into a learner's cognitive processes as well as the role of mediation (e.g., graduated prompt, oral feedback) on a learner's developmental growth trajectory.

Factors Affecting the Use of Diagnostic Feedback

Evaluation of the effectiveness of feedback needs to consider individual and contextual factors that advance or hinder its intended use. As noted, learners do not simply respond to external feedback; rather, they actively seek to configure their states of knowledge and learning progress by filtering external feedback through their own beliefs and goal orientations. Diagnostic feedback is potentially more effective when it provides information about the learner's progress toward a set of goals rather than when it is about discrete responses to individual tasks, as it reduces uncertainty about the status of mastery. It also helps the learner to stay focused on task performance. When the goals are challenging for the learner in a meaningful and attainable way, it motivates the learner to self-regulate his or her own learning (Butler & Winne, 1995; Hattie & Timperley, 2007). Hattie and Timperley (2007) argue that effective feedback should invite teachers and students to ask three essential questions:

1. Where am I going? (What are the goals?)
2. How am I going? (What progress is being made toward the goals?)
3. Where to next? (What activities need to be undertaken to make better progress?)

These authors reduce these questions to three corresponding elements of feedback systems: feed up, feed back, and feed forward. All of these elements contribute to learners' understanding at task, process, self, and metacognitive levels.

Not all learners, however, appear to make goal-driven efforts in task performance. Learners' goal orientations contribute to how they perceive and respond to these questions. According to goal orientation theory (Dweck, 1986), learners can hold a mastery or a performance goal orientation toward tasks. Mastery-oriented learners tend to enjoy challenging tasks to enhance their skills and competence, whereas performance-oriented learners aim to demonstrate their competence to others, seeking positive responses from them.

Goal orientation theory further explains why learners with equal ability show marked differences in response to challenging tasks. Mastery-oriented learners seek challenging tasks, use more complex learning strategies, and welcome constructive feedback about how to improve their skills. Performance-oriented learners tend to avoid challenging tasks in the face of failure, seek less challenging tasks and materials so that they can demonstrate success, and like to receive marks about their discrete responses to tasks (Dweck & Leggett, 1988). Performance-oriented learners who perceive their current ability as low may hold the view of ability as a fixed entity and therefore avoid challenging tasks because their efforts signal a lack of ability (Dweck & Leggett, 1988, citing work by Bandura & Dweck). These learners may view constructive, diagnostic feedback that explains their areas for improvement as a threat to self-esteem, show anxiety and shame, devalue tasks, and express boredom. In contrast, mastery-oriented learners can get bored when they achieve success with minimal effort. They enjoy intrinsic rewards and take pride in recognition of their success.

Cognitively diagnostic feedback can serve as a means to reorient learners toward goal-driven learning and efforts partly because students' goal orientations drive their motivation (Ames, 1992). Goal-oriented feedback may help the learner understand that ability can be enhanced through effort and that failure and mistakes are part of the competence-building process (Hoska, 1993). It can help learners to self-regulate their cognitive engagements with tasks.

As we discussed earlier, the context in which learning and assessment take place influences how learners perceive and use feedback. If classroom structures involve highly competitive and performance-oriented learning environments, feedback from assessment may have a detrimental effect on student learning. Ames (1992) argues that students' learning is hindered when a classroom context is performance oriented with excessive focus on grades and competitions. She further suggests that if students are given the opportunity to improve their skills (i.e., provided with feedback with an opportunity to improve, rather than receive a final score), then they exert more effort and are concerned with self-improvement rather than "performing." Therefore, not only does the learning environment influence how students receive and use feedback depending on their individual goal orientations, but the context may also shape the learners' orientations. As Hyland and

Hyland (2006b) aptly state, “we actively construct a context that relates feedback to specific *learners*” (p. 213, emphasis in text).

The interpretation and use of feedback by learners may also be influenced by their cultural influences and individual backgrounds (Sully de Luque & Sommer, 2000; Hyland & Hyland, 2006a; Nelson & Carson, 2006). Additionally, the delivery of feedback by teachers is also a reflection of their belief systems and cultural experiences (Hyland & Hyland, 2006a). Hyland and Hyland (2006a) note:

Ideologies help establish cohesion and coordinate understanding through mutual expectations but cultural variation in these assumptions can intrude into classrooms through the expectations that teachers and students have about instruction and the meanings they attach to the feedback they are given. (p. 11)

Therefore, the delivery and use of feedback may be mediated by the shared and individual cultural experiences in a classroom; however, the extent to which culture plays a role in these exchanges is not easily understood.

Sully de Luque and Sommer (2000) examine the relationship between feedback and four “cultural syndromes,” which they identify as specific holistic orientation, tolerance of ambiguity, individualism–collectivism, and status identity. These authors proposed these syndromes following a comprehensive search of the literature across multiple disciplines, and identify characteristics that inform the interaction between the receiver and provider of feedback. Sully de Luque and Sommer subsequently propose a feedback model incorporating these cultural facets across various feedback activities. For example, these authors propose that in organizations (or classrooms) where there is a low tolerance for ambiguity, the feedback provided will be more structured and procedural than in a high tolerance context. At the same time, learners with low tolerance for ambiguity will seek feedback more frequently than students who are not similarly influenced. It should be noted that Hyland and Hyland (2006a) caution against an overdependence on cultural factors as explanatory tools in the feedback loop. While aspects of students’ cultural dimensions should be used to inform interactions and multiple perspectives, particularly in language-learning contexts where multiple cultures are represented, overused labels and stereotypes should be avoided.

In addition to the influences we have addressed thus far, the context of assessment may also influence the impact and use of feedback. For example, if assessment is perceived to have high stakes by learners, the effect of feedback from such high stakes assessment is inevitably limiting if not negative, as Collins (1990) warns:

One notion afoot is that because we can diagnose the precise errors students are making, we can then teach directly to counter these errors. Such diagnosis might indeed be useful in a system where diagnosis and remediation are tightly coupled . . . But if diagnosis becomes an objective in nationwide tests, then it would drive education to the lower-order skills for which we can do the kind of fine diagnosis possible for arithmetic. Such an outcome would be truly disastrous. It is precisely the kinds of skills for which we can do fine diagnosis, that are becoming obsolete in the computational world of today. (pp. 76–7)

Research on diagnostic feedback in the context of assessment should seek fuller accounts of its effects by considering its interactions with individual learner differences and a broader social context of assessment in practice.

Challenges and Future Directions

In this chapter, we argue that cognitively diagnostic feedback about learners' cognitive skills may be potentially more effective to advance students' language learning than other types of feedback, including evaluative or those that mainly correct errors. Cognitively rich feedback requires much finer descriptions of learners' cognitive engagements with tasks. Existing theoretical frameworks appear to be too "coarse" to provide such accounts. As diagnostic assessment is still in its infant stage in language assessment, future research should seek to gather qualitatively rich accounts of various sources of conceptual errors and states of knowledge by employing tasks designed to elicit and analyze cognitive strategies and processes.

One aspect of the research in this body of literature that needs to be addressed is that of grain size. While diagnostic feedback may provide information on the basis of inferences about learners' strengths and weaknesses in the broad areas of skills, much of the focus in investigations of L2 education has been on specific linguistic features (e.g., past tense, possessive pronouns, infinitives). Although more specific diagnostic feedback is desirable, too specific diagnostic feedback increases undesirable complexity for the learner. Therefore, it is crucial to specify a proper grain size for diagnostic feedback in determining the cognitive base of feedback.

Maximizing the effect of feedback depends on the extent to which teachers are equipped with diagnostic assessment competence: "the ability to interpret students' foreign language growth, to skillfully deal with assessment material and to provide students with appropriate help in response to this diagnosis" (Edelenbos & Kubanek-German, 2004, p. 260). However, it has been repeatedly reported in the literature that many teachers (including language teachers) in North America and the UK do not possess an adequate understanding of the principles of assessment (Stiggins, Conklin, & Bridgeford, 1986; Black & Wiliam, 1998; Childs & Lawson, 2003). Teachers' lack of sound assessment knowledge, in classrooms where increasing globalization has resulted in classes with increasing numbers of language learners, means that there is a greater demand for teachers with the ability to diagnose students' language strengths and areas for improvement and provide them with ample, specific feedback that will allow them to improve their language skills alongside their acquisition of curricular content. The provision and use of diagnostic feedback in classrooms may be facilitated or impeded to the extent that teachers possess the diagnostic competence to provide it.

In this chapter, we discussed the potential of diagnostic feedback in the context of assessment and learning and differentiated it from evaluative and outcome-based feedback. We believe that the emergence of research on diagnostic assessment and resulting feedback calls for the reconceptualization of feedback to entail a learner's cognitive strengths and areas for improvement beyond the accuracy

of a final product. Research on the effects of feedback on learning should further consider the interplay among features of assessment tasks, individual differences, and assessment contexts in order to account for how feedback mediates performance and may further facilitate self-regulated learning.

The authors wish to thank the anonymous reviewers for their insightful comments on an earlier version of this chapter.

Self-Assessment in the Classroom

Mats Oscarson

University of Gothenburg, Sweden

Introduction

A human cognitive ability, such as the ability to use a foreign language, can be viewed and assessed from two fundamentally different perspectives:

- the *internal (or intrinsic) perspective*, which underlies the individual's own assessment, and
- the *external (or extrinsic) perspective*, which underlies an assessment made by somebody else, that is, an outside agent.

In other words, an internal assessment is made from “within” and reflects a direct experience of one's own ability. External assessment reflects an outside view of someone's ability and will thus always be indirect. In focus here is the former kind of assessment, more commonly referred to as self-assessment, and the question of its relevance and applicability in the foreign language classroom.

The practice of learner self-assessment of language ability has attracted increased attention over the last few decades. Although it may be argued that it has always been an important component of good teaching and effective learning, it was only during the 1980s that students' own estimation of their achievement in the study of languages began to be more widely practiced and researched. Many of the activities that have been reported grew out of the seminal language education work initiated by the Council of Europe, particularly through the modern languages project. This strongly emphasized the learner's own role in various phases of the educational process, including that as active participant in evaluation and assessment procedures (Council of Europe, 1981, 1988; Girard & Trim, 1988). A renewed interest in portfolio methodology, with its defining characteristics of learners' selection and evaluation of their own work, has been

another influential factor behind the heightened attention to self-assessment as a pedagogic tool.

The purpose of this chapter is to give a background to and illustrate the nature and possible functions of self-assessment in foreign and second language learning. The primary focus is on research evidence and on the issue of how such assessment may be practically realized in the language classroom, in particular for the purpose of ongoing *formative (improvement-oriented)* assessment, or assessment *for learning*. The chief objective of this is feedback on learning activities for the benefit of future performance. Reference will also be made to self-assessment used for *summative (outcome-oriented)* purposes, or assessment *of learning* (Wiliam, 2011, pp. 9ff.). Such assessment is undertaken in order to determine achievement as an end result, for example on completion of a learning unit or a more comprehensive sequence of study. (For a discussion of the conceptual differences between formative and summative assessments, see, e.g., Scriven, 1967, 1996.)

Toward More Learner-Oriented Language Assessment

In recent decades, many language teaching environments have undergone profound changes in classroom activities and evaluation procedures. Particularly with regard to the goals of learning and the role of the student, there has been a distinct reorientation. Many educational principles and practices that formerly characterized school-based language study have given way to new trends. Communicative objectives and standards-based education have, for instance, eased the pressure of studying formal grammar and syntactic rules. Instead, emphasis has increasingly been placed on the training of practical communication skills more closely aligned with commonly felt language needs. Thereby the goals of instruction (as defined in course descriptions, teaching materials, test specifications, etc.) have become generally more transparent and comprehensible to learners and it has, in principle, become easier for them to conceptualize and relate to the targets aimed at.

A likely effect of these developments is that students today are better aware of *what* they are set to work on, and *why*. This is advantageous, not least in view of the opportunity it offers for learner participation in assessment. A raised level of awareness is also a necessity in this respect, because, as has been pointed out, “pupils can assess themselves only when they have a sufficiently clear picture of the targets that their learning is meant to attain” (Black & Wiliam, 1998b, p. 5).

The quest for authenticity in language study has also helped to make learning aims more tangible and to put the learner’s interests in focus. Particularly when the target language is English, learners often have a rich source of out-of-school experiences that they can bring to bear on classroom activities. Many encounter the language in their daily lives in both spoken and written forms: in films, television programs, commercials, videos, song lyrics; in newspapers, brochures, magazines; and so forth. This can make them sensitive to a lack of correspondence between the two types of language contact (i.e., in and out of school). If learners find that there is a mismatch between the two, they are likely to attempt to sway classroom activities in a direction which better meets their interests and perceived needs.

It is thus probably safe to say that learners today, in comparison with an earlier generation of learners, are more conscious of how common classroom activities are functionally related to the stated goals of their language studies. The positive effects of learners' consciousness of educational goals have been noted in many contexts. Leow (2000) concluded that learners who show an awareness of learning targets obtain better achievement test results than students who demonstrate a lack of such awareness. There is also evidence that language learners will produce more accurate self-assessments if the criterion relates to achievement of concrete functional skills and explicitly stated behaviors rather than if it is a criterion that exemplifies proficiency in a more abstract sense (Ross, 1998). A comprehensive meta-analysis of studies investigating the formative functions of test instruments showed that students were, as noted above, able to make dependable assessments of their achievements only to the extent to which they had a clear perception of the goals of the instruction they received (Black & Wiliam, 1998b).

Clarity of goals and accuracy of learner self-assessments can thus be regarded as inter-related phenomena. The more explicitly stated the goal, the greater the likelihood that the learner can estimate his or her learning in a meaningful way. Now that learning goals are often laid out in more transparent and comprehensible terms, as noted above, it may be assumed that student self-assessment is capable of playing an increasingly important role in future language education.

Cooperative Needs Analysis and Feedback Functions

Another change in the field that tied in with the emergent communicative approach to language education has been the growing recognition that learners need to be consulted on a more regular basis, in many contexts as a matter of principle, at the stage when course content is being planned and defined. The concept of participatory learning has been extensively explored and learners' views on goals and ways of achieving them have become an increasingly important consideration. A case in point is what is known as the negotiated curriculum. In this approach to course design it is laid down that the learner should have a say both in defining content and in choosing methods of evaluation (Nunan, 1988). The negotiated curriculum has proved to be a viable concept which contributes to the development of more accessible and learner-centered forms of study. This in turn facilitates learner involvement in the monitoring and assessment of activities in many areas of language study.

Clearly specified goals, access to authentic language, and participation in needs analysis are thus some of the factors that support learners in their critical and constructive evaluation of what takes place in the classroom. Less relevant and less effective activities, as experienced by learners, are likely to be queried while activities that are felt to accord well with clearly conceived and preferred objectives will tend to be endorsed. This mechanism constitutes another important rationale for the pursuit of learner-involved modes of assessment.

Summing up, we may say that late 20th-century advances in applied language studies and linguistic needs analysis resulted in more realistic and user-oriented views of the language-learning task. From this followed elaboration of more

direct and explicit specifications of the goals that are set up for learning. This in turn tended to make it easier for the lay person to understand the nature and purposes of language instruction strategies. For learners in particular, this was an important development. It gave them a better opportunity for taking an active part in the structuring, conduct, and assessment of their own studies. Teacher-student “dialogical” learning, coupled with enhanced student self-reliance and a heightened sense of shared responsibility for learning, emerged as a natural way forward in language education.

The Changing Language Assessment Scene

For a long time, language assessment was dominated by the psychometric tradition of measuring abilities and achievement. This tradition had its roots in early intelligence testing and was characterized by extensive use of discrete-point testing (i.e., of discrete learning points) and norm referencing (relative ranking of test takers), often on the basis of administration of multiple choice item tasks (Spolsky, 1995). The tradition is being replaced by a more comprehensive model of “educational assessment” that, among other things, emphasizes the importance of the validity in measurements and the learner support functions that assessments and testing can have (Gipps, 1995). Proponents of this model strive to align methods of assessment with actual learning goal behaviors (Harris & Bell, 1994). This is accomplished through the use of more performance-oriented test tasks, particularly tasks that resemble real-world language use and, in the classroom, common learning activities. Examples are oral interaction in pairs, formal group discussion, reviewing and reporting exercises, and summarizing tasks. Performance assessment differs from more conventional testing particularly in the degree to which the test task presented is congruent with the behavior domain to which the tester wishes to make inferences.

Because authentic language is quite prevalent in many students’ daily lives, for the most part out of school, students today are frequently in a comparatively good position to make judgments about the effects of the instruction they receive in the classroom, namely in relation to what they feel they need. The chances are, therefore, that they can provide useful information about the quality of their learning in school. Seen in this perspective too self-assessment can be both a natural and a valuable complement to teacher assessment.

The inter-relationship between the variables discussed in this introduction is graphically represented in Figure 43.1.

Theoretical Framework

As the foregoing summary of trends in language education makes plain, there are several practical explanations for the heightened interest in student self-assessment. But also, more theoretical arguments speak in favor of it. Work in this field has centered on the question of the general significance of self-observation and reflective monitoring of learning and achievement (e.g., Bandura, 1986, on a range of

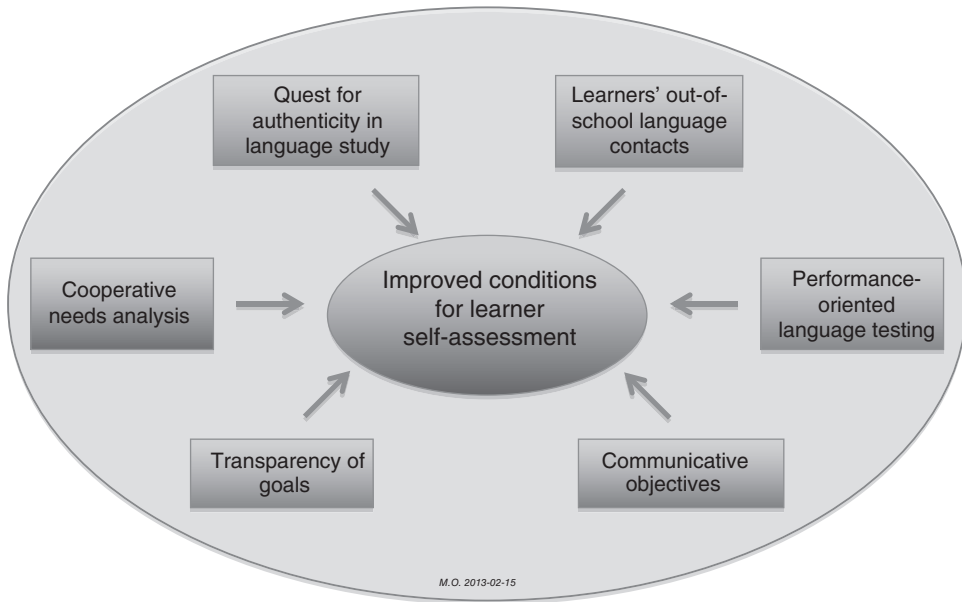

Figure 43.1 Factors influencing conditions for learner self-assessment in language education

significant self-regulatory mechanisms in human behavior and the functions of self-observation, self-judgment, and self-reaction; Boekaerts, Pintrich, & Zeidner, 2000, on metacognitive processes and the principles of self-managed learning). For arguments concerning raised levels of awareness, see, for instance, Holec (1988), and for arguments related to increased motivation and improved learning, McDonald and Boud (2003) and Butler and Lee (2010).

In particular, cognitive and constructivist theories of learning hold that self-assessment can be seen as an integral part of effective acquisition of knowledge and skills. Dale H. Schunk, a leading researcher in the field of metacognitive and self-regulatory processes, makes the point that “goal setting and self-evaluations of progress are important components of self-regulated learning. If a certain instructional method requires students to set goals and evaluate their progress, then we might predict that students who received such instruction would show gains in self-regulation and achievement. That prediction can be tested in a research study” (Schunk, 2008, pp. 466–7).

In the next section we will look into some of the language education work that has been done in this respect.

Research

Research into self-assessment in language education has in particular focused on the question of the significance and validity of the approach and its results: To what extent are language learners, in general, able to make accurate and useful

judgments of their own (linguistic) ability? What faith can be placed in the results self-assessment procedures generate? Questions have also concerned development work in the area of methodology. In what forms and by what means can self-assessment be realized in common language-learning situations, primarily in the foreign language classroom? Issues of validity and practicality have thus been at the forefront of the research conducted.

An early meta-study in the field of psychological assessment indicated that self-assessment can be reasonably accurate and that it can, under certain conditions, yield results that are comparable to external assessment methods (Shrauger & Osberg, 1981). Generally positive correlation between self-assessments and teachers' marks was obtained in a similar meta-analysis conducted by Falchikov and Boud (1989). They also found that the degree of agreement tended to be functionally linked to certain other variables such as level of learning (a higher degree of correspondence at more advanced levels) and quality of the research (higher correspondence in more carefully designed studies). The type of assessment task, on the other hand, did not seem to be clearly coupled with the variability observed.

In a literature review of studies in the particular field of language learning it was found that there is often a good deal of agreement between learners' self-assessments and external criteria (Oscarson, 1984). Variables such as learner background, previous education, and extent of preparatory training were, however, believed to impinge on the reliability of self-assessed scores. In a later summary of 16 research studies on the same topic, Blanche and Merino (1989) noted that there was "consistent overall agreement between self-assessments and ratings based on a variety of external criteria" (p. 315). They also found evidence of enhanced learner motivation in half of the studies surveyed. Ross (1998) similarly analyzed the results of 10 language studies and could confirm a statement made by Blanche and Merino that self-assessment tends to provide "robust concurrent validity with criterion variables" (p. 16). He further concluded that "learners will be more accurate in the self-assessment process if the criterion variable is one that exemplifies achievement of functional ('can do') skills" and that they may be less accurate when the instrument they use contains items of a more abstract kind. The findings also suggest that more accurate assessments are made by learners who have had more extensive experience with the skill they are asked to self-assess.

In a comprehensive and much publicized survey of the literature on classroom formative assessment, Black and Wiliam (1998a, 1998b) focused on the perceptions of students and their role in self-assessment. The authors concluded that there exists firm evidence of the benefits of formative assessment and that it is capable of raising standards. It was also pointed out that for formative assessment to be productive, students need training in self-assessment so that they can grasp what their learning tasks entail.

Research of this kind, reporting gains in academic achievement of students involved in self- (and peer) assessment, has prompted further research and critical evaluation of results obtained. In a survey reported by Sebba et al. (2008) the following vital question was posed: "What is the evidence of the impact on students in secondary schools of self and peer assessment?"

Three types of impact were considered: outcomes relating to (1) attainment, (2) self-esteem, and (3) the superordinate goal of "learning to learn." Results were based on in-depth analyses of 26 studies finally included in the survey. "All curricular areas," most of them focusing on English and mathematics, were represented.

The first conclusion drawn was that self-assessment tends to have a favorable impact on learning. In most cases an increase in attainment was observed. Positive results were also noted with regard to the development of students' self-esteem. Seven out of nine studies reporting outcomes on this variable recorded a positive effect. Furthermore, there was a clear indication that students improved their learning-to-learn skills. A majority of the studies showed positive outcomes on "goal setting, clarification of objectives, increased responsibility for learning and/or increased confidence" (Sebba et al., 2008, p. 16). No differential effects for groups of students (e.g., by gender, ethnicity, or previous learning) were observed.

It has often been assumed that self-assessment can only be effective with mature students. Research has shown, however, that it can also be used in developing an understanding of how children perceive and reflect on their learning. Butler and Lee (2010) investigated the effects of implementing self-assessment on a regular basis for a semester in a number of sixth-grade English classes at two schools in South Korea. The main research questions were: Can young learners improve their self-assessment ability over time? Does this ability influence their learning and their attitudes toward studying English? What views do teachers and students hold on self-assessment in their specific teaching/learning contexts?

Two types of self-assessments were used. One was a "summative self-assessment" of a general kind administered at the beginning and at the end of the semester, both to treatment (i.e., self-assessment) and control classes. Items were of the type "I could follow the directions delivered in English" (with reference to the domain of listening).

The other type consisted of a series of more specific "unit-based self-assessments," which together covered the course content in the textbook all classes were using. These were only administered to the treatment classes. An example of a "unit-based self-assessment" (in the domain of reading and decoding) was "I could read aloud sentences such as 'I'm thirsty' and 'Can I have some hamburgers?'"

Teacher and student attitudes were measured by means of interviews and questionnaires. The English instruction itself, as well as tests measuring student performance, were the same in treatment and control classes.

Analyses of results at the end of the semester indicated that students in the treatment group had improved their self-assessment ability (confirming earlier results with older students, reported by Chen, 2008). The control group did not improve their ability. Quantitative analyses furthermore showed significant (but rather small) treatment effects. That is, self-assessment tended to have some beneficial influence on students' learning of English. It also had a marginal positive effect on students' confidence in learning. Finally, it turned out that quite different views of the effects of self-assessment were expressed at the two schools involved. Such variations in attitudes, as well as differences with respect to the need for information and guidance, were found to have an impact on outcomes. The authors concluded that "contextual and individual factors greatly influenced the ways in which the self-assessment was situated, administered, and valued in their

[the teachers'] teaching and learning practices" (Butler & Lee, 2010, p. 27). This piece of research shows that self-assessment can have a place in the elementary school classroom too, and that attention to contextual factors such as the teaching and learning situation and teachers' and students' attitudes to the approach is of great importance.

The general pattern of research results reviewed in this section warrants an optimistic view of self-assessment. Assigning a greater role for student participation in assessment can therefore be regarded as meaningful. It seems to be equally clear, however, that students need training in this particular "learning-to-learn" skill and that teachers need self-assessment issues to be "further built into both initial and continuing professional development" (Butler & Lee, 2010, p. 19). This tallies with some other findings reported elsewhere (e.g., AlFallay, 2004; Oscarson & Apelgren, 2011).

Examples of Self-Assessment: Methodology and Materials

This section deals with applications of foreign or second language self-assessment in direct pedagogical practice, primarily in the language classroom. Illustrations are provided of some of the ways in which it can be used for very practical purposes in the day-to-day monitoring of school-based language learning.

Some preliminary early work in this area was undertaken in the Council of Europe modern languages project referred to above, and a study exploring

C1 I can use this language to express all the things I would normally express in my own language. I can join in most lively discussions. I can choose the most suitable way of saying things. I can give a presentation and hardly think about my language. I rarely search for a word or phrase, and am always understood by people who know the language reasonably well—and I more or less always manage to understand them.	date you teacher
B2 I can switch over to this language for long periods. I can talk freely and in detail about things that interest me. I can follow discussions about things that are topical and argue for my point of view. I can give a presentation without sticking to a careful plan. Even though I must sometimes search for the best word or phrase, I am nearly always understood by people who know the language well, and I normally understand them.	date you teacher
B1:2	...
B1:1	...
A2:2	...
A2:1 I can use language I've practiced to say a bit in a number of ordinary situations. I can tell a little bit about myself and things I know about well. The people I talk to must be patient and willing to help so that we understand each other.	date you teacher
A1 I can use and understand some words and phrases I have learnt. I can ask and answer some very usual questions, as long as the other person speaks slowly and clearly and is very helpful.	date you teacher

Figure 43.2 A "can-do" scale (spoken interaction) for young learners. Adapted from Hasselgreen (2003, pp. 76–7) © Council of Europe Publishing

possible forms of self-assessment for use in adult language learning was reported by Oscarson (1980). A number of “behaviorally” organized self-assessment materials, such as checklists, questionnaires, and rating scales, were designed and piloted in the project. Subsequently interest was also devoted to the development and use of other introspective materials such as learner log books (records of activities undertaken), diaries, journals, portfolios, protocols, conferences, and so forth.

Student–teacher collaborative assessment involving young learners is exemplified in a Norwegian “can-do” project reported by Hasselgreen (2003). Materials used include proficiency scales adapted to suit the 13–15 age bracket. Figure 43.2 shows an example. In this case the scale is designed to link learner and teacher assessments. Learners first judge their performance level and then “calibrate” their estimates in consultation with their teacher.

Pupils are instructed about the criteria for each level. The author comments that in using this material “Pupils and teachers are expected to be jointly involved in deciding when the pupil has reached a new level” (Hasselgreen, 2003, p. 19). Supplementary self-assessment materials in the form of “can-do” checklists accompany the proficiency scales.

Language Portfolio Assessment

The well-known portfolio concept involves students actively in the recording and reporting of their learning and achievements (Hamp-Lyons & Condon, 2000). The basic methodology has been used in many different contexts and forms, the common denominator being that of storing of work samples (such as pieces of writing and audiorecordings) for documentation and evaluation purposes. The collection of samples is based on systematic reviewing and assessment by the learner, resulting in a selection that he or she finds illustrative of successive phases of learning (i.e., through a form of self-assessment). Students may also be asked to write a text in which they reflect on their development as learners. The conversation with the teacher, or with peers, about the samples selected offers a further opportunity for self-reflection on the progress of learning.

Deliberate student reflection is thus a prominent feature of portfolio methodology in that the selection of work samples is made on the basis of personal judgment, which is, or can be, followed up by evaluative discussion. In other words, working with portfolios is a way of strengthening the learner’s capability for self-assessment.

The recently developed European Language Portfolio (ELP) uses the Common European Framework of Reference for Languages (CEFR) concept as its frame of reference (Council of Europe, 2001). It exists in a range of languages and has often been produced in different versions for different age groups, including young learners. The learners are themselves involved, by self-assessment, in the estimation of the CEFR level they have reached. A central feature of the ELP is a *language biography*, which among other things provides opportunities for self-assessment based on (1) checklists of CEFR-related “can-do” statements and (2) a global CEFR self-assessment grid. There is also a *dossier* where the learner keeps a selection

of work (such as texts, video or sound tape recordings, learning logs, and project work) which he or she thinks best mirrors his or her achievement.

It has been claimed that use of the ELP in the classroom has several advantages. In an international pilot study reported by Little (2003), participating teachers concluded that young children find the ELP entertaining and highly motivating and that it has a favorable impact on the learning process (p. 3), that “learning to be more reflective in general contributed to the students’ abilities to assess their language skills” (p. 8), and that “as a planning and self-assessment tool it helps to make the learning process more visible to the learners and as such involves them more” (p. 36). Few negative points were recorded, but it may perhaps be added that there has been some concern among teachers elsewhere that the keeping and updating of files and binders, filling out forms, responding to check-lists, and so forth may put too great a strain on some students who find this sort of “clerical paperwork” demanding.

The report referred to above also contains a wide sample of illustrative ELP pages produced by students participating in the study.

A Web-Based Model

A concrete example of how the principles of self-assessment may be realized in the classroom is afforded by a set of “materials for self-assessment in English” published on a Swedish governmental Web site (Skolverket, 2012). The set was produced as an adjunct to the annual national testing of English in the secondary school, primarily in order to strengthen the dialogue between teachers and students in matters of achievement and skills development. The Web site and the guidance and support materials have, at the time of writing (April 2012), been in place for more than 10 years. Information about this initiative is included here because it illustrates an interesting and useful way of stimulating self-assessment in schools as seen from a central administrative perspective. It also offers practical tips for teachers on classroom procedures.

Through this resource, schools are supplied with some basic ideas as to how they may introduce and maintain self-assessment as a regular feature of classroom interaction. The explanatory texts are in the national language (i.e., Swedish) while the instruments themselves and a set of questions (suggested points for discussion) are in English.

The set comprises the following components:

1. A *description of the purposes and contents* of the materials offered. It is pointed out that the content reflects basic educational tenets in the national curriculum, that these need to be considered very carefully when students’ work and attainment levels are discussed, and that students’ awareness of different modes of learning and of personal goals are crucial aspects of successful studies.
2. A brief written *account of the theoretical background* to and rationale for autonomous assessment. This text also provides references to pertinent literature on educational assessment, to portfolio methodology, and to autonomous

learning initiatives. It furthermore reports on experiences gained from the use of learner self-assessment in language education.

3. An *English usage checklist*, which can be used to give an overview of the students' use of English outside of school and thus to remind them of the degree to which they often use English in their daily lives. The checklist can furthermore stimulate students to start thinking about how they might capitalize on such out-of-school language contacts for the good of their language studies in school. Types of English usage referred to are reading of books and instruction manuals, finding information on the Internet, listening to songs, watching videos and films, writing e-mails, meeting foreign tourists in Sweden, and so forth. Response options are "Often," "Sometimes," and "Never."
4. A *self-assessment questionnaire*, which contains samples of situated assessment items covering the four skills (reading, speaking, listening, and writing) plus the variables of strategic competence and intercultural knowledge. It is intended to help students to assess their ability in relation to goals of the kind embodied in the curriculum and the syllabus for English. The advice is that the questionnaire be used at least a couple of times during the course. An example is shown in Figure 43.3.
5. A *student background questionnaire*, which contains questions on attitudes to and experiences from using English under different circumstances. For example: What strategies do you use if you get stuck when writing? What do you think you need to work more on to improve your English? It gives students an opportunity to become more conscious of their own, as well as alternative, ways of acquiring language skills and may be used as a basis for teachers and students when planning an English course.

How well do you think the following statements match your ability in English? Answer by putting an X in the boxes below. There are no correct answers. This questionnaire can be useful to you when learning English. It will help you see the different areas in Course A English that you are good at and those you need to work more on.

Speaking						
I think that the statement below matches my level of English	not at all	a little	fairly well	well	very well	perfectly
4 I can take part in conversations about things that I know well, without having to figure out what to say beforehand.	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
5 After some preparation, I can inform others about something or describe something that I'm interested in.	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
6 I know what type of language to use in different situations. I know for example the difference between speaking to an employer and to friends.	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Comments on my speaking skills:						

Figure 43.3 Self-assessment questionnaire sample items. Adapted from Skolverket (2012)

In addition to the above, there is an appendix which contains general *guidelines* for teachers on how the components are best presented and used in class, or individually. It is stated, for instance, that it is important for students to understand the rationale for and purposes of the support materials. Students need to be informed that the content and tasks are clearly related to important goals in the curriculum and the syllabus. It should also be made plain to students that self-assessment can be a useful *complement* to other forms of evaluation with which they are likely to be more familiar: teacher observation, classroom assignments, quizzes, essays, tests, exams, and so forth. The reason is, of course, that many students are not used to the idea that they can be “judges” of their own learning. In the case of the present set of materials the teacher may, as needed, refer to the accompanying text, which sets out the background to the practice of self-assessment and also quotes some research of interest.

The teacher is furthermore advised to point out that self-assessment is an essential feature of effective study habits, that is, that it is as much part of the process of *learning* as it is an alternative or complementary way of *estimating* what is being learned. Tips on how to explain and exemplify this are provided. It is recommended that the three instruments intended for students should be administered on different occasions in order not to overburden students during a particular class, and also in order to allow time for reflection and discussion. It is indicated that the self-assessment questionnaire can profitably be used more than once during the course as a means of monitoring the progress of learning.

Written responses are not necessarily viewed as the best approach in all cases. The various issues raised in materials of this kind may also be commented on by the students directly and *orally*. The activity can then be organized as a teacher-led group discussion or it can be conducted in small groups reporting back to class. In certain cases, informal discussion between the teacher and students individually may be the best strategy.

Finally, there is also included a document which provides references to literature on assessment in general, as well as to autonomous learning and self-assessment.

A Case Study: Self-Assessment of Writing Skills

Other, more detailed examples of how self-assessment may be practiced in the classroom are given in the Swedish research project “Self-Assessment of Learning: The Case of Languages” (SALL). A major part of this project centered on the technique of process writing, that is, the iterative model of practice in which a draft text is successively elaborated in a stepwise fashion to form a final “edited product” (Dragemark Oscarson, 2009). The aim was to investigate the extent to which adolescent learners are able to perceive and realistically assess their developing writing competences in English in relation to set goals. Since this research is illustrative of some of the main principles discussed in this chapter, it will be described in a little more detail. The approach and the types of activities are, moreover, directly transferable to regular classroom work, which may be of interest to some practicing teachers at this level.

A sample of four classes of upper secondary school students, with little previous experience of self-assessment, were presented with an extensive writing task which was to be completed as part of their ordinary English as a foreign language (EFL) coursework. In the initial phase of the self-assessment period, students first studied the goal of writing in the curriculum and discussed the criteria specified for each of the four grades available in the course. Typical questions to be considered were: What is required for a pass grade in written expression (linguistic accuracy, etc.)? What is required for a pass with special distinction? The students then practiced assessing a number of texts which had been produced by other students in a past national test and which had later been used in the form of annotated benchmarks (related to grade levels) in teachers' test administration guidelines. After a group discussion the students compared their estimates with the benchmarks and again discussed the results. This procedure helped students form a better picture of the goals for writing in the course and of the criteria for the different grade levels.

For the sake of comparison of methodological procedures, it may be mentioned that when it came to oral skills the groups were given samples of students' audio-recordings at various proficiency levels and were asked to mark these according to the set criteria. They were furthermore requested to judge their own ability in comparison with the examples they heard ("the same? higher? lower?"). Finally, they gave the arguments for their conclusions and discussed them, whereupon the teacher disclosed the national expert group's grading of the various examples, as well as that group's reasoning behind each grade.

After the practice session on standards of writing, the groups started working on their own texts. There were two themes to choose from: "A letter" and "The media." Following the principles of process writing, the students first discussed their writing with their teachers and made preparations for the task. They were also encouraged to cooperate with their classmates in this introductory phase of the writing. The teacher explained the marking system that was going to be used.

The actual writing was done both in class and at home. Scripts were collected twice: in draft form and as a final text. When the students handed in their first drafts for comments they were also requested to complete a self-assessment form containing items such as those shown in Figure 43.4 (in rough translation). The teachers did not see the results of the self-assessment questionnaires.

Following special *assessment guidelines* the teachers commented on the draft scripts by indicating (but not correcting) passages, phrases, and words that might be clarified or improved, and also by adding brief general questions and comments to guide students in their further work on the task.

The next step was for students to hand in their revised texts. The teacher read, added comments, and returned the texts to the class. When the texts were handed in this second time, the students were again asked to self-assess their writing skills. Figure 43.5 exemplifies the points raised.

In the analyses of the outcome, it transpired that students were quite self-critical in that they tended to underestimate their competence in the different specific writing skills they self-assessed. Expert ratings were actually higher. But practice

made a difference. Students who had participated longer in the study were rather more accurate in their estimates than students with a shorter record.

Toward the end of the project, the students took the National Test of English, which has advisory status but which historically correlates highly ($r \sim .85$) with the final grades students are awarded nationwide later in the term. At the end of the test session, students predicted the grades they were going to get in each of four language skills tested (Figure 43.6). The correlations between these self-assessments and later test data were quite low but still statistically significant ($r = .30$ and $r = .59$ for writing in two main groups compared; $n_{\text{tot}} = 100$).

The study also included interviews, with both teachers and students. In the main, both parties felt that the combination of a writing assignment with a self-assessment procedure was useful and that it increased students' awareness of their strong and weak points in the language (i.e., not only in writing). The exercise of grading sample texts in relation to syllabus goals was felt to be difficult but at the same time very informative. Students thought that it helped them to better understand the criteria for grading in the course they were taking.

Prediction of National English Test Results (Part IV: Writing)

1. Now that you have completed the Writing Test in English, what grade do you think you will receive?

Fail

Pass

Pass with distinction

Pass with special distinction

2. How certain are you that your estimation is correct?

Very certain

Certain

Uncertain

Very uncertain

3. Why do you think you will receive this grade?

Figure 43.6 Form for students' prediction of National English Test results (Part IV: Writing). Excerpted and translated from Dragemark-Oscarson (2009)

Some students were a bit dubious about the reliability of self-estimates. Certain students who were particularly ambitious and goal-directed feared that the practice of self-assessment had meant time missed "for real learning" (in the form of "study of new words," for instance).

Summing up: What we can learn from this educational project is that self-assessment in the classroom can be usefully employed for enhancing the learner's own role in language learning. In combination with the process writing model, self-assessment proved to be a fruitful strategy for teacher-student interaction in the monitoring of achievement.

Another Model

A very important aspect to consider in developing fruitful self-assessment is the definition of criteria, as was the case in the above self-assessment project, and is indeed the case in any type of assessment. Without a clear sense of what the important goals are and what they mean in a particular educational setting, it is impossible for any student to make meaningful judgments of his or her own learning. The teacher typically needs to expend a great deal of energy making sure that students are clear in their minds about what their assessment task amounts to in practical terms.

A good example of how to approach the problem is provided by Rolheiser and Ross (2012). In their four-stage model for teaching student self-evaluation, the definition of criteria is central. At Stage 1 the students are involved in defining the criteria, in negotiation with the teacher. The goal is to create a shared set that the group perceives as meaningful. At Stage 2 students are taught how to apply the criteria to their own work. The idea is to try to connect criteria to evidence in the self-assessments. Next there is a stage of moderation, Stage 3,

where students are given feedback on their assessments in order to “recalibrate” their attempts to apply the criteria. At Stage 4, finally, students are encouraged to develop “productive *goals and action plans*,” whereby it is particularly important to monitor their work and provide support when they, in due course, assess their achievement.

Conclusions and Future Directions

As will be apparent from the above, significant headway has been made in the field of self-assessment in the classroom. Both awareness of its importance and familiarity with adequate and useful procedures have increased considerably over the last few decades. It is, however, also evident that a great deal of research and development work remains to be done before we can realistically expect to see self-assessment implemented and practiced on a wider scale. So far, the field constitutes relatively uncharted territory. For comments related to what can be regarded as still largely extant issues in research on self-assessment, see Oscarson (1997, pp. 183–6).

Two areas in particular seem to require attention in future work in the sphere of classroom self-assessment:

1. research on the theoretical bases and epistemology of the approach, and
2. theory-based and empirically grounded development of purposeful and flexible materials and techniques suitable for direct application in the classroom.

Both of these areas suffer from a certain lack of clear evidence from research and development work. More empirical groundwork is thus needed, not least in the form of studies that address practical didactic issues. One problem, for instance, is that of how one may negotiate and reconcile diverging opinions about best testing and evaluation practice, among both students and teachers. Attitudes toward self-assessment as an activity in the classroom are very diverse, ranging from outright rejection of the very idea to firm conviction of its usefulness. Therefore further explication of the issues involved, as well as a continued mapping out of teachers’ and students’ conceptions of achievement and its measurement (see Oscarson & Apelgren, 2011), are very important tasks.

Some other areas in need of development are teacher training focusing on student-centered formative assessment (for an account of the issue and some results, see Oscarson & Apelgren, 2011); investigation of the effects of self-assessment procedures on motivation and achievement, relative to developmental factors such as the learner’s age and level of maturity; and analyses of the ways in which the strand of self-assessment may be incorporated into curriculum planning and course design on a more regular basis. Finally, it is desirable that more concerted attention be devoted to further development of materials and methodologies that can support continuous self-assessment, that is, self-assessment which is well integrated with day-to-day learning and teaching activities in a longer perspective, and which is smoothly coordinated with necessary external evaluation procedures.

All the above projections of possible future developments serve the dual function of instructional efficacy and productive collaboration in language education. Their ultimate objective is to enable learners and teachers alike to make the most of their potential as facilitators of purposeful language learning and helpful self-assessment in the classroom.

Peer Assessment in the Classroom

Jette G. Hansen Edwards

Chinese University of Hong Kong, Hong Kong

Introduction

Traditionally, teacher assessment has been the main form of assessment of students' language skills in second language (L2) classrooms; but, due to the increasing interest in interactive, cooperative, and self-directed learning, the use of alternative methods such as peer assessment has become more widespread. Peer assessment can be defined as "an arrangement of peers to consider the level, value, worth, quality, or successfulness of the products or outcomes of learning of others of similar status" (Topping, Smith, Swanson, & Elliot, 2000, p. 150). Peer assessment can encompass both oral and written language skills and can be done individually, in pairs, or in groups. It can be conducted on a variety of tasks such as writing assignments, portfolios, projects, oral presentations, quizzes, and tests. The outcome of a peer assessment task can be feedback, grading, or both. In the L2 classroom, it has been conducted most commonly on writing skills, in which capacity it is often referred to as peer response, peer editing, or peer review. However, as shown in first language (L1) classrooms and, on a smaller scale, in L2 classrooms, peer assessment is also a useful tool for the assessment of oral language skills.

This chapter focuses on the use of peer assessment in rating both oral and written language skills. It begins by providing an overview of peer assessment, specifically addressing how this phenomenon has been theorized and what its benefits and drawbacks are. The use of peer assessment in language classrooms will then be discussed, with a focus on modes (face to face, online, paper and pencil), together with various forms of the assessment task itself (rubrics, open-ended questions, etc.). This examination will be followed by a discussion of the reliability and validity of peer assessment. The chapter will conclude with suggestions for successful peer assessment, particularly focusing on training for it.

An Overview of Peer Assessment

Theoretical Support for Peer Assessment

A number of theoretical frameworks have been cited in support of peer assessment. These include theories of language development and acquisition such as Vygotsky's (1978) scaffolding and zone of proximal development (ZPD) theory; interactionist theories of second language acquisition (SLA) (Long, 1985); and theories of writing (e.g., a process approach to writing) and assessment (e.g., alternative assessment). Each of these will be briefly outlined below.

Because peer assessment typically involves peer interaction and feedback regardless of whether it is done face to face (in groups or pairs) or through written communication (online or on paper), social constructivist theories such as Vygotsky's (1978) zone of proximal development and interactionist theories of second language acquisition such as Long's (1985) are often cited to support its use. Among these theoretical perspectives, Vygotsky's has been the one most often cited; this is due to the belief that the collaborative nature of peer assessment activities provides opportunities for learners to be "scaffolded" in learning through interaction with more knowledgeable peers. Vygotsky (1978, p. 86) defines the ZPD as "the distance between the actual developmental level determined by independent problem solving and the higher level of potential development determined through problem solving in collaboration with more capable peers or seniors." Peer assessment activities are seen to provide opportunities for learners to give each other extended knowledge—whether content knowledge, rhetorical knowledge, or linguistic knowledge—and hence to create opportunities for scaffolding to take place. A number of studies (e.g., Donato, 1994; Villamil & Guerrero, 1998) support this framework, as they have found that collective scaffolding does take place during group work and that peers take turns guiding and supporting each other (or one another) both in terms of linguistic knowledge and in terms of content knowledge.

Interactionist theories of SLA (Long, 1985) have also been cited to support peer assessment (henceforth PA). Like Vygotsky, the proponents of interactionism focus on the communicative nature of group work and on the opportunities of peers to negotiate meaning, which is believed to foster comprehension and therefore acquisition. A number of PA studies focusing on the interaction that takes place during PA activities have found that students are able to negotiate meaning, to ask for clarification, to give suggestions, and overall to practice a wide range of language skills, all of which are hypothesized to support SLA (Mendonça & Johnson, 1994; DiGiovanni & Nagaswami, 2001).

In L2 writing classrooms, PA (also known as peer response, peer review, or peer feedback) is viewed as an integral component of the process approach to writing (Elbow, 1973). The process approach to writing instruction, which emerged in the 1960s and 1970s in L1 writing, focuses on the process of writing rather than on the end product; it regards writing as a recursive, dynamic activity that involves several stages, including multiple drafting. PA is an important component of the drafting process as students are encouraged to give and receive multiple types of feedback (teacher, peer, or self) at various stages of the writing process.

Proponents of the use of peer feedback argue that it helps writers build audience awareness and make reading–writing connections; it also enables them to receive a different—and larger—amount of feedback than if it only came from the teacher (Leki, 1990; Mangelsdorf & Schlumberger, 1992).

Finally, PA receives support from the change to an “assessment culture” that aims at “assessing the acquisition of higher order thinking processes and competencies instead of factual knowledge and low-level cognitive skills” (Lindblom-Ylänne, Pihlajamäki, & Kotkas, 2006, p. 51). As a result of this change, alternative assessment practices such as portfolio assessment and self-assessment are more commonly used in language classrooms. PA is one of the most commonly used means of alternative assessment and has gained popularity in language classrooms on account of its focus on authentic language tasks and communication, as well as thanks to the opportunities it provides for learner involvement in the development of assessment criteria. PA is often used as a kind of formative assessment that “aims to improve learning while it is happening” (Topping, 1998, p. 249), in contrast to summative assessments, which aim to assess the learning outcomes of a particular task. For this reason PA is considered a “learning tool” and, as Lindblom-Ylänne and colleagues state, “it is claimed that it is beneficial for students’ learning to be involved in giving and receiving feedback because it enhances the development of skills required for proficiency” (Lindblom-Ylänne et al., 2006, p. 52).

Yet, as Topping (1998, p. 254) notes, despite all of this theoretical support, “establishing a single overarching theory or model of the process seems likely to be difficult” because of the “many different types” of PA and the great variation in how the expression is used. Research findings may also be conflicting due to the great variation in foci, tasks, and modes of PA employed in various studies. Nonetheless, a number of consistent findings can result from the research; these findings form the basis of the discussion in the remainder of this chapter.

Benefits and Drawbacks of Using Peer Assessment

A number of benefits and weaknesses of using PA have been identified by researchers, teachers, and peers themselves (see Topping, 1998; Liu & Hansen, 2002; Peng, 2009). These benefits and weaknesses are presented in Table 44.1 below. They cover a variety of domains, such as meta-cognition and cognition, time, affect, feedback, social interaction, and linguistic development. Each of these domains will be discussed below. Suggestions for fostering the benefits and minimizing the drawbacks will be made in the final section of this chapter.

As Table 44.1 indicates, there are many benefits to using PA. It encourages reflexive learning and fosters a deeper understanding of the nature of writing and of oral presentation, depending on the foci of the language task, especially if students themselves create the assessment criteria. Creating their own assessment criteria can also help them understand what high quality work means, as it fosters higher order thinking processes when they review, reflect upon, and comment on their peers’ work. PA may also help learners develop autonomy

and independent problem-solving skills. More time on the task, which PA fosters, can encourage deeper learning. Socially PA can encourage responsibility as well as learner independence (or autonomy) and active participation in one's own learning processes. It creates opportunities for students to develop negotiation and collaboration skills, along with an awareness of their audience. One drawback is that students may not always be on task or participate actively in the PA process, and therefore they may need to be monitored during the assessment activity. In terms of timing, the use of PA takes class time, both for creating grading rubrics and for training students to use the rubrics and to give feedback; however, if used in place of teacher assessment, PA can save time for the teacher. Sufficient time should be allotted for the task in order for students to perform the assessment effectively. Affectively there are both drawbacks and benefits. A few benefits are the following: PA can motivate students as it empowers them through the assessment process; it enables them to take ownership of both learning and assessment; and in their own texts (oral or written), they, as students, are likely to be more willing to reject other students' comments instead of taking them onboard unquestioningly, as often happens with feedback coming from the teacher. However, students may feel unwilling and unable to assess their peers critically, especially if these peers are friends. Cultural issues also sometimes affect students' willingness to engage in PA activities: thus students may perceive that the teacher is the authority and therefore the one to assess and to give feedback; or they may feel that they do not have enough content, rhetorical, or linguistic knowledge to assess their peers or to provide feedback for them.

In terms of the feedback itself, as has already been pointed out, some of the many benefits of PA are that students may receive a greater quantity of it than through teacher assessment alone; and, depending on the mode of PA, this feedback could come faster, too. PA also triangulates self-feedback and teacher feedback, if those are also used on the same task; if similar feedback is given, this may help reinforce the comments. If different feedback is given, then the learner may receive a greater variety of feedback. However, students may not be as willing to accept their peers' feedback as accurate; in that case they would hesitate to adopt it. As noted previously, students may feel that they do not have the linguistic skills to provide specific feedback. They may, on the whole, prefer teacher feedback to peer feedback.

Socially PA can help students improve their collaboration as well as their negotiation skills and increase their audience awareness. It can promote active learner roles, although the teacher has to ensure that students are on task during the activity. Finally, it can foster language development, as it aids learners to improve their linguistic self-assessment abilities and it gives them more opportunities for language use, both quantitatively and qualitatively, and for negotiation of meaning.

In sum, there are many advantages to using PA as an alternative assessment method. As with any task, there are also drawbacks; however, these can be minimized through careful planning, as well as by training students to do PA—as will be discussed in the final section of this chapter.

Table 44.1 Benefits and drawbacks of peer assessment

<i>Areas</i>	<i>Potential benefits</i>	<i>Potential drawbacks</i>
Metacognitive/ Cognitive	<ul style="list-style-type: none"> • Reflexive • More time on the task • More time on thinking, reviewing, summarizing • Greater understanding of what high quality work is • Higher order thinking processes • Greater understanding of the nature of writing • Greater understanding of the nature and process of assessment • Audience awareness • Development of autonomy • Development of problem-solving skills 	
Time	<ul style="list-style-type: none"> • Saves teacher’s commenting time 	<ul style="list-style-type: none"> • Takes too much class time • Does not leave enough time to read/watch texts and respond • Requires time for training students
Affect	<ul style="list-style-type: none"> • Increases motivation • Develops student’s ownership of the assessment process • Makes it easier for the student to reject/interact with feedback comments 	<ul style="list-style-type: none"> • There can be unwillingness to assess peers, especially if friends • It may be culturally inappropriate to criticize peers • Students may not have enough confidence in their own language skills to give feedback • The teacher may be perceived to be the one responsible for giving feedback (the teacher is the authority, not one’s peers)
Feedback	<ul style="list-style-type: none"> • Greater quantity of feedback • Faster feedback • Possibly more specific feedback • Triangulation of ratings/ feedback if self- and/or teacher assessment is also used 	<ul style="list-style-type: none"> • Peer assessment may not be accepted as accurate, reliable, and professional • One may hesitate to adopt feedback from one’s peer • It may be difficult to give specific feedback • Students may question the accuracy of grading as well as linguistic, rhetorical, and content feedback coming from their peers

(Continued)

Table 44.1 (Continued)

<i>Areas</i>	<i>Potential benefits</i>	<i>Potential drawbacks</i>
Social interaction	<ul style="list-style-type: none"> • Increased negotiation skills • Responsibility for one's own learning • Independence from teacher • Audience awareness • Collaboration skills • Active learner roles 	<ul style="list-style-type: none"> • There may be a preference for feedback coming from the teacher • Students may not always be on task during the PA activity or actively involved in it (they may be chatting about something else, checking their phones, etc.)
Linguistic development	<ul style="list-style-type: none"> • Development of verbal communication skills • More opportunities for L2 use • Language development via linguistic assessment skill development 	<ul style="list-style-type: none"> • Student may not have linguistic knowledge to comment on grammar, etc. • Student may not know how to express feedback linguistically

Peer Assessment in the Language Classroom

There is a great deal of variation in how PA has been used in language classrooms. PA can be used for feedback only, for grading, or for both. It is often employed to assess written language skills but can also be used to assess oral language skills. Various means of assessment, from rubrics to open-ended questionnaires, can be employed for feedback, for grading, or for both. PA can be conducted in class, either individually or in face-to-face pairs or groups; or it can be conducted online, during or after class time. It may involve one or more modes of feedback or grading. A discussion of key issues related to the use of peer assessment in the classroom is given below.

Modes of Peer Assessment

Peer assessment can be conducted face to face, through oral interaction in pairs or groups; through individual written assessment, either by using paper and pencil or the computer; or through computer-mediated communication (CMC) modes for commenting and discussion. CMC is the use of computer networks to provide opportunities for students to interact either in a delayed time frame (i.e., in an asynchronous communication)—via listservs, e-mails, bulletin boards, blogs, and software programs such as CommonSpace—or in a real-time discussion (i.e., in a synchronous communication)—via chatrooms, instant messaging, MOOs (multi-user domains object-oriented), and computer programs such as Daedalus Interchange. Any of these modes may be mixed as well; for example, there may be use of face-to-face discussion after individual written assessment, or face-to-face discussion after asynchronous CMC. Table 44.2 presents some of the benefits and drawbacks of the various modes of PA on the basis of a number of studies (see Liu & Hansen, 2002; Liu and Sadler, 2003; Wen & Tsai, 2006).

Table 44.2 Benefits and drawbacks of various modes of peer assessment

<i>Format</i>	<i>Face to face verbal</i>	<i>Pen to paper written</i>	<i>Asynchronous CMC</i>	<i>Synchronous CMC</i>
Timing	+Instant feedback	-Too little class time to read and respond	+More time to read and reflect outside class -Delayed feedback	+Instant feedback -Enough time?
Social interaction	+Active participation			+Active participation +CMC may increase collaboration
Affect	-Uncomfortable giving criticism face to face		+Computer-based mode more motivating +Less anxiety as not face to face	+Computer-based mode more motivating +Less anxiety as not face to face
Feedback	+Opportunities to clarify meaning	+Written record of feedback -No opportunity to clarify meaning	+Written record of feedback -No opportunity to clarify meaning	+Written record of feedback +Opportunity to clarify meaning
Language	+Can use L1 to clarify meaning +Verbal skills developed +Supports interaction			+Supports interaction

One benefit of a written paper and pencil mode is that it allows peers to give concrete feedback, and in the case of PA of written tasks it allows them to give feedback on the written language task itself. However, there may not be any opportunities to clarify the meaning of the feedback or comments unless an oral discussion follows. If the PA is done in class, students may not feel they have enough time to read and assess/provide comments on their peers' papers, thus ensuring that peers have sufficient time for the PA task is critical to the success of this activity. Written PA is often followed by an oral discussion, which addresses the problem of students not being able to clarify or negotiate the meaning of the comments they receive. Oral discussion also helps to support oral communication skill development, as well as providing instant feedback and fostering active participation. One drawback of this method, however, is that students may feel uncomfortable providing feedback face to face, especially if it is critical.

CMC modes may in part help resolve some of these concerns. Asynchronous CMC is often used in place of written paper and pencil assessment, as it allows students to do the assessment outside of class, enabling them to spend more time on the task. However, this does mean that the feedback is delayed, which may be seen as a negative feature by some students. Additionally, while asynchronous CMC does provide a written record of the assessment, it does not allow students to follow up on the comments in order to negotiate and clarify meaning. For this reason it may be beneficial to follow the CMC session with an oral face-to-face discussion of the comments, as the written record can easily be printed out for discussion. Another commonly used CMC mode is the synchronous one, which provides a forum for real-time feedback and commenting. One benefit of both modes of CMC is that they are more motivating, since students may enjoy using the computer to assess and give feedback; both modes may also facilitate PA, as there is less anxiety, given that the mode is not face to face. A synchronous CMC may also support interaction, collaboration, and participation. As with the traditional modes, in order for synchronous CMC to be successful, students need to be allotted enough class time for the activity. Whatever mode(s) is (are) chosen for PA, teachers and peers will need to decide what to assess and how to assess it. This will be discussed below.

Foci and Outcomes of Peer Assessment

One of the most commonly identified benefits of PA is the fact that students are actively involved in the assessment process; in order to foster this involvement as well as to promote the metacognitive and cognitive benefits associated with PA, such as the development of higher order thinking processes and greater understanding of the nature and process of assessment, it is important that students are involved in the discussion and creation of assessment criteria and forms or rubrics. As Peng (2009) notes, PA requires at least three levels of student involvement. At the lowest level, students check their peers' work against a number of criteria set by the teacher. At the middle level, they are engaged in developing assessment criteria and in constructing answers to the teacher's or their own developed criteria. At the highest level, they are empowered to critically discuss and analyze the assessment criteria and reflect on the experience. The higher-level involvement will also help ensure that students understand the *what*, *how*, and *why* of assessment. In a peer assessment task, students typically employ a written assessment guide; this is typically in the form of a rubric or open-ended questionnaire, which can be tailored to give feedback or grading across any number of criteria. These can then be used for a written assessment task (a paper and pencil or an online one), for discussion (synchronously or verbally, face to face), or for both.

Regardless of task or mode, it is important that teachers start the assessment task with a clear understanding of, and a discussion with students about, the *purpose* and the *foci* of the assessment task. Romeo suggests that teachers start any assessment activity by answering three questions, which can help them develop an assessment plan:

- 1 For whom is the assessment being done (students, parents, administrators, ourselves)?

- 2 What is the purpose of the assessment (document progress, set a goal, monitor instruction)?
- 3 What type of information is needed (oral or written feedback, work samples, surveys)? (Romeo, 2008, p. 28)

Romeo offers an illustration of how this might be operationalized by proposing a scenario of a second grade teacher who came up with the following assessment plan by answering the three questions:

- 1 The students will edit their stories for capitalization and punctuation. This will be assessed by using a five-point rubric constructed collaboratively with the students.
- 2 The students will use adjectives to describe the characters in their story. This will be assessed during observations and via the use of a checklist.
- 3 The students will choose to write for real audiences. This will be assessed through observations and goal-setting instructions. (Romeo, 2008, p. 29)

In fact a number of key questions need to be addressed, in particular in terms of whether the PA task is to be used for feedback, grading, or both. Regardless of the expected outcome of the PA task—grading or feedback or both—it is important to create clear criteria for it, which can be easily translated into an open-ended question on a questionnaire-based form, or into a criterion on a rubric. These can encompass a wide array of elements, from ones that focus on content, rhetoric/discourse, and language use (including grammar), to ones that focus on delivery (e.g., eye contact, confidence) in the case of oral tasks. It is important for the questions and rubric criterion to be specific and clear, particularly if the students do not have an opportunity to discuss the feedback/grading, either together, as a group, or with the assessed after the assessment.

The expected outcomes of the PA task will dictate not only the content but also the form of the written assessment tool, if one is used. It may be easier to use a rubric if grades are to be assigned and an open-ended questionnaire if feedback is to be given, or a combination of both if both feedback and grading are the expected outcome. Another major issue related to the use of peer assessment is the result of the assessment—specifically, what will the feedback and/or grades be used for? Central to this issue is the role of the teacher in the assessment process. A number of scenarios are possible. For example, the assessment can be 100% peer-based, with the grades and feedbacks only given by peers. Alternatively, the teacher can also provide feedback or grades or both, as can the students themselves, on their own work. If there is more than one source of grades or feedback, the role of each needs to be clarified. If the peer grades or feedback are viewed as conditional to the teacher's in that the teacher is the final arbiter of the grade and feedback, students may not feel empowered or interested in the PA activity. However, if the PA is validated as important either by being the only feedback or grading source or by being triangulated with the teacher's assessment, the self-assessment, or both—while the grades from each source are perhaps averaged to create one final score, the feedback is synthesized to create a greater quantity and quality, and all kinds are being viewed as important—the students

may feel more invested in the PA activity, particularly if they have helped the teacher to create, or they alone created, the assessment criteria. Finally, if feedback is to be given, there should be clear expectations about what students need to do with the feedback. If students are expected to make revisions based on the feedback, they need to know to what extent they are expected to incorporate the comments (e.g., can they ignore some, and, if so, do they need to write a justification for ignoring them?).

A few examples of grading rubrics and questionnaires are given below. Tables 44.3, 44.4, and 44.5 show different ways of assessing written language tasks; Tables 44.3 and 44.4 both focus on a problem solution paper, while Table 44.3 shows an open-ended questionnaire format and Table 44.4 a rubric format. Table 44.5 shows a slightly simpler rubric than the one presented in Table 44.4. Tables 44.6, 44.7, and 44.8 present various assessment foci for oral language tasks; Tables 44.6 and 44.7 show two rubric formats, the rubric in Table 44.6 being more complex than the one in Table 44.7; and Table 44.8 shows an open-ended questionnaire format.

Rubrics can easily be used to create an overall score and are therefore useful if the foci of the task are grading, as the assessment is already numerical. However, rubrics do not actually provide the assessed with specific feedback or examples of why s/he received a certain score. For example, if, on using Table 44.4, for example, an assessor gives the writer a 2 or 3 for "Thorough development of thesis," the writer will not necessarily understand *why* s/he received a mid-range score rather than a higher one. Even if the assessment is meant to provide a grade only, with no expectation of feedback or revision, it is important for a student to understand why s/he earned a specific score. Therefore, if rubrics are used, there should be sufficient space for the assessor to jot down a few notes and examples (or to use the actual paper itself, if the task is a written one, or PowerPoint print-outs, if it is an oral presentation). In terms of using open-ended questionnaires, it is important to give sufficient space for each question, as students may write only as many comments as the space provided permits. In other words, students may judge how much to write on the basis of how much space there is. Open-ended

Table 44.3 Open-ended questionnaire for peer assessment of a problem solution paper. Adapted from Liu and Hansen, 2002, p. 135. © The University of Michigan Press. Reprinted with permission

-
1. What is the thesis statement of the essay? Does it clearly state what this essay is about? Why or why not?
 2. Does the writer give enough background information to the problem in the introduction? What else could s/he add?
 3. What three (or more) solutions does the writer suggest? Are these solutions realistic? Why or why not? Can you think of any other solutions the writer might add?
 4. What examples does the writer use to describe each solution? Should more be added? Why or why not?
 5. How are the body paragraphs arranged? Is this organization pattern effective? Why or why not?
 6. What limitations are given to each solution?
 7. How did the writer conclude the essay? Was it effective? Why or why not?
-

Table 44.4 Rubric for peer assessment of a problem solution paper. Hansen and Liu (2005). © Oxford University Press. Reprinted by permission

<i>Type</i>	<i>Content</i>		<i>Organization</i>	<i>Grammar/ Wording</i>
Score	Thesis statement	Solutions	Conclusion	Transition words
4	Clearly indicates problems to be addressed	Three relevant well-supported solutions	Clearly restates problem and effectively summarizes solutions	Sufficient and appropriate
3	Needs to be more precise in indicating problems to be addressed	Three relevant solutions but requires some additional support	Restates problem and summarizes solutions but could be more effective	One or two more transition words could be added/omitted
2	Does not indicate problem to be addressed	Three solutions that may not be relevant and/or may require more support	Does not clearly restate problem and/or does not summarize solutions	Insufficient and/or inappropriate
1	No clear thesis statement	Fewer than three solutions are presented	No clear conclusion	Missing transition words
			Not clear, making paper difficult to follow	Major errors greatly impede comprehension
			Not logical or effective. Major changes need to be made	Some minor errors, which occasionally impede comprehension
			Organization Logical and effective	Few, if any, minor errors that do not impede comprehension
			Slight reorganization required	Some minor errors, which occasionally impede comprehension
			Does not clearly restate problem and/or does not summarize solutions	Some major errors, which often impede comprehension
			No clear conclusion	Major errors greatly impede comprehension
			Not clear, making paper difficult to follow	Major errors greatly impede comprehension

Table 44.8 Open-ended questionnaire for peer assessment of an oral presentation

1. How well did the speaker use visual aids? Were they clear and interesting? Any suggestions for improvement?
2. Was there enough eye contact during the presentation? Did the speaker interact well with the audience? Any suggestions for improvement?
3. How clear was the speaker's speech? Was his/her voice loud and clear?
4. Were there any words that the presenter mispronounced? Please list them here.
5. Was there a good range of vocabulary in the presentation? Could the presenter have used different words? If so, list the words here:
6. How well prepared did the speaker appear to be?
7. Did the presentation have a clear beginning, middle, and end? Could any parts of the presentation have been rearranged? Or deleted? Please list:
8. What were the most interesting and/or creative elements of the presentation? How can the presentation be made even more interesting/creative?
9. Any other suggestions?

questionnaires can be used for giving both grades and feedback, though in the case of grading the score would be an overall, holistic one, which may be more difficult for students to give than a discrete-point score. It is, of course, not only possible but also preferable to combine elements of both types of forms, especially if the assessor is to both grade and give feedback. (For an example of how to do this for a writing task, see <http://www.nclrc.org/portfolio/formWritingRubricPeer.html#>. As this link demonstrates, it is also possible to place the grading or assessment forms online rather than having them in a traditional paper and pencil format. They can then be sent to the assessed and printed out for later online or face-to-face discussion.)

Reliability and Validity of Peer Assessment

Regardless of modes, tasks, or formats of the peer assessment, one of the major concerns that teachers, students, and researchers have is the extent to which peers can assess and provide feedback among themselves. There are several different foci in these types of studies. Some studies on the PA of writing (Mendonça & Johnson, 1994; Villamil & Guerrero, 1998) examine the types of peer feedback and the comments given in order to determine whether students can provide feedback on global matters, of content and rhetoric, and not just on editing and on local concerns such as grammar and spelling, usually in comparison to teachers' and self-feedback. Other studies that deal with writing, as well as most studies of oral language tasks, examine peer ratings usually in comparison with teachers' ratings and self-ratings (see Miller & Ng, 1994; Patri, 2002; Saito, 2004; Matsuno, 2009).

For a number of reasons, the findings derived from a comparison of these studies yield conflicting results. As Lindblom-Ylänne et al. (2006, p. 52) note:

When analyzing the accuracy of self- and peer-assessment (students' own assessments), teachers' ratings are usually considered as the reference point . . . However, there is evidence that teacher assessments vary considerably . . . and that comparison between teachers' and students' marks can be misleading because of different understandings of assessment criteria.

Another problem with interpreting the research is that, while some studies state that they are assessing validity, they actually assess reliability, as Topping (1998) states. To measure validity, students' marks need to be assessed against the marks of their peers over a length of time; this is rarely done. Typically, peers' marks are assessed against the teachers' or self-ratings, which is an assessment of reliability. As Topping notes, "high reliability may not actually be necessary" (p. 257) due to the typically different foci of teacher and peer assessment. As discussed above, teachers (and students) need to determine whether PA is to be used *in place of* teacher assessment or *in addition to* teacher assessment. If the PA is meant to triangulate with teacher assessment and self-assessment, then having different issues in focus may not be a problem, as PA and teacher assessment may have complementary roles (Berg, 1999). If the PA replaces teacher assessment, then peer involvement in the construction of the assessment task, as well as a clear

understanding of the marking or feedback criteria, should enable students to give specific feedback and valid marks.

Overall, it does appear that students are able to focus on all three main types of issues—content, rhetorical, and grammatical—when they provide feedback on writing tasks and that training is especially helpful in enabling them to focus on more global concerns (Berg, 1999). Studies have also found that assessments by teachers and students were similar, for both writing (Saito, 2004; Matsuno, 2009) and oral presentation skills (Miller & Ng, 1994; Patri, 2002; Peng, 2009).

As the research suggests, there are a number of ways in which the reliability (and, in the long term, the validity) of PA can be increased. In a summary of previous research, Peng (2009) notes several key points: (1) students need to be trained to conduct PA, (2) they need to be involved in developing the assessment criteria, (3) PA should be combined with another type of assessment such as collaborative assessment or self-assessment, (4) peer feedback and discussion should take place before the PA activity, (5) ratings should be clear and global rather than too specific, (6) the PA activity should be carefully planned and designed, and (7) PA should be conducted anonymously. Miller and Ng (1994) also suggest that students should not only be involved in the development of assessment criteria, but also choose the type of assessment to be administered and administer the assessment themselves. Further suggestions for successful PA are given below.

Suggestions for Successful Peer Assessment

One of the most consistent findings in research on PA is that training is a key factor to the success of PA (Berg, 1999; Min, 2008; Saito, 2008). In terms of training for the PA of writing skills, research indicates that instructing students in PA improves the quality and quantity of peer interactions and comments during the assessment activity and leads to better revisions, and therefore to higher-quality writing (Berg, 1999; Liu & Hansen, 2002; Min, 2008). It also increases positive attitudes toward PA. Training may help peers take on more useful stances during PA group or pair discussions, as research by Min (2008) has found. For example, in research on English as a foreign language (EFL) university students in Taiwan, Min examined pre- and post-training stances of students during the oral discussion of a written PA activity. Before training, the most common stance was prescriptive; it was followed by collaborative stances, then by probing stances, and finally by tutoring stances. After training, the stances became more facilitating in relation to PA, the most common being the collaborative stance in the form of suggestions; it was followed by problem identification (a prescriptive stance), then by tutoring (an explaining stance) and by clarification (a probing stance).

Training is therefore considered to be *the* key factor in the success of PA. Training should encompass the entire PA process and be cyclical in nature, beginning before the assessment starts and lasting throughout the actual assessment task and after it, in preparation for the next PA cycle. Nor should it be limited to the students; teachers themselves may benefit from training in PA. This will be discussed below.

Training Students

Training before the PA task commences is probably the most important component of the overall PA training cycle, though training during and after the PA should not be neglected. Specifically, pretraining for the PA task should include training toward developing reflexivity, asking intelligent questions, and “question[ing], prompt[ing] and scaffold[ing]” (Topping, 1998, p. 255) in order to develop the cognitive skills of the assessor. Pretraining should contain a discussion of the reason and purpose of the PA, as well as a clear overview of the task itself and of the expectations of the teachers in terms of how students should complete the task. Teacher modeling of the PA task, using authentic student writing or speech samples; videos of oral presentations and PA discussions; and CMC transcripts may be used in order to show students the “best” and the “worst” elements and practices. As noted previously, the PA may be especially effective if students help set and develop the criteria; and, if these criteria are holistic rather than discrete, students also need to be given directions and examples of how to interpret or how to create the marking and feedback criteria—or both. It may also be good to conduct a discussion of students’ concerns and issues; such a discussion should be based on prior experiences of PA and should be designed to examine the various pros and cons and to envisage solutions for any problems. It is also beneficial to have a discussion about, or a modeling of, the roles of the students during the PA activity, in order to facilitate use of more successful stances, such as collaboration and facilitation. If computer programs are to be used for the assessment task, training in how to use these programs should be done even if students appear to be familiar with them (such training should cover, e.g., how to use comments in Microsoft Word or how to use blogs). The role of the teacher—and the expected outcome of the assessment task—should also be discussed, together with the mode(s) to be used in the PA (paper and pencil mode, oral discussion mode, computer mode); and the latter should be done on the basis of an examination of the benefits (advantages) and drawbacks (disadvantages) of each mode for the given assessment task. Students should be given the opportunity to develop discussion and turntaking guidelines. They should also choose whether to have anonymous PA rather than working with known peers, in either a pair or group format. It would also be helpful to give them linguistic resources (see Liu and Hansen, 2002), both for commenting and for asking questions, in order to facilitate positive stances during the PA task. Practice sessions could be conducted before the actual assessment task, and a mock PA activity could be videotaped, so that students may be able to have a discussion of pros and cons and to consider what to do differently in the actual assessment task.

During the PA task the teacher should discuss any concerns and issues arising during the activity, observe students to ensure they are on task, and remind them to use positive stances (collaborative) and to ask questions about comments and responses from peers. Post-PA activities should (1) consist of a discussion of how to use peers’ comments effectively for revision, if this is part of the assessment task; (2) other students should be invited to evaluate the ratings and comments made by their peers; (3) the video of the oral discussion should be viewed and the transcripts from the CMC PA sessions should be read, in order to reiterate the

use of positive stances and turntaking and to keep track of peer feedback and ratings; and (4) there should be a small group or class discussion of problems, solutions, and benefits that arose during the task. It is also important (5) to link PA practices to other classroom language activities (Hansen and Liu, 2005) such as language logs wherein students keep track of grammar and vocabulary issues from self- and peer assessment; and (6) to regroup students in the PA group and make them watch or read the revised product and discuss what comments or feedback were used in revision and why or how these comments or feedback changed the presentation or the written task.

Training Teachers

Training should not be limited to students; the teachers themselves may need to be trained, especially in terms of their level of involvement in the PA process. It may be very difficult for teachers to let go of their control over the assessment process and empower the students during the peer task. For example, if students are creating the assessment criteria, teachers need to allow them to take the lead in asking the questions; teachers should also be open to students' views as to what is important to assess even when they have a different perspective. Teachers may also need to be trained to minimize their level of interaction with the peer groups or pairs during the actual activity; to take on a monitoring, supporting, and facilitating role; and to intervene only when disagreements arise that the students themselves cannot resolve, or when a member is not engaged in the assessment process. Finally the teacher has to respect the outcome of the assessment task and validate the students' marks and feedback either by giving her/his own in addition to that of the students (and making it clear that his/her mark or feedback carries equal weight to the students') or by not giving any mark or feedback at all but using solely those of the students.

Conclusion

PA has been shown to be an effective, engaging, and learner-centered language task for both oral and written language activities. It can promote not only the development of language skills, but also higher order thinking and social skills such as collaboration and negotiation. It can be used for a multitude of tasks and across a variety of modes (oral mode, paper and pencil mode, CMC mode) and it can be structured so as to focus on various aspects of content, discourse, and grammar as well as on aspects of delivery and performance such as eye contact and speech rate. There are several important elements that are integral to the success of peer assessment—first, teachers and students need to have a clear understanding of the focus and purpose of the assessment task; second, the role of the teacher and that of peers during and after the task need to be clarified; third, the role of the teacher as an assessor in the assessment task needs to be specified, particularly with regard to whether and why the teacher will also assess or provide feedback on the task. Fourth, the outcomes of the assessment—and of any other assessments of the same task (e.g., self-assessment, or the teacher's

assessment)—need to be discussed, in particular if self-assessment or the teacher's assessment are also conducted on the same task. Fifth, students need to be involved in the assessment process not only as assessors, but also as constructors of the assessment task, in order to be motivated to get engaged and involved in the process. Finally, training the students and the teacher to be a participant, an assessor, and a facilitator of a PA is perhaps the most important element in ensuring the success of this type of assessment task.

Test Development Literacy

Kirby C. Grabowski

Teachers College, Columbia University, USA

Jee Wha Dakin

Oxford University Press, England

Introduction

In most language-learning contexts, understanding how much learners know or can do in a language is paramount in order to maximize their learning opportunities and make fair and equitable decisions. In the language classroom, teachers are usually the ones who are responsible for making teaching and learning decisions based on assessments. In the context of program placement and large-scale assessment, it is often program administrators, admissions personnel, or even government officials who are making placement, competency, and selection decisions based on test performance. Notwithstanding a strong background in language instruction, program administration, or management experience, these individuals often have little training in test development. If particular stakeholders (e.g., teachers) are actually the ones designing assessments, training in test development is obviously crucial. If stakeholders (e.g., admissions personnel) are using pre-existing assessments, not only is training in test development empowering, but also the knowledge gained will allow them to better understand the nature of the assessment, its reliability, and the validity of any inferences and decisions made from it. Therefore, the purpose of this chapter is to orient stakeholders to various concepts they may need to consider when developing a language assessment. Training in test development should minimally include an overview of the conventional uses of tests, followed by instruction in construct definition and, ultimately, training in test construction, test administration, scoring considerations, and data analysis. Although any of these concepts can be presented singly, given the inter-relationships among them, they are nearly always best understood and made more meaningful when presented together. Last, though the concepts outlined in this chapter will be presented as though they are linear, it is important for stakeholders to understand that test development is a

process that is cyclical and iterative in nature. In other words, test developers often move back and forth between the stages as they gather more information, refine their constructs, revise their test specifications and tasks, and adjust their scoring methods to best suit the needs of their context.

Conventional Uses of Tests

The first thing that any test developer needs to determine is the way in which a test will be used; in other words, what kinds of test-score inferences and score-based decisions will be based on the information gathered from the test. For instance, test users may be interested in stratifying students into ability levels for an adult English as a second language (ESL) program and are, therefore, interested in making placement decisions. A teacher in a language program may be interested in measuring students' mastery over material taught in the class in order to determine whether or not an individual student can pass onto the next level. In this case, achievement or progress decisions are relevant. A university administrator may be interested in making decisions about an international applicant's ability to perform at a high enough level to succeed in a rigorous English-medium academic environment. In this case, competency decisions are relevant. Or perhaps a curriculum developer tasked with creating targeted training materials is interested in diagnostic decisions based on information gathered from a measurement of the strengths and weaknesses of remedial students with respect to their writing ability. These different uses and many others can be categorized into conventional types of tests.

Placement decisions are typically based on information gathered from a placement test. Placement tests should be designed with a particular course of instruction or curriculum in mind (e.g., a conversational English course). In other words, the content on the test should directly reflect the type of course content found within the program in which the test takers will be placed (e.g., conversational English and not academic English). The test content should also correspond to the range of ability of the students in the program itself (e.g., from beginner to advanced levels). This correspondence can help maximize the test scores' alignment with particular ability levels within the program.

Achievement decisions are typically made in instructional domains where the stakeholders are interested in gathering information about the extent of the test takers' mastery over the material taught, or the learners' progress, or both. Traditional classroom tests (e.g., unit tests, midterms, final exams) are all classic examples of achievement tests. They usually measure what students have learned as a result of a certain period of instruction. The test content for these types of tests is generally a direct and fairly narrow reflection of the course material (e.g., textbook, syllabus, teaching or learning objectives).

Selection and gatekeeping decisions are typically based on (large-scale) proficiency tests. Admissions officers or human resources personnel may be interested in gathering information about potential applicants' level of language proficiency to determine whether they are suited to the demands of the coursework or job requirements. The sampling of content for proficiency tests such as these is usually

very broad, is context independent (i.e., the content is not tied to any particular course of instruction), and can be general, academic, or work-related in focus. Scores from proficiency tests are also sometimes used for making program placement decisions or exit decisions if a close correspondence can be shown between the test content and the content from the learning context.

Diagnostic decisions are typically based on information gathered from assessments expressly designed to reveal the test takers' strengths and weaknesses. In terms of test content, test developers usually need to cast a fairly wide net since they may not have specific expectations about what the test takers should know or can do before taking the test. The inferences based on the information gathered can result in decisions about the format, content, or both of teaching and learning on a relatively small scale, such as in a classroom, or they may result in program or administrative reform on a larger scale, such as in transforming a curriculum to meet changing educational standards. Many different types of tests can be used for diagnostic decisions; however, if they are not designed with this purpose in mind, the information gathered may be more or less useful depending on how fine-grained it is and how far the test content is aligned with the teaching and learning context in question.

Test Development

Construct Definition

Once the use of the test and the types of decisions that are to be based on test scores have been determined, it is then up to test developers to define what the test is supposed to measure. This step should occur before the test itself is constructed. In the context of a language program, it is the responsibility of the test developer (in many cases, the teacher) to make sure that the test is adequate and appropriate in gathering information about the learners (e.g., their level of proficiency or competency). The targeted ability in question is the construct that the test is designed to measure. Construct definition is the first step in making sure that test construction is as systematic as possible.

There are a number of different ways in which constructs can be defined. One way is a construct definition based on a theory about language or language learning. This approach is typically taken when test developers are interested in designing a proficiency test, though it may be used for other types of tests as well. Test developers typically define language proficiency in terms of skills (listening, speaking, reading, writing), elements (grammar, vocabulary, phonology), or both, and may or may not integrate certain skills based on the perceived target language use (TLU) domain (i.e., the way or ways in which the language will be used in the context outside the test). Test developers may also define the construct in terms of a syllabus, textbook, or course objectives, and use these sources as a basis for choosing test format and content. Somewhat differently, constructs in standards-based assessment are defined in terms of teaching or learning standards, or both, which are then used to target abilities on a test. Although syllabi, textbooks, objectives, and standards (which are typically used as a basis for construct definition for classroom tests, placement tests, and standards-based assessments) are often

not explicitly linked to a theory of language and language learning, they are ideally informed by one, though this is not always the case. Chapelle (1998) offers a more comprehensive guide for construct definition including a number of different approaches and theoretical considerations for each.

Constructs under measure are often most transparent for test users in tests with performance-based tasks, where a rubric is used. For instance, if test takers are given ratings on a speaking test based on their performance with respect to grammatical accuracy, meaningfulness, organizational competence, and sociolinguistic competence, speaking ability is being explicitly defined in terms of these components. Therefore, when test developers are interested in including certain domains on a scoring rubric, they need to be mindful that these criteria represent the construct measured on the test. If there is a mismatch between what the test developer perceives as the construct being measured and what is actually being given a score on the test, the validity of the inferences and decisions being based on the test scores may be called into question. Compare this with multiple choice (MC) and limited production tasks where test users are often provided with no explicit representation of what is being measured on the test. In this case, it can be more difficult to see any explicit connection between the tasks on the test and the construct underlying it.

In order to trace how construct definition informs test development, take the example of academic writing for graduate students. In order to create a construct definition, a test developer would first need to ask the question: What is academic writing for graduate students? In other words, what does academic writing look like at the graduate level? What are the characteristics of this type of writing? Where is there potential for variation among writers? Since second language writing is the point of focus here, the test takers' control over grammatical accuracy and complexity, the sophistication and range of vocabulary used, the formality of the tone, and word choice, among other considerations, may be important to the measure of academic writing ability. The organization of the writing will most likely be of concern, as well as the development of the topic and the coherence of the ideas expressed. So, the construct definition might be that academic writing ability can be explained in terms of language knowledge, organizational knowledge, and topical knowledge. This is by no means an exhaustive list, but these are typical considerations used in a definition of academic writing. It is important to remember that a construct definition is simply defining what the target of measurement is—it is not the measurement itself. A test developer would still need to figure out how academic writing ability would best be measured for their purposes. Specifically, the test developer would first need to outline the ways in which academic writing is used in the university context before creating the actual test. This is where the TLU domain comes in. (See Chapter 46, *Defining Constructs and Assessment Design*.)

Defining the TLU Domain

Before test construction can begin, test developers need to first answer questions about where the test takers are ultimately going to be using the language—be it in an English-medium academic context, in an ESL or English as a foreign

language (EFL) environment, in the workplace, solely in a language-instructional context, or some combination of these. Outlining the types of language use tasks in the TLU domain ultimately helps test developers determine the types of tasks the test takers should be asked to perform on a test. In other words, test tasks are ideally drawn from or based on real-life language use tasks that the test takers need to perform in the TLU domain. For example, if learners in an academic English course will ultimately be using the language in an English-medium university environment, the TLU domain will be primarily academic, including the language used in the classroom, office hours, and formal meetings, but it may also include the language used during more informal interactions, such as social events. Thus, on a test, perhaps these learners will be asked to perform a variety of tasks, including summarizing a lecture, giving an opinion about an article, asking a professor for an extension, or inviting a friend to a discussion group, that are a reflection of the TLU domain. If the course were specifically focused on academic writing as in our example above, perhaps the TLU domain would more narrowly include specific types of writing seen in an academic context, such as essays, research articles, conference papers, annotated bibliographies, technical reports, and critical reflection papers. Even though these different types of writing all tap into the aspects of our academic writing construct (i.e., language knowledge, organizational knowledge, and topical knowledge), there may be variability in writer performance with respect to these elements depending on the type of writing they are asked to perform. Therefore, it is crucial that test developers have a clear idea of which language use tasks in the TLU domain elicit the most representative sample of the test takers' ability, so that, when it comes time to construct the test, the developers are able to choose test tasks that provide the best information about what the test takers know and can do. In this case, out of the many TLU tasks that learners may perform in a real-life university context (e.g., essays, research articles, conference papers, annotated bibliographies, technical reports, and critical reflection papers), given time and resource constraints, a test developer will probably need to select one (or two) types of academic writing tasks to include on a test. More than likely, a test developer will choose an academic essay for the test since the other types of academic writing require too much research or topical knowledge for a testing context. However, it is still important to bear in mind the importance of implementing a systematic framework of test specifications when constructing the actual test, even if a test developer has a basic idea of what the test will look like.

Test Specifications

Once the TLU domain is defined, test developers can begin the process of test construction. When designing an assessment, details about the test format and content need to first be outlined in a systematic way. Using a systematic process to create a framework within which to develop test tasks ensures that consistency of measurement (i.e., reliability) is maximized and unwanted variability due to the test method is minimized. This procedure entails designing specifications for the test and test tasks. Creating test specifications within a framework also allows for parallel forms of a test to be more easily created if that is the need of the

stakeholders. In the context of a classroom, specifications can help to ensure that the test correctly relates to a teaching syllabus or other features of the teaching and learning context. In a more high stakes situation, specifications are important because they bolster test quality and help to demonstrate that the decisions based on test scores are fair and valid. Finally, test specifications, and task specifications more specifically, can be used to link the test tasks to the TLU domain, which will help ensure a precise measure of the learner's language ability in a given context.

Bachman and Palmer (1996) provide a comprehensive framework of specifications that includes both the test as a whole and the characteristics of the test tasks contained within the test. With respect to test characteristics, test developers need to specify the characteristics of the test setting (e.g., participants, location, and time of the test) and the characteristics of the test itself (e.g., overall test instructions, test structure, time allotment, any cut scores for the test, or weighting of test sections). Test developers need to also outline a number of characteristics of the individual tasks within the test as well. These include specifying the individual task instructions, the format, language, topical and strategic characteristics of the input and expected response, scoring method, and the relationship between the input and expected response. Once these elements have been specified, the actual test tasks can be written. (See Chapter 47, Effect-Driven Test Specifications.)

Task Types

There are two main classes of task type that test developers need to know: selected response and constructed response. Selected response tasks include conventional MC (gap-fill, sentence completion, etc.), matching (fill-in with lists), and discrimination (true/false, same/different, etc.). The second class, constructed response, can be further subdivided into limited production and extended production task types. Limited production tasks typically involve brief, written responses, including short answer, fill-in-the-blank, cloze (examinee is asked to fill in several blanks within a passage), and discourse completion tasks (DCTs) (examinee is asked to provide lines of text to complete lines in a dialogue). Extended production tasks typically involve longer responses (either written or spoken), such as structured question or information gap tasks, stories, reports, essays, interviews, role plays, and simulations. The selection of a particular task type will depend on the nature of the information that stakeholders need to get from tests. There are many sources of practical information on different task types (e.g., Hughes, 2003; Coombe, Folse, & Hubley, 2007) and some are even tailored to certain skills (e.g., speaking) or specific populations (e.g., K-12 learners). (See Chapter 52, Response Formats.)

In an ideal world, there exists an alignment between the instructional tasks (if the test is to be given in the context of instruction) and the test tasks, and also an alignment between the test tasks and the real-life tasks the test takers will be asked to perform outside of the test. Now, this *authenticity of task* is achieved through the test tasks being a close approximation of the TLU tasks (Bachman & Palmer, 1996); however, sometimes stakeholders are simply interested in gathering information about, for instance, the test takers' knowledge of the past perfect or article usage and, therefore, may develop a quick, MC test. Though perhaps inauthentic,

this type of test may provide precise and sufficient information for the stakeholders with minimal negative impact in terms of time, resources, and test-taker affect. In other words, no task type is inherently bad. It just depends on the type of information that the stakeholders are interested in gathering. Ultimately, test developers should try to maximize authenticity of task (i.e., create tasks that reflect real-life situations) in their quest to capture the TLU domain in their test tasks, while still being mindful of the effect that task type may have on practicality considerations on the one hand and the types of inferences that can be based (or not) on test performance on the other.

Item and Task Writing

The type of item or task that is selected should be a function of the desired outcome (e.g., a learner's ability to comprehend a listening passage) that is being tested (Lane, Haladyna, Raymond, & Downing, 2006). Whether tapping into receptive skills (e.g., reading and listening) or productive skills (e.g., speaking and writing), test developers should design task types that result in the most adequate means of capturing aspects of a learner's language ability. Some task types require expert judgment, necessitating human raters (or machine scoring or both) to evaluate the learners' performance, while other tasks are scored objectively and require no expert judgment (e.g., MC items). Choosing the appropriate item or task format depends on what type of information is needed about the performance of test takers and what decisions are to be made about them. Again, although it is preferable to maximize authenticity of task to have the test reflect the domain in which the test taker will use the language, less authentic item types (e.g., selected response) are often preferable when teachers want to assess, for example, learners' knowledge of grammar (e.g., past conditional), their comprehension of a reading passage (e.g., "What is the best title for the article?"), or their comprehension of a radio program (e.g., "What does the man say is the most current threat to the economy?"). Although selected response items are easily scored, writing items that perform well requires extensive and extended training (Bachman & Palmer, 2010).

Whether writing selected response or constructed response items, there are a few general points to follow. Test items should try to (a) include instructions that are clear, concise, and elicit appropriate responses; (b) tap into a testing point that is connected to the test construct or an instructional objective; (c) follow standard conventions for grammar, punctuation, and spelling (of a particular language variety); (d) include clear and unambiguous language within the item, which helps avoid its being tricky or unanswerable with the background knowledge of the examinees; and when possible, (e) include an example item to minimize ambiguities, especially in the event of introducing a new item type.

Instructions should be given for each task. For selected response tasks in particular, they should be short, concise, and unambiguous, but still provide enough information so that the test taker will be able to fulfill the task. Instructions should elicit the desired output and minimize anything unrelated to the construct. Each item is composed of a "stem," which is usually a one-line question or statement (e.g., "What is the best title for this passage?") or a sentence or dialogue with a

Table 45.1 Anatomy of an MC item

Choose the best answer to complete the sentence.		Instruction line(s)	
Jack:	How ____ you?	Stem (in the form of a dialogue)	
Sara:	I'm fine. Thanks.		
	a) is	Distracter	4 options
	b) be	Distracter	
	c) are	Key	
	d) being	Distracter	

Table 45.2 General rules for MC item writing

<i>What to do</i>	<i>What to avoid</i>
Measure a single testing point (e.g., write an item measuring tense only rather than tense and word meaning together).	No option should cue another; keep items independent of one another.
Create distracters that are plausible and attractive. Avoid illogical distracters.	No item should have more than one key (correct answer).
Use vocabulary and grammar consistent with the test takers' level of understanding.	No option should "stick out" from the others. Item options should look like a coherent set.
Employ a similar level of grammatical complexity when writing options.	Avoid negative forms in the stems and in the options, when possible.
Write options that are similar in length.	No option should cancel another one out. Avoid using words like "always" and "never."
Include all necessary information in the stem (e.g., if words are repeated in the options, move them up to the stem).	Avoid creating an item that taps into more than one testing point (e.g., word meaning and morphosyntactic form together).

fill-in-the-blank. Stems need to be accurate and contain only the necessary information to target the testing point. Extraneous information will only require more reading on the examinees' part, which might detract from what is the object of measurement. Most MC questions have three or four options, composed of one key and three distracters. The "key" is the correct answer, which should unequivocally be the best answer among the options. Ideally, the three (or two) distracters are equally "distracting," but this rarely occurs. Typically, only one or two distracters are chosen by examinees at lower levels of ability. Table 45.1 exemplifies the anatomy of an MC item.

Before attempting to write test items, it is important to be aware of what to do and what to avoid. Table 45.2 outlines some general rules to keep in mind.

Since writing successful MC items is often challenging, test developers should reconsider using MC items unless there is a process of item analysis, whether qualitative or quantitative, that aims to evaluate the test content. Seeking the help of qualified experts to look at the content of the test and the items themselves can be helpful, but the item review process should be as systematic as possible, including, at a minimum, the use of item-writing checklists.

As an alternative, constructed response tasks, when designed well, can provide stakeholders with a great deal of information about test takers. Since more learner output is encouraged in this item type, there are more opportunities for the stakeholders to directly view the evidence of what the test takers can do in a given task. The challenge comes in honing the prompt to elicit the targeted response from the test taker. For example, prompts that are too generally worded will result in wide variability in test takers' responses. More narrowly focused prompts will lessen ambiguity and will help focus the test takers into providing the desired language, structure, or both for a given task (Bachman & Palmer, 2010). (See Chapter 48, Writing Items and Tasks.)

What is most important in writing items and tasks is that they adhere to the test specifications as written by the test developer, since they refer back to the construct or instructional objectives. Many testing organizations compose elaborate item-writing guidelines or checklists, which can provide indispensable guidance for novice and experienced test writers alike. Documents such as these typically include example items that help add clarity and purpose to a test writing session. Test developers working with a team of test writers should consider creating a set of guidelines for a given test. Finally, asking a colleague who does not have familiarity with the test takers to give feedback on a newly revised test can also be a valuable exercise (Davidson & Lynch, 2001).

Ultimately, no matter what kind of items or tasks are used, issues of test fairness must always be addressed so that stakeholders can determine whether the difference in examinees' test performance involves factors that are related or unrelated to the examinees' true language ability. Kunnan (2004) creates a Test Fairness Framework in which he suggests how test developers can make mindful decisions about possible systematic bias related to (a) dialect, content, and topic, and (b) group performance (e.g., gender, age, language group, etc.). When such biases are identified, Kunnan recommends flagging these items for a thorough content review, from which decisions about reviewing, modifying, or deleting items can be made. (See Chapter 66, Fairness and Justice in Language Assessment.)

Test Administration

Although test developers may not necessarily be the administrators of a test, they, too, need to consider a number of variables that may affect test performance, and how these things relate back to test development. If the test administrator is also the test developer, they likely have even more information at their disposal to minimize unwanted variability in scores due to the administration process. First, the test environment should be comfortable and free of unwanted distractions (e.g., construction noise outside a classroom during a listening test). Second, test takers will feel more prepared if the format and content of the test tasks are familiar (e.g., ones similar to those they have previously encountered during classroom instruction) or the tasks reflect the TLU domain. Third, test takers should be given access to as much information about the test as possible without unfairly advantaging some test takers over others (or giving them the answers, obviously). Practices such as mock exams and giving out copies of the rubric well in advance

can maximize test-taker performance. Transparency is key in helping the test takers feel prepared, relaxed, and focused during a test.

Some test developers are interested in obtaining feedback, either before, during, or after the test administration, in order to improve a test for future administrations. This feedback may include information about the test administration or the test items or tasks themselves. It is important to keep in mind that asking the test takers to complete a checklist, questionnaire, or interview during a live administration of a test can induce anxiety in some. Although it is possible to minimize the negative impact of such information-gathering techniques, it is preferable to obtain feedback during a pilot version of the test. (See Chapter 53, *Field Testing of Test Items and Tasks*.)

It is also important to note here that despite efforts made by test developers to adhere to a particular set of guidelines and specifications, an influx of test preparation courses have cropped up in recent years on a global level. These test preparation courses feature a range of test-taking strategies intended to increase examinees' level of test-wiseness, including making efficient use of time and guessing. While some test preparation courses equip examinees to prepare for the content of the test (e.g., speaking ability tasks), some less ethical courses prepare them to become familiar with the idiosyncratic characteristics of a test developer, making the score results of the examinees questionable. In other words, have the examinees reached a level of proficiency (or achievement, mastery, etc.) or were they merely using their ability to decode or "game" a test (test-wiseness) according to their knowledge of item construction patterns of a particular test? Such issues make it difficult to make genuine and informed decisions about an examinee's true language ability. Ideally, this is not something most stakeholders will encounter, but it is certainly something to be aware of. (See Chapter 68, *Consequences, Impact, and Washback*.)

Scoring

Scoring Methods

There are a number of different scoring methods that all test developers should be aware of. The process of test scoring obviously comes after the test has been administered (or during the test, in some cases), but test developers should be thinking about what kind of scoring procedures would be most useful and beneficial when designing and operationalizing the test constructs into test tasks. Specifically, the test developer (and possibly other stakeholders as well) should identify the type of information that is needed and also how detailed that information needs to be in order for the best possible inferences and decisions to be made in a given context. In some cases, coarse-grained information, such as a total score, will be sufficient; in other situations, stakeholders will want highly detailed, fine-grained information on which to base their decisions. Thus, selecting the appropriate scoring method is crucial, particularly in high stakes situations.

There are three main types of scoring methods: right/wrong scoring (with one or more criteria for correctness); rating scales with limited production items

(which are typically limited in both the number of scale levels and also the level of detail in the descriptors); and holistic or analytic rubrics with extended production items (which are typically broader in both scale length and the level of detail in the descriptors). Right/wrong scoring is used when test items can be scored as either “right” or “wrong,” typically on one dimension. Conventional selected response (e.g., MC) items are typically scored right/wrong, or dichotomously. In this case, when a response is considered right, or correct, it is usually given a score of “1”; responses that are wrong, or incorrect, are given a score of “0.” Dichotomous scoring is the most straightforward to implement, but provides the least detailed feedback for the test users when compared to other methods. Test responses can also be scored right/wrong on more than one dimension. For instance, a limited production item (e.g., cloze) may require the test taker to produce both the correct form (e.g., *had run* as opposed to *ran*) and the correct meaning (e.g., *run* as opposed to *walk*) of a particular verb in a blank. The response can be scored as either correct or incorrect on two dimensions (i.e., correctness of form and correctness of meaning). In this case, test takers could be given *two* scores for each blank in the cloze test—each score being dichotomous in and of itself. In this case, right/wrong scoring with multiple criteria for correctness would be being implemented.

The second type of scoring involves rating scales. Rating scales are typically used in scoring limited production items. In this case, the test taker is producing more than single words or phrases; therefore, there may be degrees of correctness on one or more dimensions, rather than being right or wrong. For example, test takers are asked to complete a conversation as part of a DCT by producing one or two short sentences. Responses may be fully precise and meaningful or full of errors and incoherent, but they may also be somewhere in between. In this case, the test developer may decide that responses should be scored on a continuum rather than simply right/wrong. Therefore, individual responses are scored for grammatical accuracy and meaningfulness, each on a scale of 0–3. It is up to the test developer to decide what is being operationalized, elicited, and feasible for scoring in a given task (e.g., perhaps pragmatic appropriateness is also elicited). Using rating scales provides more information for test users than does right/wrong scoring, but it is typically more coarse-grained than information about test takers obtained through the use of scoring rubrics, since there are usually more score bands and detailed descriptions of behavior associated with rubrics.

The third type of scoring, using rubrics, is typically associated with extended production items or tasks, such as in performance-based speaking or writing assessments. Since extended production responses contain a great deal of language, right/wrong scoring or relatively simple rating scales are often insufficient to capture the heterogeneity along several, potentially distinct, dimensions of test-taker performance (e.g., organizational competence, topic development, and language control in a compare-and-contrast essay). In addition to accounting for several domains of knowledge or ability, rubrics allow for these domains to be scored on multiple bands, or levels. Each level ideally has a detailed description of what the performance looks like at that particular score band, and the descriptions should use parallel language in all bands (e.g., adverbs of frequency, comparative adjectives, etc.). These descriptors help raters identify the characteristics

of a particular performance and link it to the appropriate score. This alignment helps objectify the rating process and maximize accountability. Holistic rubrics collapse all domains under measure (and their associated descriptors) within one large scale. With holistic scoring, test takers receive a single score for their performance. By contrast, analytic rubrics separate each knowledge or ability component into its own separate scale, thus giving test takers as many scores in their analytic score profile as there are domains in the rubric. Quite obviously, analytic scoring provides more fine-grained information about test-taker performance, but it is usually more labor intensive in terms of rater training and the time required for scoring. Ultimately, it is up to the test developer to decide which type of scoring, holistic or analytic, is most appropriate given the type of information the stakeholders require. However, no matter which type of scoring is chosen, it is important to remember that the construct under measure should always be reflected in the domains and descriptors in the scales. (Sess Chapter 51, Writing Scoring Criteria and Score Reports.)

Raters and Rater Training

Training raters to score written or oral test samples is an important step in the test development process. Providing solid rater training contributes to reliable and valid interpretations of examinees' scores on test tasks that elicit extended learner output (Cizek & Bunch, 2007). For constructed response tasks (e.g., a persuasive essay or an oral task), raters are needed to score the examinees' written or spoken performance. Ideally, ratings should be blind to reduce bias and raise the notion of fairness. Ultimately, it is important for raters to have a strong knowledge base in matters related to scoring procedures. This is achieved through (a) systematized training, (b) well-defined, unambiguous benchmarks, and (c) a precise rubric whose descriptors depict the domains (i.e., match the construct) of a given task. Without these, raters will fail to agree on what constitutes superior performance on a given task.

The first step in rater training is to have the raters methodically follow standard setting procedures (Cizek & Bunch, 2007). The goal of a standard-setting activity (often called a norming session) is to train raters to be consistent (and equally severe) in their ratings. Before a standard-setting session takes place, it is common for raters to be given training materials that provide examples of different levels of performance that are identified as being representative of each band of the rating scale. During the actual standard-setting session, an impartial arbiter (e.g., the test developer) provides the panel of raters with writing samples that they are asked to score. Raters then compare results in a substantive discussion about the examinees' individual performance. As long as the descriptors are adequate, raters should not be more than one band apart. However, when disagreements arise, an adjudication process occurs in which discrepant raters are asked to provide rationales for their scores using the rating scale descriptors to support their argument, and differences are usually negotiated to reach a "normed" score across the raters. Even if raters appear normed after a standard-setting activity, it is important that they are re-normed periodically to maximize consistency. (See Chapter 80, Raters and Ratings.)

Reporting Test Results

The first thing to consider when thinking about reporting test results is the audience. Are they test takers, teachers, administrators, parents, employers, governments, or some combination of stakeholders? Different types of stakeholders often require different types of information, and making the information transparent and accessible is key. Therefore, it is up to the test developer to create test tasks to elicit the targeted information, and also choose scoring procedures (e.g., holistic versus analytic scoring) that let the grain size of the information needed be made available for reporting. What would be most helpful given the context? Perhaps for some stakeholders, a single numerical score is sufficient for their purposes (e.g., meeting a cut score for university admissions). However, for other stakeholders, detailed, diagnostic information may be indispensable for prescribing future teaching and/or learning, or both, as in the case of an English for academic purposes program. Of course, diagnostic feedback is not always practical to give (or, for that matter, available), but since many test takers are also learners, providing as much feedback as possible can prove beneficial to them and their future learning, and hopefully enhance the positive impact of the test. (See Chapter 58, Administration, Scoring, and Reporting Scores.)

Test Data Analysis

Test developers may or may not be the individuals responsible for analyzing test data, but understanding the most commonly used approaches is important for completing the chain of test development. Since data analysis provides insight into the psychometric properties of a test, research findings often lead to subsequent iterations of test revision, and hopefully, improved versions of a test. As part of this process, test developers may again be called on to make changes to test specifications, items or tasks, test administration, scoring procedures, or a combination of these. At a minimum, test developers should understand the purpose of various statistical analyses, what kind of information they provide, and how this information relates back to future test development decisions. If test developers are interested in a more in-depth study of these analyses, Bachman and Palmer (2010) provide a treatment that is specific to language testing, and Carr (2011) provides a tutorial for analyzing language test data using Excel. (See Chapter 56, Statistics and Software for Test Revisions; Chapter 69, Classical Test Theory.)

Descriptive Statistics

Descriptive statistics provide measures of central tendency and dispersion. Central tendency refers to how well (or how poorly) the broad middle of the test takers performed. Knowing about where our students are “on average” can help inform teaching, learning, and future test revisions (i.e., was the test easier or harder than expected? If so, how can teaching, learning, or testing be changed?). Typically, central tendency is described using the mean, median, or mode. The

most commonly used measure of central tendency, the mean, is the average score on the test. Similar to the mean, though not interchangeable, is the median. The median is the middle score on the test. In other words, if you physically ordered the test papers from lowest score to highest score and then found the test in the middle of the pile, that score would be the median. Since the procedure for obtaining the mean involves an averaging process where even very high (or low) test scores become part of the numerical calculation, the median is not as sensitive to outliers, because the ordering of the test scores in terms of highest, second highest, third highest, and so forth, does not take into account the magnitude of the differences between the scores. Therefore, in cases where outliers' scores skew the mean to be either significantly higher or significantly lower than the true representation of the broad middle test takers' performance, the median may be a better indicator of central tendency than the mean. The mode, or most commonly occurring score, also provides information about the central tendency of the group. Bimodal, or even trimodal, distributions may be seen when there are distinct subgroups of test takers within a test-taker population (e.g., heritage language learners, ESL vs. EFL learners, etc.). If any of these measures of central tendency indicate a different result from what was expected of the average, middle, or most common performance, this may be an indication that test developers need to revisit the design of the test.

Dispersion tells us about the variability in the test-taker population. Are the test takers similar to one another, or very different? In other words, do the results indicate a homogeneous population, and thus one whose members' needs can be addressed in a similar way? Or is it heterogeneous, and, therefore, may we need to contend with a host of diverse teaching, learning, or testing issues? There are two principal measures of dispersion: range and standard deviation. The range is the interval between the lowest and highest scores on a test. Though potentially useful if the population is very large, the range is sensitive to sample size, and thus may be misleading if there are outliers in the data. For example, if most test takers receive scores in the 90s or 100 out of 100, but there is one test taker who receives a score of 10, the range will encompass nearly the entire score spectrum (i.e., 90 points) even though only one test taker received such a low score. In this case, the range of scores on the test would not really be a good reflection of the variability (or the central tendency) of the group. In contrast, the standard deviation is typically a better indicator of how much variability there is in the test scores, since it is an average of how much all the scores deviate from the mean. A high standard deviation would be an indication of a lot of variability in the scores (i.e., heterogeneous population, platykurtic distribution), whereas a low standard deviation would be an indication of very little variability in the scores (i.e., homogeneous population, leptokurtic distribution). A score distribution can also be skewed in such a way as to indicate that test takers did either better or worse than the mean. In other words, the test was relatively easy or hard in terms of probability. Score distributions that are negatively skewed show that a test was relatively easy, and a positive skewness indicates relative difficulty. Classroom achievement test scores are often expected to show negative skewness, whereas a pre-unit check or diagnostic assessment might show positive skewness. Again, if the results are unexpected, this may be an indication that the test developer needs to revise the test

(e.g., perhaps add more difficult or more easy items) so that the distribution of the scores matches the expectations of the measurement for future administrations.

Reliability Analysis

In order for test developers to determine the utility of an assessment, the reliability, or consistency of measurement, must be determined to show that the test results are trustworthy. If very different test results are obtained when any number of different conditions of the assessment vary (e.g., items or tasks, occasions, raters, forms, or a combination of these), the quality of the information obtained can be considered untrustworthy. Ideally, test scores (i.e., observed score variance in measurement terms) are a close approximation of the test takers' knowledge or ability (i.e., true score variance in measurement terms). The better the test scores represent the test takers' true ability, the higher the reliability will be. However, since measurement is never without error and reliability is never perfect, test results are expected to vary somewhat, but it is up to the test developer and other stakeholders to determine the level of consistency that is acceptable in a given context. Obviously, the higher the stakes of the test, the more important it will likely be for a high level of reliability to be obtained.

Reliability can be maximized through systematic test development procedures, but it is not until the data analysis phase that reliability can be statistically determined. A number of different reliability estimates can be obtained, one internal and three external. Arguably the most important type of reliability estimate is internal consistency reliability. Internal consistency reliability, usually measured with Cronbach's alpha, gives an estimate for the extent to which a test score (i.e., observed score variance) reflects the test takers' theoretical score (i.e., true score variance), rather than error. The better this correspondence is, the higher the reliability will be. There are three different types of external reliability that can be estimated. First, test-retest reliability can be calculated when the same test form is administered on multiple occasions. This type of reliability indicates the extent to which the test taker gets the same score from administration 1 to administration 2. Second, parallel forms reliability can be obtained when one or more forms of a test are given. This type of reliability indicates the extent to which scores on one form of a test are comparable to scores from another test form (created with the same set of test specifications). Last, rater reliability, though external to the test itself, is often calculated as another indication of the consistency of measurement. Inter-rater reliability can be calculated when two or more human raters assign scores to test performance samples, as in a writing or speaking assessment. A high inter-rater reliability would be an indication that the raters are assigning similar scores. Intra-rater reliability can be calculated as an alternative to inter-rater reliability, when a single rater (as opposed to more than one rater) is assigning two or more scores to each test performance. Multiple ratings of a test performance by a single rater sometimes occur, for instance, when a teacher is solely responsible for rating students' work, and would like to rate each student's test twice to minimize any ordering effect. Which reliability estimates are calculated will ultimately depend on the format of the test, the context of the test administration, and scoring procedures used. (See Chapter 70, Classical Theory Reliability.)

Item Analysis

Once data have been collected from a test administration, item-level information can be used to modify, and hopefully improve, a test. Statistics that indicate item difficulty (also known as item facility) and item discrimination are commonly calculated by test researchers as a first step in item analysis. Item difficulty for dichotomously scored items is usually given in the form of a p -value, which is the proportion of test takers who answered an item correctly divided by the number of test takers who answered the item (which is usually the same as the number of test takers who took the test). P -values (which are equivalent to item means for dichotomously scored items) range from 0 to 1, with values closer to 1 indicating very easy items and values close to 0 indicating very difficult items. Item difficulty for items not scored dichotomously would be determined simply by calculating the mean for an individual item or task, and would not necessarily range from 0 to 1. The values that would indicate difficulty or ease of an item or task would be interpreted relative to the scale on which the items or tasks were scored and the expected performance of the test takers given the context. Item difficulty can be examined to determine the extent to which the difficulty of the items meets the expectations of the measurement. If the items are too difficult (or too easy), stakeholders, who can include the test developer, may decide that certain items, or the test as a whole, need(s) to be revised.

One goal in testing is often to separate test takers from one another in terms of their knowledge or ability (e.g., masters from nonmasters). Thus, test developers ideally create items that high ability test takers are able to answer correctly more often than low ability test takers. Therefore, another item-level statistic, item discrimination, is useful for determining how well an item performs in terms of separating high ability test takers from low ability test takers. Item discrimination (for dichotomously scored items) is typically calculated using a point biserial correlation. Values above .3 indicate that an item is effectively separating the test takers in terms of their ability, and can be retained as is. Values of .2 to .3 indicate borderline effectiveness and potential for item revision, and values lower than .2 show strong evidence that an item needs to be revised or deleted from a test. Item discrimination values below 0 indicate that lower ability test takers performed better on a given item than did higher ability test takers. Since this finding runs completely counter to expectations, any item showing negative discrimination should first be examined for miskeying, double-keying, potentially confusing language in the instructions or in the item itself, or a combination of these, before it is revised or ultimately rejected. It is important for test developers to keep in mind that any time an item is removed from a test, item discrimination statistics for the other items will change slightly. Therefore, it is best to perform these calculations again for each iteration of the analysis and subsequent test pilots, since item-level statistics tend to become more stable as improvements to a test are made. Finally, once items (and their associated statistics) can be considered acceptably stable for a given context, an item bank can be constructed so that test developers can pick and choose from a pool of items of varied difficulties to create new forms of a test. As part of the item bank, statistics such as item difficulty and discrimination can be catalogued and revised each time an item is administered.

Not only is item banking useful for testing companies in terms of cost savings, but also classroom teachers may find item banking useful either for themselves when teaching the same level year after year, or to share with colleagues who may be teaching in the same program. (See Chapter 49, Item Banking.)

Higher-Level Analyses

Even if test developers are not the ones responsible for performing the actual analysis of test data, it is important that they have an awareness of the higher-level analyses that are available to researchers, since test revisions, (re)piloting, and changes to scoring procedures that often occur as a result of research findings usually become the responsibility of the test development team (and administration personnel). The most commonly used statistical models in language assessment research are item response theory (IRT), structural equation modeling (SEM), generalizability theory, and their related models. The specific statistical model that is employed will depend on the types of questions the stakeholders want answered. A comprehensive treatment of these models is beyond the scope of this chapter; however, information relating to each that is also specific to language assessment can be found in Chapter 72, *The Use of Generalizability Theory in Language Assessment*; Chapter 73, *Exploratory Factor Analysis and Structural Equation Modeling*; Chapter 75, *Item Response Theory in Language Testing*; and Chapter 77, *Multifaceted Rasch Analysis for Test Evaluation*.

Conclusion

The purpose of this chapter is to provide the fundamental concepts that anyone developing a language test needs to consider. Oftentimes in a context where there are limited resources, one person (e.g., a classroom teacher) is tasked with having to develop a test for the assessment of their learners. Having an understanding of the basic concepts of test construction is obviously critical, but also having working knowledge of test administration practices, scoring procedures, and data analysis is important since any and all of these elements of the assessment process can directly affect test development. This chapter provides an overview of the conventional uses of tests, followed by instruction in construct definition and, ultimately, training in test construction, test administration, scoring considerations, and data analysis. The systematicity with which such processes are conducted can greatly affect the quality of a language test.

Defining Constructs and Assessment Design

Joan Jamieson

Northern Arizona University, USA

Introduction

As researchers we often seek to understand why phenomena vary. Why are some students better speakers, why are others better writers? We observe phenomena in different situations, record their states, and try to account for their differences. Our hope is to understand the factors that account for these differences, and to effect change. We express these explanations and their inter-relationships in theories. As explained by Alderson, Clapham, and Wall (1995, pp. 16–17), a theory about language is an “abstract belief about what language is, what language proficiency consists of, what language learning involves, and what learners do with language. This belief is more or less explicit, but it is always there—even if it is not articulated in metalanguage. . . . Every test is an operationalization of some beliefs about language. Every theory contains constructs (or psychological concepts) which are its principal components and the relationship between these components.”

In second language instruction we may be interested in learners’ fluent, accurate, and appropriate use of abilities in areas such as vocabulary, pronunciation, and grammar, and in skills such as reading, writing, listening, and speaking. However, all of these are intangible. In second language research, they can be represented by what are widely known as *constructed variables*, or *constructs* for short. For now let us define a construct as an organized representation of an abstract idea that has properties and on which people vary; as part of a larger theory, it is distinguished from other constructs. That said, considering the role of constructs in the design of language assessments can be confusing even for testing specialists, because the meaning of *constructs* has changed over time, leading to many different denotations. This chapter describes the evolution of constructs and

then illustrates current construct issues that have an effect on the design of second language assessments.

Historical Overview

To understand the term *construct* better, overviews are presented from two perspectives. First, educational and psychological measurement perspectives are briefly reviewed in terms of the *Standards for Educational and Psychological Testing* (hereafter, the *Standards*). Work in language testing often followed these developments and so will follow here, using the *Standards* as a backdrop to issues in language testing.

Construct Views in Educational and Psychological Measurement

In the United States, the *Standards* is a key reference work that has been jointly published about every 10 years since 1966 by three groups—the American Educational Research Association (AERA), American Psychological Association (APA), and National Council on Measurement in Education (NCME). In the 1950s, *Technical Recommendations* were published separately by APA and AERA/NCME. The *Standards* have represented a consensus among scholars and practitioners on what information is most helpful and important for guiding the development and use of tests. A *construct* has been one element in discussions of validity since the 1950s. Considering the scope of this chapter, the changing descriptions of three terms—*validity*, *content*, and *construct*—are presented. Table 46.1 contains citations from each of the *Standards*' five editions (noted by the year and pages in the top row) for each of these key terms.

The 1954 and 1966 editions defined validity in terms of the purpose of the test (the degree to which certain aims were met). Content validity was defined as the degree to which the sample of items on a test matched the target domain, also termed the class or universe of situations. In the first two editions of the *Standards*, content validity was illustrated with achievement tests. For example, a vocabulary test used to measure a student's present level of vocabulary would cover the material taught in the course; the extent to which the test met this aim was evidence for its content validity. An appeal to a theory of vocabulary knowledge was not necessary. Such an approach to using course objectives as the basis for constructing achievement tests was described in Tyler (1934). Since the 1920s, content validity and criterion validity (comparing a test's scores to scores on some concurrent or predictive measure) had been used to establish the quality of educational and psychological tests (e.g., Gulliksen, 1950).

The addition of construct validity in the first edition of the *Standards* was viewed by Cronbach and Meehl (1955) as its most important innovation. According to the first two editions of the *Standards*, construct validity investigated the psychological characteristics that a test measured. Explanation of these characteristics would provide some basis for determining what evidence could be used to support the proposed interpretation of the test scores. If the test developer intended to interpret the scores as a construct (i.e., trait or ability), the theoretical

Table 46.1 *Standards' definitions of the key terms validity, content, and construct*

<i>Key term</i>	1954 (pp. 13–16)	1966 (pp. 12–24)	1974 (pp. 25–30)	1985 (pp. 9–11)	1999 (pp. 5–15)
Validity	Degree to which a test meets certain aims; 4 types	Degree to which a test meets certain aims; 3 types	Appropriateness of inferences from test scores; 4 types	Appropriateness, meaningfulness, and usefulness of the inferences made from test scores; unitary concept	Degree to which evidence and theory support the interpretations of the test scores; unitary concept
Content	Degree to which content of test matches class of situations about which conclusions are to be drawn	Determining how an individual performs at present in a universe of situations that the test is claimed to represent; most achievement tests	Degree to which behaviors demonstrated in testing constitute a representative sample of behaviors to be demonstrated in desired performance domain	Degree to which the sample of test items is representative of some defined universe or domain of content	Themes, wording, item format, administration, and scoring guidelines and procedures; adequacy of content domain representation
Construct	Degree to which a person possesses some trait or quality	Degree to which certain explanatory concepts (constructs) account for performance on test	Degree to which a dimension or theoretical idea is understood or inferred from a network of inter-relationships	Degree to which a test score is a measure of psychological characteristic of interest	Concept or characteristic a test is intended to measure

interpretation needed to be clearly stated and distinguished from other interpretations. Theories were associated with predictions and were validated by examining data to see whether the predictions, or hypotheses, were confirmed. At the time, it was acknowledged that many theories were not well developed, but the authors of the *Standards* stated that this process of making and verifying predictions would help both the test developer and the theorist in creating and understanding tests.

In the 1950s and 1960s, factor analysis was the major method used to identify what we are calling a *construct*—an abstraction of an underlying ability to describe, explain, or in some way capture what we observe in individuals' language use.

Factor analysis assumes that a variety of phenomena within a domain are related and that they are determined, at least in part, by a relatively small number of functional unities, or factors . . . Observation and educational experience lend plausibility to the conception that the mental abilities are determined by a great multiplicity of causes or determiners and that these determiners are more or less structured or linked in groups. (Thurstone, 1947, pp. 55–9)

In the 1974 edition, the focus of validity was modified from a test's aim or purpose to "the appropriateness of the inferences based on test scores" (p. 25). The view of three (or four) types of validity as content, criterion (predictive and concurrent), and construct remained unchanged. Content validity as an estimate of how an individual performs on a sample of tasks from a universe of situations remained consistent with previous editions, but the placement of the vocabulary test example changed. That same test of the level of present vocabulary, which had been used to exemplify content validity in the two earlier editions, was now used to exemplify construct validity. Construct validity was also more precisely defined in this edition:

A psychological construct is an idea developed or "constructed" as a work of informed scientific imagination. It is a theoretical idea developed to explain and to organize some aspects of existing knowledge . . . construct is much more than a label—it is a dimension understood or inferred from its network of interrelationships . . . formulating hypotheses about the characteristics of those who have high scores on the test in contrast to those who have low scores . . . taken together such hypotheses form at least a tentative theory about the nature of the construct the test is believed to be measuring. (pp. 29–30)

In the 1985 edition of the *Standards*, meaningfulness and usefulness were added to the definition of validity along with appropriateness of the inferences, but most importantly, the conceptualization of validity as a unitary concept was introduced. Content-related evidence remained as the degree to which the sample of items represents a defined universe or domain of content; however, recall the vocabulary achievement test that was used first to exemplify content validity, and later for construct validity, and consider the following statement in this edition: "There is often no sharp distinction between test content and test construct" (p. 11). Construct-related evidence for validity focused on the test score as the measure of the psychological characteristics (i.e., constructs) of interest. In this edition, the

construct needed to be embedded in a conceptual framework that specified its meaning and indicated how it should relate to other variables, regardless of how imperfect. Here we see the influence of Embretson (1983) on a construct that is defined and is part of a theory.

By the 1999 edition of the *Standards*, the construct had become the centerpiece of validation, along with consideration of the test's consequences reflecting Messick's (1989) position. The focus of validity was on the accumulation of support for an interpretation with theory and evidence. Although the idea of content domain representation remained, there was a shift in its definition to the actual format of the items, their scoring, and their administration. Another shift in focus occurred in the definition of *construct* as "the concept or characteristic the test was intended to measure" (p. 5), explicitly stating the perspective on content that had been reflected in the two earlier editions—that is, what once had been categorized as content was now categorized as construct. However, perhaps tension in this usage remained, as throughout subsequent sections of the 1999 *Standards* there was a pairing of the terms *construct or content domain* as the object of measurement. The broadening definition of a construct now included a vocabulary achievement test as well as the more traditional theory of vocabulary knowledge. However, treating an achievement test as a construct demanded much more evidence than representative sampling of a domain. In sum, by 1999, the *Standards* (the latest edition at the time of writing) had endorsed the position that a construct should provide the basis for score interpretation, and that a construct could be based on theory as well as curriculum.

Construct Views in Language Testing

In language testing, the term *construct* did not come into regular use until the late 1970s; however, interest in the underlying abilities indicated by test performance was evident earlier. For example, Carroll (1941) explored the domain of speech and language behavior by describing Thurstone's *V factor* of verbal relations as being comprised of two or three factors—*C* or linguistic resources, *J* or semantic relations, and *G*, which he could not interpret, being represented by measures such as speed of handwriting, picture description, and oral reading. Although there was continuing focus on content coverage and criterion relations seen in the work of Lado (1961) and Valette (1967), between 1960 and 1975 there was research activity to understand language proficiency and how to test it. Interest in underlying abilities accounting for language can be found in the work of Carroll (1958) and in Briere's (1975) description of 1969 research by Spolsky, Upshur, and Jakobovitz "to identify the variables which define the competence of a speaker in any act of communication" (p. 221). Similar interest was reflected in Heaton's (1975) language testing text in which he described a construct as the "existence of a certain learning theory underlying the acquisition of skills and abilities" (p. 154).

By the 1980s, applied linguists were developing the *construct* of communicative competence in terms of both definition and theory. Grounded in the work of Halliday (1970) and Hymes (1972), both language functions and language in social settings were added to the characterization of language as grammatical forms. A

model of language proficiency for teaching and testing was described by Canale and Swain (Canale, 1980; Canale & Swain, 1983), and served as the theoretical construct for test and theory development (e.g., Bachman & Palmer, 1981; Palmer, Groot, & Trosper, 1981; Duran, Canale, Penfield, Stansfield, & Liskin-Gasparro, 1985). Several language-testing studies were devoted to theory building—for example, whether language proficiency was a unitary or componential trait and the degree to which it was related to general intelligence—some seeming to search for the one, true theory (e.g., Oller, 1973, 1983; Oller & Perkins, 1978; Bachman & Palmer, 1982; Hughes & Porter, 1983; Lantolf & Frawley, 1988). The work that went on at this time closely paralleled the recommendations in the *Standards* and Embretson's (1983) nomothetic span by testing predictions regarding the relationships among constructs.

In the 1990s models of language ability based on Canale and Swain's earlier work (Canale, 1980; Canale & Swain, 1983) were put forward by Celce-Murcia, Dornyei, and Thurrell (1995) and Bachman and Palmer (Bachman, 1990; Bachman & Palmer, 1996). Both componential models included language ability (made up of the language knowledge components (linguistic knowledge, discourse knowledge, pragmatic knowledge, and sociocultural knowledge) and strategic knowledge; Bachman and Palmer's model also included personal characteristics, topical knowledge, affective schema, and context of the situation. These models coexisted with others (see the review in McNamara, 1996), though at the time of writing Bachman and Palmer's model (*communicative language ability*, CLA) is dominant in language testing.

The CLA model was presented as a theoretical definition or framework. Bachman (1990) wrote that his framework provides structure for future work: "I do not presume to present this framework as a complete theory of language abilities . . . This framework is, however, presented as a guide, a pointer, if you will, to chart directions for research and directions for language testing" (pp. 81–2). The term *model* was used in 1996: "Here we will present a theoretical model of language ability [essentially that proposed by Bachman (1990)] that we believe provides a valuable framework for guiding the definition of constructs for any language testing development situations . . . consideration of language ability in its totality needs to inform the development and use of any language test" (Bachman & Palmer, 1996, p. 67). It seems that Bachman and Palmer did not really distinguish between the terms *model* and *framework*.

Was the CLA model an outline of important components or an attempt at a complete theory? This notion of the totality of language ability seems to indicate that by 1996 the model was intended to represent an entire domain. On the other hand, Mislevy (2009, p. 11) wrote that a model serves as a representation or a metaphor:

A model is a simplified representation focused on certain aspects of a system . . . The entities, relationships, and processes of a model constitute its fundamental structure. They provide a framework for reasoning about patterns across any number of real-world situations, in each case abstracting salient aspects . . . and going beyond them in terms of mechanisms, causal relations, or implications at different scales or time points that are not apparent on the surface.

Here we see a difference in interpretations of *model* based on scale; it seems that Bachman (1990) was more in agreement with Mislevy's view.

Now, let us examine the ways that Bachman and Palmer related the model to a construct:

In order to justify a particular score interpretation, we need to provide evidence that the test score reflects the area(s) of language ability we want to measure, and very little else . . . For our purposes we can define a *construct* as the specific definition of an ability that provides the basis of a given test or test task and for interpreting scores derived from this task . . . we can define our construct from a number of perspectives, including everything from the content of a particular part of a language course to a theoretical model of language ability. (1996, pp. 21, 66–7)

They reflected the 1985 and 1999 *Standards* definition of a construct much more than the 1974 definition in which a construct was equated not with content but rather with a theory underlying ability.

In keeping with the contemporary edition of the *Standards*, Bachman and Palmer described two types of constructs used in language tests—theory-based constructs and syllabus-based constructs that are sampled from classroom content covered in instructional settings. Note that this combination of both theory and content under the broader category of construct reflected the shift described above in educational and psychological measurement, from examining achievement tests in terms of validity as content to treating them in terms of validity as construct.

Bachman and Palmer's CLA model has been extremely influential. Lyle Bachman's editorial work with Charles Alderson resulted in the publication of several language-testing textbooks between 2000 and 2004, and framed much of language-testing teaching and research. As illustrated in Table 46.2, the varying definitions of *construct* in these texts lead us to issues that are relevant in assessment design today regarding both the type of construct definition and the role that context plays. Purpura (grammar, 2004) referred only to an underlying ability; Read (vocabulary, 2000) and Weigle (writing, 2002) referred to syllabus or theory; Alderson (reading, 2000), Buck (listening, 2000), and Louma (speaking, 2004) referred to the underlying ability and the operationalization. These definitions reflect some haziness, though they are clearly in line with the 1999 *Standards*. Whereas Buck, Louma, and Weigle all explicitly referred to the role of context in their definitions of language ability, Alderson, Purpura, and Read treated their constructs as more independent of context.

Construct Issues and Assessment Design

As we have seen, many of the changes regarding constructs and theories in education and psychology have been mirrored in language testing. This continues to be the case. Today, there are four inter-related issues in these fields that confront the design of second language assessments: the scope of the term *construct* in a particular assessment, the move away from the *Standards* view of construct validity,

Table 46.2 Examples of constructs by language area

<i>Language area</i>	<i>Definition of construct</i>	<i>Construct of language area</i>
Grammar (Purpura, 2004, chs. 2, 3)	Abstract, theoretical concepts	Grammar: basic underlying model of form–meaning relationships; same in all situations; no one “right way” to define grammar Grammatical knowledge: set of informational structures accrued by experiences, stored in long-term memory; varies by contexts Grammatical ability: grammatical knowledge and strategic competence; varies by contexts
Vocabulary (Read, 2000, chs. 2, 6)	Mental attribute or ability the test is designed to measure	Syllabus based: lexical items and vocabulary skills determined by course objectives Theory based: variety of concepts and frameworks proposed to account for vocabulary acquisition, knowledge, use
Listening (Buck, 2001, chs. 1, 4)	Thing we are trying to measure Two steps: (1) theoretical or conceptual definition informed by context; (2) operational definition with texts and tasks	Listening ability: framework of language competence and strategic competence; use framework for different construct definitions for different purposes Listening task characteristics: setting, input, expected response, interaction between input and response
Reading (Alderson, 2000, chs. 1, 4)	Ability we wish to test Psychological concept (though not real) that derives from the theory of the ability to be tested Abstractions that we define for particular assessment purpose; may be a subset of overall ability	No agreement on best construct for reading assessment; understanding of reading is faulty and partial Test designers need to consider numerous skills and subprocesses such as word recognition, automaticity, synthesis, and evaluation, but carefully consider background knowledge, first language reading ability, linguistic skills, strategies, purpose, affect
Speaking (Louma, 2004, chs. 1, 5, 6)	Thing we are trying to assess Abstract definition of the skill we are trying to assess	Context dependent; describe speaking for set of learners, envision tasks and good, average, poor performance Relate to parts of theoretical frameworks: linguistic, communication, situation
Writing (Weigle, 2002, chs. 1, 3)	Ability we want to test	Theory based: use model of writing/ language ability with information on test takers, context, purpose Course syllabus based: use course objectives

the way one's worldview affects the role of context in construct definitions, and the way construct definitions affect the types of inferences we want to make on the basis of test scores.

The Scope of the Construct

One confusing element regarding the construct is its scope. Does the test developer mean the construct for the test or the theoretical construct? Throughout the literature, there is explicit reference, and distinction, made between the observed performance that is based on a test task (which in turn is an operationalization of the construct) and the construct itself. There may be a distinction between the overall theory and the subset included in a given test (cf. *Standards* 1974, 1985, 1999; Messick, 1975; Bachman & Palmer, 1996).

Chalhoub-Deville (1997) recommended that test developers clearly explain how the subset of abilities targeted on a test is different from, but relates to, a broader theory. She distinguished between a theoretical model and an operational model (which is a subset of the theoretical model used in a test). Such a distinction can also be seen in Alderson's (2000) definition of constructs and in Fulcher and Davidson's unit on constructs and models (2007).

Fulcher and Davidson (2007, p. 36) wrote that a language model is an abstract, theoretical description of all that we know about language knowledge and language use. They contrasted a theoretical model from an assessment framework by positioning the latter as a subset: "Frameworks are selections of skills and abilities from a model that are relevant to a specific assessment context. We will reserve the word *construct* as describing the components of a model" (p. 36). Chapelle (2006) had a different idea about the term. She envisioned two levels of constructs that explicitly linked the theoretical model and the operational models with inferences. One is called a *construct inference*, which links the observed performance to the delimited construct used in a test. The other is called a *theory inference*, which links the delimited construct used in a test to the overall theory of interest.

This separation of an operational construct from its larger theoretical construct has implications for test developers. The test developer can write a clearer construct definition by focusing only on the aspects of language that are included in the test. Chalhoub-Deville (1997) proposed that test developers work with the operational model for a particular purpose:

When the purpose for which the model is to be used is clearly delimited, a parsimonious model, which relates to the theoretical model, but includes only contextually salient components, is more appropriate. Furthermore, when such a parsimonious model had been derived with the help of its end-users, researchers are on a firmer ground to ensure that the model will not only be of practical value but also meaningful and useful. (p. 11)

Such an operational construct definition can provide the basis for test specifications to guide test development (Fulcher & Davidson, 2007; Jamieson, 2011). The test developer can then separately explain how the delimited operational construct relates to the broader theoretical construct.

Moving from Construct Validity to Argument-Based Approaches

A second issue involves difficulties with the 1999 *Standards* and its approach to validity. More recently, the notion of a test's validity in terms of construct and consequences (e.g., Messick, 1989) has given way to a belief that a test's meaningfulness and appropriateness can be justified with a series of inferences rather than framing the intended score interpretation within the confines of a construct (Kane, 1992, 2006; Kane, Crooks, & Cohen, 1999; Bachman, 2005; Mislevy & Yin, 2009). This more recent view has been called an *argument-based approach to validity* and has two parts: an interpretive argument that lays out a network of inferences from observed performances to decisions, and a validity argument that evaluates the interpretive argument.

In Kane's conceptualization of an interpretive argument, tests for different purposes have different inferences, depending on the types of interpretations one wants to claim and one wants to reject (2002). Kane, Crooks, and Cohen (1999) described three inferences: evaluation, generalization, and extrapolation. Evaluation links the observed answer or performance to a score. Generalization links the observed score to a universe of scores. Extrapolation links the score back to performance in a target domain. In their framing of the interpretive argument for the Test of English as a Foreign Language (TOEFL), Chapelle, Enright, and Jamieson (2008) added three more inferences that are pertinent to this discussion of constructs: domain definition, explanation, and utilization.

Domain definition links target language use to test tasks. This inference provides the space for detailed information about authentic tasks in the target domain; as such, it delimits the domain of interest and allows for inclusion of salient context in the characteristics of the test tasks. This inference is particularly relevant for syllabus-based achievement tests that do not include links to theory, as it provides space for moving *content* out of *construct*. Extrapolation links the performance on the test tasks back to target language use. While relevant for most tests, in particular this inference provides space for those who are interested in situation-specific, performance-based tasks, or what McNamara (1996) called the *work-sample* approach. Explanation links observed test performance to a theoretical construct. This inference provides space for identifying cognitive abilities and psychological processes that account for performance. This is particularly relevant for language testers who want to interpret test scores as indicators of some underlying complex of abilities. Utilization links test scores to decisions and consequences.

Inclusion of other inferences beyond an all-encompassing construct gives test developers more conceptual space to describe the content (and statistical) characteristics of their assessments that are most meaningful for their particular purposes. In this way, the quality of different types of assessments can be addressed, without the apparent necessity of all tests having a theoretical construct.

Types of Construct Definitions and Context

A third issue in assessing language ability is how we deal with context. The ways applied linguists view context's role in a language-related construct is affected by beliefs about the form and nature of reality and the relationship

between the observer and the observed. In this section, three views will be described (e.g., Chapelle, 1998; Bachman, 2006; Creswell & Plano Clark, 2011).

A post-positivist worldview reflects a belief in which the observer can be separated from what is observed; there is an objective, if imperfectly apprehended, reality. In such a reality, abilities can be treated as traits, which are usually the same regardless of the context or situation in which they are used. Constructs are defined in terms of the knowledge and fundamental processes of the test taker. Two examples of such tests (although there are many) were seen in the structure section of the old computer-based TOEFL and the grammar and vocabulary section of the Michigan English Language Assessment Battery (MELAB) (Stoynoff & Chapelle, 2005, pp. 87–91). In both cases, test takers answer a series of unrelated discrete items. As Purpura noted in his review, these same items could have been tested in the context of situated events or themes, such as a doctor's office for medical professionals.

Examples of language testers with a post-positivist stance include Bachman and Palmer's (1996) CLA model, Purpura's (2004) view of grammar, Read's (2000) view of vocabulary, and Alderson's (2000) view of reading. These are all built on underlying language and strategic abilities. Testers in this tradition acknowledge the role of task-based features and context, but see these as separated from language abilities and strategies.

A constructivist worldview reflects the belief that the observer cannot be separated from what is observed. The interaction between the observer and the observed forms subjective realities that are affected by context. Language testers with such a view attribute consistencies to contextual factors (e.g., the relationship of participants in a conversation) and so define the constructs with reference to the situation and the conditions under which the performance took place (Chapelle, 1998, p. 34). Much work in the testing of speaking, writing, and tasks in language testing has been constructivist in its orientation, for example the American Council on the Teaching of Foreign Languages Oral Proficiency Interview (ACTFL OPI) (American Council on the Teaching of Foreign Languages, 1986), which was much criticized by those with a positivist stance because of its appeal to situation rather than underlying traits or abilities of the speaker (cf. Bachman, 1990, 2002; Byrnes, 2002; Lantolf & Frawley, 1988; Norris, 2002).

An interactionist worldview reflects perhaps a pragmatic perspective; pragmatists see primarily objective realities influenced by multiple perspectives that reflect different contexts. Language testers with such a view see performance as the results of traits, situational features, and their interaction, and so delimit the scope of their constructs by including this interaction (e.g., Chapelle, 1998; Chapelle et al., 2008). Post-positivists and constructivists are open to working with an interactionist language construct, as is evident in the work of Douglas (2000) in language for specific purposes, Buck (2000) in listening, Louma (2004) in speaking, and Weigle (2002) in writing, and in the revisions of the Test of English as a Foreign Language (Mislevy, Steinberg, & Almond, 2003; Chapelle et al., 2008). Another example is *Assessing Comprehension and Communication in English State-to-State for English Language Learners* (ACCESS for ELLs), in which children are tested for their social and academic English using language associated with language arts, mathematics, science, and social studies within a school context (MacGregor et al., 2010).

How Constructs Affect Test Score Interpretations

The final issue concerns the types of interpretations we want to make on the basis of test performance. In the argument-based approach, *construct* refers to a model-based, theoretical interpretation (Kane, 2002) that is supported through the explanation inference, much as it was before the 1999 *Standards*. However, ambiguity results when the proposed interpretation of the test can be referred to as its construct (*Standards*, 1999, p. 9). Construct can mean a decontextualized trait in which one's grammatical knowledge is unvarying, or performance on a speaking ability that is dependent on an interlocutor, or speaking ability that varies in different contexts, such as with a friend versus giving a talk before a class. It would be useful if test developers made explicit reference to the situated meaning of *construct* for those using the test or interpreting its scores.

If a construct definition were based on a post-positivist trait perspective, language ability could be defined in terms based on Bachman and Palmer's (1990, 1996) CLA model. The test developer would try to limit the role of context so that the test score could be interpreted as an ability that would be manifest across a wide range of situations. In an interpretive argument for a test such as this, the domain definition inference may not be included, as context and authenticity are not seen as necessarily relevant. The extrapolation inference would be of interest, as the test designer would want to claim that the test taker would exhibit the language tested in future situations. Because there would be a direct use of theory in this case, the test developer should plan for evidence to support the explanation inference (a *construct* is included). For example, there should be hypotheses about expected performance profiles, relationships with other measures, and explanations for task difficulty. The Comprehensive English Language Test and the Listening Comprehension Test (Stoyhoff & Chapelle, 2005, pp. 63–5, 79–81) exemplify this approach.

If the construct definition were based on a constructivist perspective, language ability could be defined on the basis of a sociocultural model. Ability would be viewed not in terms of an individual but instead in terms of the participants who are co-constructing meaning in a specific context. The test developer would be interested in observing and recording language in use in naturalistic settings. Test scores may be replaced by conversational analysis and other qualitative techniques. This approach can be seen in formative assessments for the classroom described in terms of *assessment for learning* (e.g., Rea-Dickins, 2001; Colby-Kelly & Turner, 2007) as well as *dynamic assessment* (Poehner & Lantolf, 2005). Paired speaking tasks also reflect a constructivist perspective (e.g., Galaczi, 2008; Brooks, 2009). Swain (2001) explained how this constructivist approach could inform teachers in the classroom and second language acquisition theory. She described how the focus on vocabulary and grammar in dialogues based on a jigsaw task and a dictogloss task resulted in language-related episodes (LREs) that could be incorporated into tests designed to measure language learning. In such an example, different pairs of students could receive different tests, depending on the LREs they produced. In such linguistically focused tasks, domain definition inferences and extrapolation inferences may or may not be relevant, but explanation inferences bound by the task context (and thereby, a *construct*) would be included.

If the construct definition were based on a post-positivist interactionist perspective, language ability might be defined by using the CLA framework, but it would be augmented by the inclusion of context and the interaction between the cognitive and social dimensions, using for example Chalhoub-Deville's (2003) "ability-in language user-in context" approach. The test developer would try to delimit the interpretation to those settings that had been included in the test on the basis of the characteristics of the context in the domain definition inference. Here again, a theoretical construct is included and so the test developer would need to state as clearly as possible hypothesized relationships with other measures, predictions of difficulty drivers, and characteristics of high and low scorers. This approach can be seen in the TOEFL Internet-based test (iBT) (Chapelle et al., 2008), the Business Language Testing Service (BULATS) speaking test, and International English Language Testing System (IELTS) academic modules (Stoynoff & Chapelle, 2005, pp. 43–8, 73–8).

If the construct definition were based on a class syllabus, there might be no apparent philosophical stance and no appeal to a theory of language ability. Here, the test developer might be most interested in domain definition so that the scope and sequence of activities covered in class would be proportionately represented on the test. This was the classic case of content representativeness. The test score is to be interpreted as current knowledge of the sampled domain, such as vocabulary encountered in class. While coherent, this interpretation would seem to be a disservice to the students. The class content should be interpreted in terms of a larger domain. Inclusion of an explanation inference for a theoretical construct such as academic reading or expository writing could lead to deeper and more sophisticated understanding of language learning and teaching; but still, it is not essential.

Conclusion

Construct definition is one step in the design stage of test development (Bachman & Palmer, 1996). The four construct issues discussed above currently confront test developers in education, psychology, and applied linguistics. The decisions that we make when addressing them will affect the design of future second language assessments.

Effect-Driven Test Specifications

Introduction

The process of test development can be compared to architectural design and building. Fulcher and Davidson (2010) illustrated three main layers of architectural documentation for test development, namely models, frameworks, and test specifications (hereafter “test specs”). As the most general documents, models provide theoretical foundations of knowledge, skills, and abilities that are necessary for successful performance in a domain of interest. Frameworks state test purposes, lay out constructs to be tested, and explain how to elicit the evidence for the constructs and to translate the observation of the evidence into a score. Dealing with test purposes for a particular context, this layer forms the skeleton of a test.

The last documents in test architecture are test specs, which are the focus of this chapter. Test specs are generative documents from which equivalent test items or tasks can be built. To continue the architectural simile, they are like the actual production blueprints that a builder would use during construction. Test specs contain two key elements (Fulcher & Davidson, 2007, chap. A4). One is the guiding language that specifies all detailed information necessary to produce items or tasks and the other is at least one sample item or task.

There is no single best format for test specs, and several models for spec design are available in the literature (e.g., Alderson, Clapham, & Wall, 1995; Bachman & Palmer, 1996; Davidson & Lynch, 2002, *inter alia*). For example, Davidson and Lynch (2002) based their model on the earlier one developed by Popham (1978), which includes four elements: general description, prompt attributes, response attributes, and sample item. This is the model our sample spec will follow, below. In well-constructed test specs, guiding language (i.e., everything except the sample

items or tasks) includes whatever information the test developers deem necessary to produce the test.

As a blueprint of a test, the classical utility of test specs is to generate items or tasks. In modern validity theory, test development itself has been considered as part of the validation process, and test specs are now seen as one source of validity evidence. Even though there has been increasing interest in building and testing a validity argument during test development, there has been little research on how to redesign and use test specs to allow them to actively fill this new role. This is noteworthy because the modern paradigm of test validation is consequential: Messick's (1989) definition specifically asserts that validity includes the impact of a test. In this chapter, we review the nature and role of test specs, and argue that they need to be developed with effect in mind and to articulate that development as an actual component.

Test Specs and Validation

As several researchers (Chapelle, 1999; Weir, 2005; Fulcher & Davidson, 2007) have described, validity theories have changed over time. Messick's (1989) work has been the most significant in changing how we understand validity. In his view, validity is not an inherent property of a test, but the degree to which we are justified in making inferences about a construct based on a test score. Therefore, empirical validation is required to ensure the defensibility of the inferences, and one way to provide a framework for validation efforts is to structure them in terms of plausible evidence-based arguments (Cronbach, 1988).

Under the influence of Messick's view of test validity, argument and evidence are now seen as the key components of validation. Kane (1992) provides a framework with which a test developer builds evidence-based arguments and tests them. In the past, it has often been believed that a validity inquiry begins after a test is developed and operated; however, it has been suggested that a validity inquiry should start as a test is planned. Kane's interpretive argument was later expanded to test design and test development. Briggs (2004) suggested an expanded two-stage argument for validity: The first stage is design validity and the second is interpretive validity. Similarly, Weir (2005) distinguished a priori validity evidence collected before a testing event from a posteriori evidence gathered after the test is administered. For design validity and a priori validity evidence, for example, evidence-centered design (ECD) (Mislevy, Steinberg, & Almond, 2002, 2003; Mislevy, Almond, & Lukas, 2004) provides a systematic assessment framework with which test developers explicitly structure a design argument and collect a priori validity evidence by using evidential reasoning.

Several researchers have suggested the additional utility of test specs beyond their classic role as a blueprint or a formal item-writing guideline. Davidson and Lynch (2002) pointed out that the versions of a test spec over time can document a record of evidence gathered to address validity issues and this record becomes a "validity narrative." For test specs as a validity narrative, Li (2006) adopted from the fields of business and accounting the idea of an "audit trail," which is a "formal tracking system of change, of response to feedback and of accountability"

(Fulcher & Davidson, 2007, p. 318). Li's study presented a conceptual model of the relationship of evolutionary test specs to validation, and illustrated how auditing can serve as the evidence of test validity. Kim et al. (2008) similarly showed that documenting a consensus-making process between a test developer and a stakeholder in the form of a consensus log as specs evolve is a useful way to articulate and collect a priori validity evidence.

An Example of a Language Test Spec

Below, we present an example of a test spec. As mentioned above, it follows a model outlined by Davidson and Lynch (2002), who in turn based their work on Popham (1978). This model has four basic components:

- *General description (GD)*: This is a brief introduction of the test and its setting. What is the test's purpose? Where is it used? What knowledge and skills does it assess?
- *Prompt attributes (PA)*: This section provides detailed information about what will be presented to the test taker. What are the specific attributes of the stimulus materials? What specific directions or instructions will be given to the test taker?
- *Response attributes (RA)*: This part of the spec gives detailed information about how the test taker will respond and about how the response will be scored.
- *Sample item (SI)*: Here, we see an example of whatever the spec is intended to produce, that is, the item or task that the spec will generate. As we have seen, all spec models have two basic components: guiding language and example(s). In this spec model, the GD, PA, and RA are the guiding language, and the SI is the sample.

GD: The context is South Korea, an English as a foreign language (EFL) situation, in which there is an annual national test to screen secondary-level teacher candidates. This example is about developing an English writing test for the English teacher candidates. Renowned English-teaching educators (most of them faculty members) are invited as a committee in charge of developing the test.

PA: Test takers are asked to provide feedback on a given student error or errors. Specifically, test takers are asked to (1) identify or explain the error(s), or to do both, and (2) rationalize the way they give feedback. An example of error(s) produced by a typical Korean middle or high school student is presented as a prompt. The guiding language for the prompt includes:

1. Use either written or spoken errors.
2. Use types of errors commonly made by a Korean EFL learner.
3. Ensure the length and the complexity of language are suitable for the target learner.
4. Errors are indicated or not indicated depending on the task.

Read this high school student's writing below and follow the directions. [30 points]

My Favorite Season
Summer is my favorite season. The temperature is good for me. I like the summer clothing and the outdoor activities. I am never bored during a summer. Sometimes I don't like the hot weather because it make me uncomfortable. I can go outside anytime without puting on much clothing. A light shirt and shorts with sandals for my feet are always enough, while jeans and a light jacket is usually enough for cool evenings. On special events I can dress me up without making everything wrinkled by wearing a heavy coat. Actually, I have bought a heavy coat on sale from the department store yesterday. What I like most about this season are participating at outdoor activities. I really like swimming when the air is warm and the sun is shining. I also like a winter sports. Basketball is fun too. Our friends like to go to the court in the afternoon for an exciting game. Both basketball and the bike riding to the court are pleasant ways to start a summer morning. They made me excited. These are my reasons of liking summer. It is really my favorite season.

Complete the following three tasks. First, write one paragraph providing summative feedback to indicate the strong and weak points with regard to the content and organization of this student's writing. When stating the strong and weak points of the content and organization, provide at least one concrete example of both strong and weak points. Next, you are to prepare a simple table using correction symbols (e.g., "S" for incorrect spelling) to give feedback on this writing with regard to grammar and mechanics. There are a total of twelve errors in the student's writing that are categorized into six different error types. Each different error type is represented by each of the six underlined words in the student's writing. Find all the errors (including the six underlined ones) and draw a table on your answer sheet which lists errors found and correction symbols and their meanings. Your table on the answer sheet should look like the following. The first row has been completed for you.

Error(s) found	Correction symbol and its meaning
<u>puting</u> on	"S" for incorrect spelling

Finally, write another paragraph which states two advantages and two disadvantages of using correction symbols when giving feedback.

Figure 47.1 Sample task used in the 2010 Korea National Secondary Teacher Selection Test: Secondary Test for English

RA: The task of feedback giving will be evaluated on the following criteria:

1. content: whether the test takers correctly identify and effectively explain the errors;
2. organization: whether the response is well organized; and
3. language: whether language use is correct.

Note: A detailed assessment rubric is not provided here due to length constraints.

SI: This is shown in Figure 47.1.

All test specs can evolve over time and improve, as argued by Li (2006). The reader is encouraged to ponder: How might this sample spec evolve as it is trialed and as additional feedback is obtained? Our goal in this chapter is not to outline that evolutionary process, but rather to explore how this spec may or may not consider test impact, an idea that is under active scholarly discussion at the present time.

Effect-Driven Testing and Effect-Driven Test Specs

Fulcher and Davidson (2007) explained the importance of test effects during test design via pragmatic reasoning, and specifically, via “retroduction,” a philosophical term promoted by C. S. Peirce. By working from end to explanation, they argued that the outcomes or impacts of a test, that is, test effects, should drive final design decisions on how to craft specific test items and tasks. They call this approach “effect-driven testing.”

Fulcher (2010) noted that in effect-driven testing, a higher-level model, such as the Common European Framework of Reference (CEFR), can act as a source of ideas for the selection of constructs that are relevant to the design of tests for specific purposes. A framework can then prioritize test purposes or effects and provide rationales for the relevance of the constructs to a specific context. The last level is test specs, which lay out decisions and strategies for bringing intended effects through items or tasks. This commitment to effects often requires test specs to evolve through discussion and feedback and to explicitly link design decisions to intended effects.

A model can be seen as equivalent to national standards in the case of teaching. The assessment framework corresponds to a school curriculum, which is developed for the specific context and users. Then, based on the assessment framework, test specs lay out details about items or tasks to be developed. Similarly, a lesson plan is written with reference to the school curriculum, documenting specific details about classroom teaching.

Comparing the test development process to the classroom teaching planning process, consider the following two questions: (1) Who are the agents of action for effects? (2) When do the effects start?

As to the first question, undoubtedly, they are a classroom teacher and an item writer, and (in our example above) the renowned test development committee. Some of these players may not be involved in designing the middle level of architecture, that is, a school curriculum or an assessment framework. In the case of teaching, classroom teachers design a lesson plan with reference to the school curriculum and with consideration of their teaching contexts. In the case of testing, especially in large-scale testing development, an item writer often does not design test specs; rather, a writer is asked to produce items or tasks by following the messages written in given test specs. This is similar to the situation in which a newly hired teacher (or a substitute teacher) is asked to teach with a lesson plan written by another teacher. In this case, it is not surprising that the new teacher has a hard time understanding the logic of the lesson plan and enacting teaching with it.

As Kim et al.’s (2010) study illustrated, when an item writer, an agent of action, is asked to produce item or tasks following test specs written like a user manual, it is not likely that they will be able to produce items or tasks that are appropriate to the intended effects. The best way to avoid this problem is to invite item writers to design test specs.

Our answer to the second question (that of when the effects start) is that effects start when a lesson plan or test specs lay out learning outcomes or test effects.

Test specs are the last stage of the three-level approach to testing; however, they are in fact the front door of test effects in the sense that specific design plans for test effects are embodied in that layer. In order to actively take the role of a seeding document for test effects, test specs should include an effect argument, as Kim (2008) suggested. In other words, test specs need to explicitly state how specific test design decisions are driven by the effect considerations. That is the essence of effect-driven test specs.

Effect-driven specs are quite similar to the notion of “backward design” put forth by Wiggins and McTighe (2005), who provide a useful tool for educators to utilize to design teaching or a curriculum using backward reasoning. The process is to specify learning outcomes of teaching first, then decide acceptable evidence of the outcomes, and lastly plan specific details about classroom activities. This process brings the end of teaching to the beginning of its design, and links outcomes, evidence, and decisions. Using backward design not only makes a curriculum or a lesson more systematic but also makes an argument for alignment among those components strong and explicit.

Conclusion: Reconsidering Our Spec from an Effect-Driven Perspective

And so we return to the fundamental question: Does our sample spec reflect a consideration of test effect and impact? Suppose that we interview these educators who developed it. Here is what we uncover.

We learn that they first thought of its target language context and stakeholders. In our example, the candidates who pass this exam will teach a middle or high school English class in Korea. The target language context is the English class, where Teaching English in English (TEE) is strongly recommended. The target stakeholders include the Ministry of Education, which is in charge of English education in Korea; the schools that hire the screened teachers; the students and parents in the schools; a native teacher who co-teaches with the Korean teachers (TEE is often performed like this); and finally the English teachers themselves, who would be, here, the test takers. The most significant stakeholders probably would be the students and co-teachers, who will communicate with the teachers closely.

After considering the target language context and stakeholders, the test developers consider what the desired effect of the writing test on the class would be. The developers agree on this: “The screened English teachers are able to successfully communicate in a written form of English.” Then the developers ask the next question: “How do we know that the test achieved the effect?” This is the central question about acceptable evidence for the desired effect. At this point in their deliberations, the test developers consider specific types of performance implied in the effect. In other words, they specify observable behaviors of “successful written communication.” After deciding on the evidence for the effects, the developers think of authentic situations where the behaviors are usually required, and specific characters or attributes of the behaviors that determine how far the desired effect is achieved. These are questions about “where” and “how,”

and the questions are answered in detail in the form of “assessment task or item” and “assessment criteria” in an effect-driven test spec.

The sample spec is effect-driven if and only if we also have evidence about the process by which it was developed. An effect-driven spec will detail what types of tasks or items can elicit the behaviors serving as evidence of the desired effect, and it will determine criteria to evaluate the behaviors elicited from the tasks or items. We only know this if we also know what the developers debated and considered as the spec was written.

Evidence of effect-driven test development obligates the test developers to include (in the spec) evidence of how it was developed and of how that development proactively considered the effect the test is intended to achieve. This may be as simple as adding a new element to the guiding language in this spec model which does exactly that. We could call this new element: “effect considerations” (or “EC”). At the most basic level, the “EC” is but an assurance—a guarantee that the developers did think about outcome along the line as they wrote the spec. Perhaps it might read as follows (and as with all spec-based work, the reader is encouraged to critically revise and expand this new addition as well):

- *EC*: The developers of this test spec carefully considered the various stakeholders who will be impacted by this test task. Given that consideration, they then decided upon the observable behaviors of authentic written communication as seen and experienced by those stakeholders. The result is shown here in this spec.

We do not see this as a new idea. Our experience tells us that the authors of test specs do routinely consider test impact as the spec is written. Furthermore, this chapter does not present a new model or form for test specs, other than a suggestion for a new element (“EC”). What we are (simply) asking is that spec authors keep a record of how they develop the spec, and (simply) articulate how effect is kept in mind, and then (simply) include that record in the guiding language. In so doing, they produce a test spec that is not only effect-driven but provides evidence that it is such, and that contributes to validity.

Writing Items and Tasks

Mary Schedl

Educational Testing Service, USA

Jeanne Malloy

Educational Testing Service, USA

Introduction

For high stakes testing a construct for testing is defined, and detailed test and item specifications exist before items (selected response questions) and tasks (constructed response questions) are written. Content specifications function as the blueprint for developing items and tasks that measure the abilities defined by the construct. But, once the blueprint exists, there are still many decisions left for item writers to make in producing the test items, such as creating items and creating or selecting stimuli for testing the abilities and determining which points to test. Item writers decide what questions to ask and whether questions are of appropriate difficulty and fair for the test population. While in textbooks and research there is a fair amount of agreement about appropriate guidelines for item writing, these sources provide very little explanation regarding the significance of individual guidelines, and they seldom include supporting examples and data. In this chapter we explicate important principles for both selected response items and constructed response tasks; and we provide representative examples of weak and strong items to illustrate why the principles matter. We use reading comprehension items to illustrate selected response principles, and writing and speaking tasks to illustrate constructed response principles; however, similar issues exist for other types of items and tasks.

Previous Views or Conceptualization

Before Haladyna and Downing (1989a) published a taxonomy of 43 multiple choice item-writing rules, very little attention was given to the design and construction of test items and tasks. Even today, very little empirical consideration has been given to the subject. Haladyna and Downing's taxonomy is a compilation

The Companion to Language Assessment, First Edition. Edited by Antony John Kunnan.

DOI: 10.1002/9781118411360.wbcla025

of suggestions from textbook authors and other sources. Characteristics of the stimuli in item development are not considered. In another study, these two researchers analyzed the results of 96 theoretical and empirical studies to see what support they provided for each rule (1989b). Two rules received the greatest attention—a rule about the number of options an item should have and a rule about the need to balance (vary) the position of the correct answers in test questions. For nearly 50% of the rules no research was found. More recently Haladyna, Downing, and Rodriguez (2002) published a taxonomy of 31 multiple choice item-writing guidelines for classroom teachers. The authors considered the validity of each guideline both on the basis of collective opinions of textbook authors and on the basis of empirical research, but even here they state that “item writing is still largely a creative act” (p. 328). In 2005 Frey, Petersen, Edwards, Pedrotti, and Peyton compiled a separate list of 40 item-writing rules for classroom assessment, using an approach similar to that of Haladyna and Downing. There was substantial agreement in their results.

Also modeling their study on the taxonomy of Haladyna et al. (2002), Hogan and Murphy (2007) compiled advice on crafting and scoring constructed response tasks, identifying 12 recommendations for preparing constructed response tasks and 13 for scoring. Rationales underlying some of these recommendations are discussed, among others, in Schmeiser and Welch (2006) and McClellan (2010). In his book *Constructing Test Items* (1989), Steven Osterlind considers important issues in item writing, including the relationship of items to test validity and reliability. He also addresses the difficulty of establishing evidence for good items in absolute terms, and the fact that constructing test items demands complex technical skills and sophisticated levels of thinking. In addition, he attempts to synthesize the technical skills needed to construct test items. The Association of Language Testers in Europe (ALTE) published an extensive set of course materials for item writers (1995, updated 2005; we used the updated version) that presupposes the need for item writers to have a good background in models of language ability (Module 1), the test production process (Module 2), and item-writing issues and item types (Module 3). Nevertheless, while pointing out that “it is essential for an item writer to be trained in the techniques of item writing” (p.106), the authors list, but do not elaborate on, guidelines similar to those found in other taxonomies.

Given the paucity of empirical evidence related to item-writing rules, many testing programs produce their own version of tips and guidelines for item writers. In our experience taxonomies of item-writing rules alone are insufficient to guide novice item writers. They need detailed explanations and examples of both good and bad items. In this chapter we provide recommendations for writing good items and tasks, and we do so on the basis of many observations of items and their statistics over many years. To our knowledge, there are no extensive discussions in the literature that use pretest data to explain how writing items and tasks is related to principles of validity, fairness, reliability (the consistency of test scores across different forms of the same test), item or task difficulty, and discrimination (the power of an individual item or task to separate high ability test takers from low ability test takers). Explaining these relationships is our goal. We also consider characteristics of the stimuli as part of the item and task design.

Current Views or Conceptualization: Writing Test Items and Tasks

Once a valid construct has been defined and a test framework has been created, test specifications are developed. The specifications indicate the item types, the number of items of each type, and the knowledge, skills, and abilities to be tested. Item writers must be knowledgeable about the test construct and the framework in order to write appropriate test items on the basis of the given specifications and to ensure that the materials, too, are appropriate for the specified test population and purpose—which are also defined in the construct and framework. Test-taker performance on items offers evidence from which we infer the degree to which test takers have or lack the knowledge, skills, and abilities of interest, so the validity of the measurement depends on the degree to which the test items assess these appropriately. Poor item writing causes construct-irrelevant variables to influence measurement. Something that is irrelevant to the construct is not part of the knowledge, skills, and abilities that a test is supposed to be measuring. Item and task validity, discrimination, and difficulty can be negatively impacted by construct-irrelevant variables.

Fairness is a fundamental assessment principle that is directly related to validity. Xi (2010) argues that fairness is an aspect of validity and conceptualizes it as comparable validity for all relevant groups. An item that is unfair allows some test takers or groups of test takers to perform better or worse than other test takers of the same ability. It is the item writer's responsibility to ensure that test materials are equally accessible to test takers from different backgrounds, because failure to do so may lead to construct-irrelevant variance. The reliability of measurement across different forms of a test is directly related to the item writers' ability to create comparable and valid test questions of appropriate difficulty and discrimination.

We divide this section into three parts. In the first part we consider the craft of item and task writing as it relates to validity and fairness in the design of test questions and tasks. In the second part (selected response items) and in the third part (constructed response tasks) we discuss more subtle and craft-oriented features of item construction, which can affect the difficulty and the discriminating power of items and tasks. In particular, we examine how various components of items and tasks can influence difficulty and discrimination.

The Craft of Item and Task Writing: Fairness and Validity

The language in which selected response items and constructed response tasks are presented must be clear, precise, and unencumbered by superfluous or difficult language. If the item text is more difficult than it needs to be, then it will measure a test taker's ability to understand the item text in addition to the test taker's ability to comprehend the stimulus. This is neither as fair nor as valid a measure as it could be. The following excerpt is from a passage about nestling birds, and the question that follows it is an example of poor item text. Here and in all the examples, the asterisk marks the correct answer.

Passage excerpt

Many signals that animals make seem to impose on the signalers costs that are overly damaging. A classic example is noisy begging by nestling songbirds when a parent returns to the nest with food. These loud cheeps and peeps might give the location of the nest away to a listening hawk or raccoon, resulting in the death of the defenseless nestlings. In fact, when tapes of begging tree swallows were played at an artificial swallow nest containing an egg, the egg in that “noisy” nest was taken or destroyed by predators before the egg in a nearby quiet nest in 29 of 37 trials.

Item

According to the paragraph, the experiment with tapes of begging tree swallows established which of the following?

- * (1) By making excessive noise in order to obtain the attention of a parent returning to the nest with provisions, nestling birds may put themselves at the mercy of predators.
- (2) Predators are drawn to nests inhabited by nestlings more frequently than they attack nests in which only eggs are available.
- (3) Tapes containing the sounds of nestlings begging for food may entice more predators than the noise made by real nestlings.
- (4) Predators have no means at their disposal other than the begging calls of nestlings to help them locate nests.

In this example each of the options contains difficult words and phrases that are unnecessary for testing the examinee’s understanding of the information about the experiment. Option 1 (the correct answer) is complex grammatically and includes lower frequency vocabulary than is used in the passage excerpt. Examinees may understand the text but not the words “excessive” or “provisions,” which are not used in the passage itself. The phrase “at the mercy of predators” is essential to expressing the result of the experiment but may not be known by many non-native readers.

Option 2 contains the idiomatic phrase “drawn to” and the participle “inhabited,” which is more difficult than necessary; option 3 contains the difficult word “entice,” which is not part of the passage excerpt; and option 4 contains the fairly uncommon idiomatic phrase “at their disposal.” A version with simpler options would better allow test takers to demonstrate whether they understand what the experiment shows.

Another example of testing the item text rather than the author’s intended point is provided below. The use of the negative in both stem and options is confusing.

Item

According to the paragraph above, which of the following is NOT true about the noisy begging by nestling songbirds?

- (1) It may not go unnoticed by predators.
- (2) It may occur when a parent returns with food.

- (3) It may result in the death of nestlings.
- * (4) It may not attract predators to the nest.

With negatives both in the stem and in the options, it is difficult to keep in mind what is true and what is false. In this case Options 1, 2, and 3 are true, but Option 1 includes a negative. Option 4 is not true but does include a negative. Revising options 1 and 4 to eliminate the negatives would make this a more reasonable item, as the following example illustrates.

Revised

- (1) It may be noticed by predators.
- * (4) It may keep predators away from the nest.

Similarly, the language of constructed response tasks must be as clear and unencumbered by superfluous or difficult language as possible. A test taker who does not completely understand a task is less likely to produce a work sample that accurately represents his or her ability. Precise action verbs and specific descriptive phrases delineating performance expectations are preferable because they better convey the nature or purpose of a task. For example, it is clearer and more precise to ask test takers to “summarize” another piece of writing than it is to ask them to “discuss” it.

Tasks or their directions should include information indicating the type and amount of detail or elaboration expected, hence the inclusion of comments such as “be sure to support your ideas with specific reasons and examples” and the mention of a typical word range for high quality responses. The absence of specific guidance concerning performance expectations can lead to construct-irrelevant variance. For example, in a constructed response assessment of writing proficiency, able but stylistically economical test takers may leave out examples or other supporting information, unless they are informed that this level of detail is expected.

Constructed-response tasks such as integrated skills tasks have multiple components, and directions are necessarily more complex when such tasks are administered. In TOEFL integrated writing tasks, for example, test takers read a brief passage and then listen to a lecture on the same subject before writing a response on the basis of what they just read and heard. In a staged item such as the one just described, directions for each component are supplied as appropriate: “Now listen to a lecture on the subject you just read about.” If preparation time is an item component, the amount of preparation time allowed before responding should be indicated. For example, in a constructed response task measuring speaking proficiency, test takers may be given 30 seconds to make an outline or to mentally prepare a response after learning what the specific speaking task is, and then 60 seconds to deliver their oral response.

When multiple constructed response tasks are included on an assessment and test takers must make decisions about allocating their time, they should be told the point value for each task.

Items and tasks should avoid taking for granted content knowledge that might not be present to the same degree in all test takers and hence might unfairly

disadvantage or advantage certain groups in the test population. Cultural differences in outside knowledge could lead to a significant difference in performance of test takers on an English language test. Consider the following excerpt from a passage on European art:

Passage excerpt

Academic practice and theory were based on the study of officially approved models . . . and the belief that art was governed by rules akin to the laws of nature or grammatical structures. These precepts were challenged by the Romantic notion of individual genius, which cast the true artist as a rebel who necessarily rejected rules and conventions. In reality, the divide was sometimes less clear-cut than this: for example, J. M. W. Turner, the British artist who revolutionized landscape painting and was acknowledged as an important influence by many later avant-garde artists, remained a passionately loyal member of London's Royal Academy.

The assumption here is that the reader is familiar with Romanticism as a movement, has a good idea of what London's Royal Academy was, understands the implications of being a member of this society, and knows what avant-garde artists stood for. It is unlikely that non-Europeans would be as familiar as Europeans with these matters.

Care must also be taken that the stimuli for items and tasks are not too time-consuming. In a timed reading comprehension test, the amount of time needed to process passage information must be considered in the item construction process. If more time is required than is available to a test taker, the test taker may try to guess the correct answer or may omit an item, both of which are likely to affect item discrimination and validity.

Similarly, some constructed response tasks may burden the memory. If a stimulus is long, or if there is a delay between the presentation of information in the stimulus and the response (as sometimes occurs in staged tasks), individual differences in the ability to recall rather than in language ability may influence performance. Shortening the stimuli, shortening the time between presentation of the stimuli and response, allowing test takers to take notes during the presentation of stimuli, and giving test takers access to parts of the stimuli while they are responding are ways to reduce the need to recall. For example, in some writing tasks based on reading stimuli, test takers can view the reading stimuli as they write.

Difficulty and Reliability

In this part we consider the individual components of selected response items and how the construction of these components influences item difficulty and discrimination. As noted earlier, discrimination is the power to differentiate high ability test takers from low ability test takers. The higher the level of discrimination, the better. The range of the classical item analysis discrimination index is -1.0 to 1.0 . Statistics are reviewed for pretest items, and items with low discrimination may

be revised and then re-prettested before being delivered operationally. TOEFL items that discriminate below 0.30 are routinely reviewed for item flaws.

Items should test knowledge and skills that are appropriate for the test purpose and population. For a typical test, items range in difficulty from easy to hard for the intended group, and the greatest concentration of items is in the range in which 30% to 70% of the test takers get the item correct. Items significantly easier or more difficult discriminate among members of a relatively small proportion of the test population.

Different parts of a text may vary in lexical, syntactic, and conceptual difficulty. It is important that items that test different parts of such a text correspond in difficulty to the parts they are testing. Ideally, the specific part needed to answer a question should determine the difficulty of that question. Difficult items should not be written about easy parts of a text, because the inferences we draw about test takers' abilities are based on their responses to items. Low ability test takers should answer questions about the easy parts of a text correctly, but they should answer incorrectly questions about the difficult parts of a text. In the following discussion we consider each item component separately and provide examples of items we consider flawed. Some examples represent item development problems that new test developers commonly create and some are from actual TOEFL pretests. For the latter, we look at the item analysis after initial pretesting and compare it with the new item analysis after re-prettesting.

Item Stem

The stem can be written as a question or as an incomplete statement that is to be completed by selected response options, but the stem should not be undirected. For example, a stem that simply states "the author believes that . . ." is undirected because it forces the test taker to read the options in order to understand what is being asked. Test takers who understand a point being tested should be able to formulate an answer to the question without first reading the options.

Well-crafted stems are free of ambiguity and direct the test taker's attention to the part of the stimulus that contains the information needed for answering the item. The following example is from a TOEFL reading comprehension pretest.

Passage excerpt

The undisputed pre-Columbian presence on the Pacific islands of Oceania of the sweet potato, which is a New World domesticate, has sometimes been used to support Heyerdahl's "American Indians in the Pacific" theories. However, this is one plant out of a long list of Southeast Asian domesticates. As Patrick Kirch, an American anthropologist, points out, rather than being brought by rafting South Americans to Oceania, sweet potatoes might have just as easily been brought back by returning Polynesian navigators who could have reached the west coast of South America.

Question

Why does the author discuss the presence of the sweet potato on the Pacific islands?

- (1) To present evidence in favor of Heyerdahl's idea about American Indians reaching Oceania
- (2) To emphasize the familiarity of Pacific islanders with crops from many different regions of the world
- * (3) To indicate that a supposed proof of Heyerdahl's theory has an alternative explanation
- (4) To demonstrate that some of the same crops were cultivated in both South America and Oceania

This item was flagged after pretesting because, although 46% of the TOEFL test population chose Option 3, the intended answer, 14.2% of the most able test takers chose a different option. The stem was found to misdirect readers from the intended key and thus was revised to be more directed: "Why does the author mention the views of Patrick Kirch?" When the item was pretested again, 57% chose the intended option and discrimination improved significantly (from 0.44 to 0.55), only 5% of the most able test takers choosing an incorrect answer. The stems of items should also pose questions that are independent of each other.

Since every question on a test contributes to the inferences drawn about a test taker's ability, it is important that the items be independent in the sense that each test question tests a separate point. Lack of independence reduces overall test reliability. The following examples are based on a passage about nesting birds.

Passage excerpt

Further evidence for the costs of begging comes from a study of differences in the begging calls of warbler species that nest on the ground versus those that nest in the relative safety of trees. The young of ground-nesting warblers produce begging cheeps of higher frequencies than do their tree-nesting relatives. These higher-frequency sounds do not travel as far, and so may better conceal the individuals producing them, who are especially vulnerable to predators in their ground nests.

Item

This paragraph indicates that the begging calls of tree-nesting warblers

- (1) put them at greater risk than ground-nesting warblers experience
- * (2) can be heard from a greater distance than those of ground-nesting warblers
- (3) are more likely to conceal the signaler than those of ground-nesting warblers
- (4) have higher frequencies than those of ground-nesting warblers

If another item were to ask the following question, then test-wise examinees would know that it must be true that the begging calls of tree-nesting warblers can be heard from a greater distance:

Which of the following can be inferred from the fact that the begging calls of ground-nesting warblers do not travel as far as those of tree-nesting warblers?

Because the second question provides the information requested in the previous question, examinees may be able to answer the first question without understanding this point in the passage itself.

Item Key

The key, like the item stem, should be as precise and unambiguous as possible. The following is an example of an imprecise key taken from a TOEFL pretest.

Passage excerpt

More recent evidence suggests, however, that autonomic activity may not be as broad and diffuse as Cannon contended. Some studies of autonomic activity show clear differences in the autonomic patterns that accompany such emotions as anger and fear. And people across cultures report bodily sensations that differ depending on the emotion: they generally report a quickened heartbeat and tense muscles both when angry and when fearful, but they feel hot or flushed strictly when angry and cold and clammy strictly when afraid. However, even with these refinements, the fact remains that . . .

Item

The word “refinements” in the passage is closest in meaning to

- *(1) adjustments
- (2) variations
- (3) findings
- (4) applications

In the original version above, 46% of TOEFL test takers answered correctly, with a discrimination value of only 0.28, which is below the 0.30 threshold for item review for TOEFL items. The key was replaced with “small improvements”; this was designed to make it more precise, after which 45% of test takers answered correctly, with an improved discrimination of 0.41.

Distracters

The purpose of distracters, or incorrect answer choices, is to make it possible to discriminate test takers in terms of the knowledge, skills, and abilities being tested. Able test takers select the correct answer (the key) and less able test takers select distracters.

Because distracters must be wrong but plausible, it is usually more difficult to create distracters than it is to create the stem or the key. Distracters can be based on a statement or idea that is taken from the passage and then modified so as to become incorrect, or they can be plausible answers to the question that are not supported by information in the stimulus. In general, the finer the distinctions that must be made between the key and the distracters, the more difficult the item. The abilities of the test population and the purpose of discriminating among the test takers must be kept in mind in determining how fine the distinctions need to

be. There are two major considerations in designing distracters and many ways for item authors to go wrong, as illustrated in the following examples.

First, distracters must be attractive to test takers who do not sufficiently understand the stimulus material or the point being tested. Therefore they should be at least superficially related to the stimulus or topic. If the key uses vocabulary from the stimulus, so should the distracters. For questions covering only a small part of a large text, distracters are generally drawn from the same area of the text as the key, because this is the area of the text where test takers expect to find the answer. The item testing the following text includes poor distracters that do not utilize vocabulary or ideas from the stimulus.

Passage excerpt

Off and on throughout the Cretaceous period, large shallow seas covered extensive areas of the continents. Data from diverse sources, including geochemical evidence preserved in seafloor sediments, indicate that the Late Cretaceous climate was milder than today's. The days were not too hot, nor the nights too cold. The summers were not too warm, nor the winters too frigid.

Weak version

According to the paragraph above, which of the following is true of the Late Cretaceous climate?

- (1) The climate was very similar to today's.
- (2) The climate supported a large number of species.
- (3) The climate was extremely dry.
- *(4) The climate did not change dramatically from season to season.

In this weak version, Options 2 and 3 are unlikely to attract test takers who are guessing because they do not include vocabulary from the stimulus, which does not mention "species" or "dryness."

A reasonable item can be created by revising these two options:

Revised version

- (2) Summers were very warm and winters were very cold.
- (3) Shallow seas on the continents caused frequent temperature changes.

Similarly, distracters need to be written so that they cannot be eliminated on the basis of common sense or common knowledge. If a question were to ask for a reason why dinosaurs became extinct, a distracter stating that humans hunted them to extinction would be easy to eliminate because virtually everyone knows that humans and dinosaurs did not coexist.

Test takers are sensitive to positive and negative connotations in stimuli, even when they do not understand specific details, so care should be taken that distracters do not violate test-taker expectations in this regard. In the following example, the immediate context for the word tested is more negative than positive, so the distracters should be either negative or neutral.

Passage excerpt

To the extent that the coverage of the global climate from these records can provide a measure of its true variability, it should at least indicate how all the natural causes of climate change have combined. These include the chaotic fluctuations of the atmosphere, the slower but equally erratic behavior of the oceans, changes in the land surfaces, and the extent of ice and snow.

Item

The word “erratic” in the passage is closest in meaning to

- (1) dramatic
- (2) important
- * (3) unpredictable
- (4) beneficial

Option 4 (in context, “beneficial behavior of the oceans”) does not fit the comparison to the “chaotic fluctuations of the atmosphere,” making this a distracter likely to be eliminated by test takers who are guessing.

Distracters are also unattractive when they include absolute terms, such as “never” and “always.” It is easy to eliminate a distracter that is absolute, because very few things are either always or never true.

The second major principle concerning the development of distracters is that they need to be clearly false. In the following example, one distracter proved to be too close to the key, resulting in an item that discriminated poorly.

Passage excerpt

Over long periods of time, substances whose physical and chemical properties change with the ambient climate at the time can be deposited in a systematic way to provide a continuous record of changes in those properties over time, sometimes for hundreds of thousands of years. Generally, the layering occurs on an annual basis, hence the observed changes in the records can be dated. Information on temperature, rainfall, and other aspects of the climate that can be inferred from the systematic changes in properties is usually referred to as proxy data.

Item

According to this paragraph, scientists are able to reconstruct proxy temperature records by

- (1) studying regional differences in temperature variations
- * (2) studying and dating changes in the properties of substances
- (3) observing annual changes in the properties of substances as they are deposited
- (4) inferring past climate shifts from observations of current climatic changes

When the item was first pretested, 30% of the top-ability group selected Option 3. Only 25% of the TOEFL population selected Option 2, the intended key. The

item discrimination was only 0.23. When Option 3 was revised to “observing changes in present day climate conditions,” 47% of the TOEFL population selected Option 2, so the item became easier and its discrimination value increased to 0.48.

The Craft of Writing Constructed Response Tasks: Difficulty and Discrimination

In constructed response tasks, discrimination in test-taker performance levels is achieved by assigning scores along a performance continuum with well-defined score points. A primary reason for trying out constructed response tasks before administering them operationally is to detect tasks that are easier or more difficult than desired, so they may be revised or eliminated. Task difficulty is typically determined by analyzing score distributions and by computing the mean or average score. Normally scores should be distributed across the full range of score points, and score averages for supposedly comparable tasks should be similar.

For a high stakes decision scores should be highly reliable, meaning that a test taker would receive the same score on a different but comparable task of the same type, but one scored by different raters. For lower stakes uses such as providing diagnostic feedback, a lower level of reliability may be adequate. Typically, reliability in constructed response tasks is measured in terms of consistency across applications of the measurement procedure. One method for achieving consistency is to have clear, detailed specifications for prompts and stimuli. For example, in prompts based on stimuli, stimuli characteristics such as length and complexity should be defined.

The method or methods for determining reliability depends on the testing situation. If multiple raters are used to score responses independently, for example, the consistency of test-taker scores across raters (inter-rater agreement) can be used to measure reliability. Reliable scores require reliable scoring procedures.

Developing a Scoring Rubric

A scoring rubric is essential for reliable scoring. A scoring rubric delineates the criteria by which responses to constructed response tasks are discriminated.

Typically, the scoring rubric for a given task type is developed as the item specifications are being determined, and it is refined as the task types are being prototyped and piloted. The criteria for scoring must reflect the purpose for which the item has been designed and must focus on the response characteristics necessary for evaluation. As mentioned above, these characteristics are defined along a continuum.

Scoring rubrics typically are either analytic or holistic. In analytic rubrics, each desired feature of a response is identified and awarded a specific point value. In holistic rubrics, score points are defined on the basis of the overall impression of a response. In both cases, a range of possible score points is specified and verbal descriptors are created for each score point. Generally, as many score points are used as can be consistently and meaningfully delineated and evaluated.

Identifying, Training, and Monitoring Raters

Raters must have the necessary educational qualifications and experience to rate responses. They must also be able to demonstrate mastery of the scoring training materials. In TOEFL and GRE, for example, this is achieved by requiring raters to pass a certification test upon completion of training. Raters retrain briefly before each scoring session and perform satisfactorily on a calibration exercise before being permitted to score operationally.

Rater training materials include benchmarks and range finders. Benchmarks are responses that have been selected as exemplars of responses at each score point on the rubric. Range finders are responses selected to guide raters in scoring responses that may be harder to match to the rubric. They may be examples of responses that, for example, are almost, but not quite, good enough to be awarded the higher of two adjacent score points.

Benchmarks and range finders are selected as soon as it is possible to obtain an adequate sampling of responses, and raters should be able to consult these materials as needed throughout operational scoring.

To ensure that raters are making appropriate distinctions at each score point on the rubric, rater performance is monitored during operational scoring using both statistical methods (inter-rater agreement rates, rater agreement rates with monitor responses, and the distribution of scores assigned) and qualitative measures (having scoring leaders selectively read rated responses to check for accuracy during scoring sessions).

Refining Constructed Response Tasks on the Basis of Review and Tryouts

It is difficult, perhaps impossible, to judge whether constructed response tasks are clear and appropriate for a given population without subjecting them to meaningful review and tryouts, preferably both, for tasks on high stakes assessments. Like many other aspects of test development, crafting high quality constructed response tasks is a recursive process of successive refinements rather than a linear process.

Various approaches can be used for reviewing tasks. For example, test developers can perform a task themselves and then use the rubric to score their responses. However, because test developers' abilities tend to be significantly different from those of the test takers, trying out tasks on a subgroup of the test population generally provides more meaningful results. Tryouts should be administered under the conditions to be used for operational administrations, and responses should be scored by experienced raters.

Tryouts can be helpful in determining whether (a) the test takers understand what they are supposed to do; (b) the tasks are appropriate for the test population; (c) a particular subgroup of test takers seems to have a nonconstruct-related advantage over other subgroups; (d) the tasks elicit responses of the length and complexity desired; (e) responses are distributed across the full range of score points, or they cluster at selected score points; and (f) the responses can be easily and reliably scored using the existing rubric (for example, responses scored independently by more than one person are awarded the same or adjacent scores).

It should be also be noted that, for practical reasons, it is not always possible to obtain enough responses through the tryout process to reliably determine score distributions and mean scores.

Decisions concerning which items of a given type to use operationally are based on item analysis and rater input. For test forms to be comparable, tasks of a given type should have similar mean scores and similar score distributions across the rubric score points from form to form.

Analyzing rater data is helpful in selecting pretested items for operational use. In cases where multiple raters score the same response, high inter-rater agreement is a possible indicator of quality. However, inter-rater agreement must be examined in light of score-point distributions, as it is necessarily high when only a limited number of the available score points are being awarded to responses.

The TOEFL integrated writing item discussed below was crafted with care and received multiple reviews by test developers before it was tried out, yet some problems were not apparent until test-taker responses were examined.

EXAMPLE: Stegosaurus Plates

In this item test takers read a short passage explaining three theories about why stegosaurus dinosaurs had bony plates on their backs. The reading is illustrated with a drawing of a stegosaurus, so that test takers are sure to understand the type of animal being discussed, and their ability to visualize is thus minimized as a possible source of construct-irrelevant variance. After completing the reading, test takers listen to a part of a lecture in a biology class in which the professor rebuts each of the three theories presented in the reading. Test takers hear the lecture only once but are permitted to take notes while listening to it. A few seconds after the lecture concludes, test takers are presented with the prompt, which asks them to explain in writing how the lecture they just heard challenges information in the reading. They are given 20 minutes to write and told that good responses are typically between 150 and 225 words long. They can view the reading passage (and the illustration) as they write.

One of the theories presented in the reading is that the plates protected the dinosaurs against attacks by predators. In the lecture, a professor rejects this explanation by arguing that the plates were ineffective at providing protection. In a tryout version of this part of the lecture, the professor says that the plates were thin and “could have been bitten through easily.” Tryouts revealed that some test takers who write well misinterpreted the word “bitten” as “beaten.” It was hypothesized that the comprehension problem was due to the short vowel sound in the word “bitten.” Accordingly, the wording of the lecture was changed to “would be able to bite through them [the plates] easily,” in which the vowel sound is more distinctive.

Another of the theories presented in the reading is that the plates helped lower body temperature when the animal became overheated. The reading points out that the plates contained blood vessels and that blood vessels can carry heat to the body’s surface, where it then radiates into the atmosphere. In the lecture, the professor rebuts this argument by pointing out that the blood vessels were not

located where they would have been useful for this purpose, namely near the surface. The rebuttal of this point was presented in the lecture as follows, when the item was first tried out:

Second, the temperature regulation theory. A closer look at the actual pattern of the vessel channels in the plates undermines this theory. If the cooling theory were correct, the vessels would be leading the blood along the surface of the plates where the blood would cool, and then carrying the cooled blood back into the body. But the actual pattern of the vessels seems different, suggesting that their real function was to direct blood toward the living tissues in the plates, supplying them with nutrients and helping them grow. So, the blood flow pattern inside the plates was suitable for supplying nutrients to living tissues rather than for temperature regulation.

In the tryout it was discovered that some high ability test takers had difficulty understanding why the blood vessels were unsuitable for radiating excess heat from the body, possibly because the lecture was not explicit about the location of the “living tissues of the plate.” The contrast between the plate surface and the inner tissues of the plate was made explicit in the revised version. The revised version was also simpler: the information that blood vessels carry cooled blood back into the body was removed as nonessential. Here is the revised text of this part of the lecture:

Second, the temperature regulation theory. This theory is inconsistent with how the blood vessels were arranged in the plates. If the cooling theory were correct, the vessels would lead the blood along the surface of the plates where the blood would cool. But the vessels were not arranged in this way. Instead, their arrangement suggests a very different function: the blood was mostly directed toward the living tissues inside the plates, supplying them with nutrients and helping them to grow. So the main function of the blood flow in the plates was to supply nutrients to living tissues rather than temperature regulation.

In subsequent administrations there was no significant pattern of test takers with high writing ability having trouble understanding the information conveyed in the revised wording. The revised wording appears to have improved the validity, fairness, and discriminating power of the task.

Current Research and Future Directions

Proposals for research that compares test tasks and the abilities they require to real-world tasks and abilities are called for in the TOEFL Committee of Examiners 2013 Research program. A study evaluating the relationship between authentic stimuli and test stimuli was conducted for IELTS (International English Language Testing System) in 2010 (Green, Ünalı, & Weir, 2010) and one is currently underway for iBT TOEFL (the Internet-Based Test of English as a Foreign Language) (Sheehan, in press).

A promising area of research is work on text analytics tools, which automate basic linguistic analyses of stimuli or other materials. These tools may, for example, analyze word frequency, syntactic complexity, and lexical and semantic cohesion in a given stretch of text in ways that are relevant to predicting difficulty. In addition, tools are being created to model item difficulty and to support item authoring by test developers. ETS (the Educational Testing Service) is also currently researching and developing automated engines for scoring both spoken and textual responses.

Technology plays an increasing role not only in testing but also in learning. New assessments will likely re-examine language constructs in light of computer learning and investigate whether new abilities are required and new items and tasks are needed to assess them. The TOEFL program is currently updating the language frameworks that guided the iBT TOEFL in light of possible changes to these constructs over time.

Challenges

As the examples in this chapter indicate, there are many possible challenges to item and task validity, and many design and language variables that can influence item and task difficulty, discrimination, and reliability. For this reason, pretesting of items and tryouts of tasks are highly desirable.

Perhaps the greatest challenges for programs using constructed response tasks are the time and expense involved in using human raters and ensuring that item difficulty is consistent across forms. As the previous discussion makes clear, high quality human scoring requires a considerable investment of time and resources. Fortunately progress is being made in creating and improving engines for automated scoring, and some engines for measuring writing performance produce results comparable to those produced by human raters. However, less progress has been made in developing effective strategies for detecting and minimizing variations in item difficulty in constructed response tasks across forms. Although some techniques exist (e.g., establishing mean item scores, determining comparable score distribution), these methods depend on adequate sampling and high quality scoring. For practical and test security reasons (e.g., it is easier to memorize constructed response tasks than it is to memorize multiple choice items), it may not be possible to obtain large enough samples through tryouts to detect and eliminate some item flaws and variations in difficulty across forms.

Item Banking

Susan Nissan

Educational Testing Service, USA

Robert French

Educational Testing Service, USA

Introduction

Testing programs that produce multiple forms of a test each year require a large number of new items for the construction of new forms. As new items are written, they are stored in a database called an item bank. Beyond serving as a storage area for items, item banks serve two main roles: to facilitate the selection of items for new test forms; and to enable easy tracking of item inventories and metadata. (The term *metadata* refers to all information associated with items. See Appendix for a list of metadata typically contained in item banks.) The ability of an item bank to serve these purposes largely depends on the system software and the quality of the metadata. For selected response items, the metadata typically include item classifications, item keys and other scoring information, item history and use information, and possibly statistics from operational or pretest use. For constructed response items, they consist of item classifications, item history and status, and, for some items, an indication of item difficulty or topic notes for raters of constructed response items.

In this chapter we provide some general background information about item banking, including definitions of key terminology. We then discuss features to consider when designing an item bank, followed by sections that address the role of item banks for test assembly and inventories. Throughout the chapter we highlight the importance of designing an appropriate item classification system and its role in assembling test forms. We conclude with brief remarks about item banks for classroom assessments.

The approach and examples used here are drawn mainly from the authors' experience working with several item-banking systems at the Educational Testing Service (ETS), where they work on the development and assembly of test forms for a variety of testing programs, both computer-based and paper-based.

Background

Some Key Terminology

An *item bank* is a collection of items and metadata belonging to a testing program. An *item-banking system* is an item bank and the software that allows users to manipulate the items and their metadata.

An *item pool* can be defined as a subset of items or tasks in an item bank from which a test can be assembled for a specific purpose, for example a pretest or an operational form. The pretest item pool might consist of all of the items in the bank that are eligible for pretesting. Similarly, the operational item pool refers to the items in the item bank that have been pretested and are eligible for operational use in a form, if their attributes are in the range of both content and statistical specifications.

In computer adaptive tests (CATs), the term *vat* is sometimes used to refer to all of the items contained in the bank that are available for operational testing, or to “the full universe of available items” (Way, Steffen, & Anderson, 2002). A vat is partitioned into CAT pools. A CAT pool is the collection of items from which an individual test taker’s test will be created, so the items in each CAT pool need to have a similar range of statistical and content properties. A large pool with robust statistical and content coverage can help limit the exposure of items, making it less likely for test repeaters to see the same items. We will not discuss CATs any further, however; we refer interested readers to Way et al. (2002) for elaboration on the way item banking can help CAT item pools remain adequately populated.

In a selected response (SR) item—for instance a multiple choice item—the test item consists of a question, or a stem, and a number of possible answers. A constructed response (CR) item consists of a prompt that describes the task that a test taker needs to do. The response to CR items is the written or spoken text provided by the test taker. Every item in an item bank contains content and metadata. (Srestasathiern & Davidson, 2002, use the term “record” to refer to “the basic unit of an item bank,” which is the item and its associated metadata.) Metadata describe key aspects of an item, including its classification(s), status (see section “Intended Use of Items”), and measurement properties (statistics), as well as attributes such as topic, key, and word count. (Van der Linden, 2000, uses the term “attribute” rather than “metadata.” He distinguishes categorical attributes such as response format from quantitative attributes such as item difficulty. In his terms, item classifications would be a categorical attribute.)

Literature

There is a large literature on item banking. The focus of many of the articles written during the 1980s was on the practicality of using an item bank for classroom testing. Later works focused more on the need to calibrate the items in an item bank, typically using item response theory (IRT), and on the availability and practicality of commercially available item banks and item-banking software. We cannot do justice to this literature here. Instead, in subsequent sections we will

cite a few publications that pertain directly to issues we address, and we will briefly discuss criteria to consider before purchasing a commercially available item bank.

Considerations for Item Bank Design

The main concerns in designing the internal structure of an item bank are: (a) how the items in the repository will be used; (b) which other systems connect to the item bank (e.g., item development, test delivery, scoring); and (c) the security of the bank, including controlling access to items. Space limitations may not be a major concern nowadays for item-banking systems stored on servers or personal computers. However, if an item bank contains thousands of items and associated sound or graphics files are also stored in the item bank, space may be a concern, as the sound files for a five-minute audio lecture can easily require 1 MB of computer storage space, and storage requirements for video are much greater.

Intended Use of Items

Items in an item bank might be used for a number of purposes, including providing scores for test takers of either low stakes or high stakes assessments, pretesting, equating, and making diagnostic assessment, formative assessment, self-assessment, commercial or institutional test preparation products, item-writing instruction and research. Design features of the bank will depend on the intended use of its items. If the items in a bank are to be used for diagnostic or formative assessment, for example, the banking system will need to include a mechanism for storing appropriate feedback for test takers. If a testing program engages in pretesting and equating, then a decision needs to be made about whether pretest or equating items should reside in an item pool distinct from the pool of new, unused items, or in the same pool but distinguished from unused items by means of a classificatory attribute that creates a functional partition. Tracking how an item *has* been used and how it *can* be used in the future is a critical piece of metadata, which we refer to as the *item status*.

Connection With Other Systems

Item banks can be standalone tools, or they can be part of larger test management systems. In the latter case, they might be the final stage of an item creation system, accessible to an automated test assembly system. This arrangement has the advantage of making it easier for items in the item bank to be returned to the item creation system for revision after pretesting, if that is necessary.

Item banks are ideally able to get information from or send information to other systems needed to deliver and score tests. For example, they could be connected to systems that record item statistics, or to systems that raters use to record scores of responses to CR items. In this latter case, it would be helpful if the actual prompts and their topic notes (which summarize key content points that ideal

responses to CR items would include) were available to raters. They might also be connected to systems responsible for producing paper and pencil tests, or to systems that deliver computer-based or internet-based tests.

Sharing and Security

In secure item banks belonging to testing organizations, multiple users (e.g., authors, reviewers, editors) must have access to the system and the items it contains. At the same time, the system must enable administrators to restrict access to just those people authorized to use the item-banking system, or to allow access only to specific parts of it.

Item banks can also be shared among educational institutions or school districts, which makes the balance between sharing and security potentially even more complex. For example, the Galileo Educational Management System (see Bergan, Burnham, & Bergan, 2011) is one commercially available banking system that has items aligned to K-12 common core state standards available to teachers in multiple school districts.

Item Banks and Test Assembly

The main use of the items in an item bank is for operational testing, so the highest priorities for an item bank are to facilitate the creation of multiple, parallel test forms that are consistent in representing the construct, and to facilitate the tracking of items and associated metadata. And it is item metadata, especially item classifications and status, that enable individuals or software to carry out those functions in an efficient, systematic manner.

Millman and Arter (1984) identify a number of different types of metadata that might be used to facilitate item selection, including such features as the source of an item, links to previous versions of an item, and the identification of the item author. For the testing contexts with which they were concerned, which included classroom testing, such variables might indeed play a role in item selection, to accommodate changes in a curriculum or to ensure security. For the large-scale standardized tests we have worked on, a more limited set of variables has been relevant to item selection – namely construct-based features, which are typically encoded in an item record as item classifications.

The significance of classificatory metadata is also revealed by considering their role in the assessment design framework of Mislevy, Steinberg, and Almond (2002). Their framework is composed of four models: a student model, a task model, an evidence model, and an assembly model. (See Fulcher & Davidson, 2007, for an elaboration of this framework.) Items belong to the task model. Item classifications describe the content of items and are also in the task model. Classifications derive from a test construct, and thus they connect the task model to the student model, which allows claims to be formulated about test-taker abilities on the basis of evidence. It is scored tasks that provide the evidence, and it is an item's classifications that specify what sort of evidence the item provides, so classifications connect the task model to the evidence model. Finally, it is item

classifications that assembly rules refer to, so they connect the task model to the assembly model. So, in a sense, item classifications are a point of intersection for the four models.

The following sections address the significance of item metadata, and of item classifications in particular, for test assembly as a way of illustrating the significance of metadata for the functioning of item banks.

Test Construct, Test Assembly, and Item Classifications

Designing a language test requires that the designers identify the knowledge, skills, or abilities that the test will assess. The designers will, ideally, make explicit claims about the test and about the inferences concerning test-taker abilities that the test is intended to support. The test items are intended to provide evidence for those claims, that is, to capture some aspect of a construct claim. Different item types provide evidence about the different skills that underlie the test construct.

Once the test construct has been defined, the skills and abilities to be assessed have been delimited, and the item types have been designed, complete test specifications need to be written. These provide a blueprint for the test and describe its precise makeup. They specify, for example, how many sections the test can or must contain, the order of its sections, how many items each section can or must contain, and how many items of certain types each section can or must contain, and the preferred statistical properties of items. By specifying which task types a test will contain, test specifications connect the test content to the test construct.

Test assembly is the process of populating a test or test section with items that have an appropriate use history and appropriate characteristics. The assembly process may be done manually or with the assistance of special software. However it is done, the assembly of a test follows rules and guidelines, which are basically a reformulation of test specifications and thus are derived from the test construct. In other words, test assembly rules and guidelines are test-level constraints (van der Linden, 2000). They ensure that individual test forms adhere to a testing program's specifications for individual forms. Adhering to the rules ensures that each test form provides similar evidence about the appropriate skills, as called for by the test specifications and the test construct (see also the section "Metadata and the Comparability of Forms").

Note that assembly rules are followed with varying degrees of rigidity. For example, if a language test is designed to contain a section of 20 multiple choice grammar items with ten error identification items and ten error correction items, there will be a test assembly rule reflecting that requirement, which cannot be violated. The test might also have a rule that, in the grammar section, no more than three of the items be classified for the same content area, such as life science in a test of academic language or personnel issues in a test of workplace language. Variety in subject matter is usually desirable, but the requirements for what points to test take priority. A test assembler would try to honor the subject matter rule, but he or she could violate it if higher priority requirements could be satisfied only by including four items from the same content area. This type of lower priority rule might more properly be referred to as a guideline.

Illustration

As an illustration of the connection between a test construct, item classifications, and the selection of items from an item bank during test assembly, consider the listening section of a language test. This section might be intended to test the ability to understand English language conversations and lectures typical of those that would be encountered in first year courses at a university. The construct might be broken down into more specific listening skills that are required in such a context. So the ability to understand lectures might be defined so as to include the ability to understand the main points of a lecture, the ability to understand important details of the lecture, the ability to distinguish between more important and less important information, the ability to integrate information presented in a lecture, the ability to understand the function of utterances in a lecture, and so on. The designers must define the range of skills to be assessed, and do so in accordance with assumptions about content representativeness. The test specifications for the listening section will give details about how the section will provide relevant evidence. Tasks or item types will be designed so as to provide evidence about those skills and to support inferences about the broader listening abilities of the test taker.

Each item type must be labeled or classified in such a way that it is clear what type of evidence the item is intended to provide about a test taker's performance. Each skill that the test is intended to provide evidence about will be reflected in a set of item classifications. These classifications must be housed in the item bank with item content and they must be accessible to the test assembly system.

For example, the listening section of the TOEFL iBT (Test of English as a Foreign Language, Internet-based test) presents test takers with four lecture excerpts, each followed by six questions, and two conversations, each followed by five questions. So each listening stimulus is classified for its type, lecture or conversation. This classification aligns with the construct claim that TOEFL listening measures the ability to understand lectures and conversations. Items are classified in a way that also aligns with construct claims:

- The claim "the listening section measures the ability to understand the main point of a lecture" corresponds to the item classification "Gist."
- The claim "the listening section measures the ability to understand important details" corresponds to the item classification "Detail."
- The claim "the listening section measures the ability to understand information that is (not) explicitly stated" corresponds to the classification "Explicit" (or "Implicit").

If the test specifications require the listening section to provide evidence for the ability to understand the main point of a lecture, a test assembly rule will encode this requirement by requiring the selection of a number of items with the classification "Gist." A test assembler (or test assembly software) does not look initially at the content of items but at the item classifications. Classifications must be stored in an item bank so as to be easily visible to a test assembler and/or test assembly software.

Note that the classifications “gist,” “detail,” “explicit,” and “implicit” serve multiple purposes. In addition to capturing an aspect of the construct claims, these classifications also allow for information to be collected about performance on item types. This empirical information can be used to support claims about test-taker abilities. Performance on items classified as “implicit” might allow a statement such as: “High proficiency and intermediate proficiency test takers are able to understand information that is implicit in lectures.” Such statements in turn might help inform individual or classroom instructional objectives.

Items may also have classifications that do not align directly with a specific construct claim (i.e., with some ability). For example, TOEFL listening items classified as “detail” are also classified for location of point tested. This classification specifies where in a stimulus (beginning, middle, or end) the information that is being tested was presented. Yet location of information within a stimulus is not a feature of any construct claim. Rather, the classification reflects a supposition of test designers that information presented at the beginning of a stimulus might be more difficult to recall than information presented at the end. Classifying items for location of point tested allows the testing program to investigate the supposition and to act on it if this is deemed appropriate. If it turned out that “detail” items that test information at the beginning of a stimulus were typically more difficult than items testing information at the end of a stimulus, the program would have to consider the possibility that such items test memory more than other items do, and it would have to decide whether that degree of reliance on memory was a construct-relevant or a construct-irrelevant feature. Of course, things are never quite so simple. A detail that is presented at the beginning of a stimulus but is heavily reinforced or emphasized might be much more salient or memorable than a detail mentioned only briefly, without emphasis or reinforcement, at the end of a stimulus. Thus TOEFL iBT listening items classified as “detail” are also classified for the existence and type of reinforcement.

Non-classificatory item features may also play a role in assembly. An assembly guideline for this test suggests that every test form have a variety of speakers (both for reasons of fairness and to avoid confusing test takers, who may subconsciously have begun to associate a particular voice with a particular role). Yet TOEFL lectures are not classified for speaker; rather, speaker designations are indicated as part of the actual item content. Since assemblers (and automated assembly rules) typically do not examine item content in making initial item selections, this assembly guideline refers to item content that must be checked manually after the initial assembly phase. If speaker designations were coded in classificatory fields, it would be possible to write assembly rules to ensure their variety.

The decision about whether or not to code a feature in the metadata is complex. On one hand, when a feature is coded it can be accessed by a test assembly program or algorithm. On the other hand, a classification system can become overly cumbersome and make test assembly specifications difficult to meet. One approach is to link the codes of this type of variable to the codes for a different field, which varies in a similar manner. For example, suppose that in a listening test with four lectures there are four content areas, and each test form includes just one lecture from each content area. By having a distinct pool of

possible speakers for each content area and by linking speaker designations to the content codes, it is possible to ensure that each speaker will be used only once in a form.

In general, the number of items that an item bank or pool must contain in order to meet regular assembly needs depends on a number of factors—such as the number of forms needed, whether item development is for one specific form or for a pool that needs to support multiple forms, the number of assembly rules, the number of possible values there are for classifications relevant to assembly, and the possible ranges for statistical requirements.

In sum, item classifications, which are attached to every item in an item bank, are derived in part from a test construct and indicate which construct claims an item type is meant to provide evidence about. They also indicate the types of potentially construct-relevant or potentially construct-irrelevant information about items that a program wishes to track. Test assemblers select items initially on the basis of their classifications, and thus they focus on items' construct-related metadata. An item bank must store its items and their classifications in such a way that the classifications are easily accessible for the test assembly process.

Metadata and the Comparability of Forms

A crucial role of test specifications and assembly rules, and thus of item bank metadata, is ensuring that forms that are created are as comparable to one another as is possible—namely in construct coverage, content representativeness, difficulty, and fairness.

Construct Comparability As discussed above, ensuring that every form assesses the same skills in the same way is addressed by constructing each form according to the same set of test specifications as those encoded in test assembly rules. These will provide precise requirements for some features, such as the number of items in a form, but more flexible requirements for other features. Test assembly rules typically are formulated in terms of narrow ranges for item classes. In this way each test form will provide close to the same amount of evidence for each claim of the test construct.

For example, for TOEFL iBT listening, the construct definition includes three abilities: the ability to understand main points and important details, the ability to understand speaker intention, and the ability to integrate information. The first is considered more fundamental than the other two. So, half of the items in the listening section of the TOEFL iBT are used to provide evidence for the first ability. Measurement of the other two abilities is informed by evidence from one quarter of the items each. These specifications have been operationalized into ranges: there are 34 items on the test, so 16–21 of the items provide evidence for the ability to understand the main point and important details, 6–10 items provide evidence for the ability to understand the speaker's intention, and 6–10 provide evidence for the ability to integrate information.

Content Representativeness Given suitable classification systems, assembly rules can be written to make sure that close to the same proportion of topic areas appear

on every form, thus reducing the impact of content knowledge as a construct-irrelevant variable.

Such rules help avoid the creation of forms in which a content area is over-represented, thereby reducing the possibility that content familiarity might compensate for weaknesses in language proficiency. This is especially important if a test has several sections, each of which draws items from different pools (e.g., reading, speaking, grammar, etc.). If each section is assembled by a different person, with items from different pools, it would be up to the person or persons responsible for the entire test to check for content overlap across sections.

If an item bank allows item classifications for both the broad topic of an item (such as geology or economics) and a more narrowly described topic (such as plate tectonic theory or the concept of economic bubbles), a test assembler can easily avoid content overlap across items in a section. If assembly is automated, both the broad and the narrow topics will need to be visible to test assembly software. However assembly is done, the classification information associated with items helps ensure consistency across forms in content representation.

If an item bank provides a field for individual item records in which keywords can be listed, assigning carefully selected keywords to items can also satisfy this function, in addition to or in lieu of item classifications. This might offer an efficient alternative to requiring an individual to examine every item as a way of checking for content overlap within a section or across sections.

One cannot use test assembly rules to protect against trends across forms. To avoid creating several forms in a row with a passage about the origin of Earth's moon, it is necessary to track the content of forms as they are created. Including a field that allows an item to be cross-referenced to other items on the same topic can be useful, but is typically not sufficient to prevent such occurrences. See Millman and Arter (1984), appendix B, for a robust list of other types of metadata that item bank designers might consider including.

Item Difficulty Two forms that are constructed in accordance with the same test specifications may differ in difficulty. Equating procedures can accommodate some degree of difference in difficulty between forms, but can become less reliable as the difficulty difference becomes larger. Thus selected response items in an item bank typically have statistical information associated with them that can be used to create forms similar in difficulty and discrimination.

When multiple choice items are administered, either in pretests or operationally, statistics on test-taker performance are collected and calibrated on a common scale. These calibration statistics can include some classical measure of difficulty and discrimination. Item difficulty measures can be supplied either by determining the percentage of test takers who answer correctly or through item response theory analysis—be it one-parameter (Rasch analysis), two-parameter (item difficulty and discrimination), or three-parameter (item difficulty, discrimination and guessing) analysis. Whatever statistics are used, they need to be available and accessible as metadata in the item bank. In programs that allow items to be used operationally for more than one form, the statistics metadata fields must be able to accommodate and to keep separate statistics from multiple administrations.

Test specifications should provide ranges for the desired statistical properties of pretested items that will be used operationally and for items that will be used for equating purposes. Following assembly rules for statistical properties ensures that every form is of comparable difficulty, helps ensure sufficient measurement data at the targeted proficiency level, and provides appropriate information for equating.

Metadata of Constructed Response Items The situation is quite different for constructed response items. Writing and speaking items can be included in pretests or tryouts, and scoring information (such as mean score, rater reliability, and score point distributions) can be used to determine whether the items need revision and further pretesting or are ready for operational use. Yet the same type of calibration is typically not carried out on constructed response as on selected response items. Thus it is critical that constructed response items be created according to very specific item-writing guidelines, so as to make task requirements as similar as possible across forms despite differences in item content. For example, a task on a K-12 language test that requires a test taker to write an essay in response to a written text might have specific requirements about the text's length and complexity (vocabulary level, ratio of simple to complex sentences, etc). CR items may have classification fields to encode this type of information, to which assembly rules would refer. Metadata associated with CR items may also include key points that must be included in a response at the highest score band.

Metadata and Fairness A testing program may require forms to be balanced in their representation of gender, race, and culture, even though these features are not directly relevant to the construct. For example, an item testing understanding of grammar might ask test takers to identify a grammatical error in a sentence about an individual. Whether that individual is a man or a woman, or of a particular race or culture, is not likely to be part of the construct definition for that item type. If grammar items are coded for those features, one can determine whether the item bank has relatively equal numbers of items about women and men. A balanced pool is the best way to ensure that assembly rules requiring gender balance in forms can be satisfied.

Summary

The main function of an item bank is to feed a test assembly system so that the assembly of forms satisfies test specifications. An item bank can do so only if its items have classifications associated with construct claims that are visible to, and easily accessed by, assembly rules, and calibrated statistics that assembly rules can access. The actual content of items need not be visible to the test assembly system. When item content is not visible to test assembly, item classifications and statistics are the link between the item bank and the test assembly system. The usefulness of an item bank then depends on the quality of the item classification scheme, the quality of the statistics and equating procedure, and the efficiency of the test assembly system in accessing information.

If a construct is defined with only a few component skills, then only a few distinctions are needed among item types. Few classifications would then be needed, and assembly rules would be less complex. An item bank for a test of a simple construct might need only the most rudimentary information to be associated with its items.

Item Banks and Item Inventories

Another key function that item banks can serve is to enable the tracking of data that help to inform program decisions about item acquisition and development, work processes, item costs, and scheduling.

Keeping track of the number of available items in an item bank is critical. For example, for testing programs that require all operational items to have been pretested, it is essential that there are sufficient numbers of pretested items with appropriate statistical and content properties to meet operational test specifications. If a new operational form is administered once a month, then the item bank needs to be sufficiently robust in size to support 12 forms each year. Equally importantly, there needs to be a sufficient number of items in the bank with the range of properties required to assemble parallel test forms. (There are complex algorithms available that can help determine the ideal pool size. These algorithms are beyond the scope of this chapter. See Ariel, van der Linden, and Veldkamp, 2006, for an example.)

An inventory of the number of available items in a pretest pool or an equator pool is critical for programs that do pretesting and equating. It is essential to be able to identify which items are available for which purpose, and to be able to separate them from, for example, disclosed items that have been published in test preparation materials.

Item Status

A metadata field that refers to item *status* is useful for identifying if and how an item has been used in the past, and what an item is eligible to be used for in the future. Different programs will make different choices about possible values for item status, but typically item status will convey uses such as “new,” “in a pretest but without statistics,” “pretested but needs revision,” “pretested and available for operational use,” “eligible as an equator,” or “disclosed.”

To see the importance of such a field, consider pretesting and equating. A test assembler must be able to discern whether an item has already been selected for a test that has not yet been administered (“in a pretest but without statistics”). Without a *status* field, one might have to manually compare lists of item identification numbers to determine whether an item has been placed in a pretest or is available to use in a new pretest. Once selected response items have been pretested and deemed acceptable, they are calibrated with other items in the item bank, and their statistics are attached to them in the item bank. They may then be used operationally, to contribute to a test taker’s score, or perhaps as anchor items, for equating (calibration) purposes. For some testing programs, or for some tests,

anchor items contribute to a test taker's score, whereas for other tests or testing programs anchor items do not contribute to a score. A test assembler must be aware of a program's policies with regard to item use, so an item bank must contain a field in which an item's status is indicated.

Knowing how many pretested items a bank contains, or how many anchor items are in a bank, is critical—for obvious reasons. Thus a status designation for items in an item bank serves to create functional pools and to inform decisions relating to the size of those pools.

Item Classifications and Item Inventories

Item classifications are as important to the inventory function of item banks as they are to the test assembly function. Knowing how many items of a particular type or on a particular topic are available in an item bank can help inform item acquisition and development schedules and can ensure that proper proportions of items are available in the item bank so that content specifications will be met for future forms. For example, a test of grammar might have a specification that 5 (out of 20) operational items in each form need to measure verb tense. If the test is administered once a month, and each form must have non-overlapping items, then a minimum of 60 grammar items that measure tense need to be available and eligible for operational use in the bank each year. Typically, an overage of at least 25% is recommended, so the number of items in the pool that measure tense and are eligible for operational use should be at least 75. The overage percent for an entire bank might need to be higher for tests with complex or numerous specifications, as mentioned earlier.

One reason why overage is necessary is that items may be lost after pretesting, either due to poor fit with a statistical model or for content reasons. After a selected response item is pretested, its statistics are examined to determine if the item is of the appropriate difficulty level and if it discriminates well enough between proficiency levels. Any statistical oddity might trigger an additional content review. It is not uncommon for pretest statistics to reveal that some items, although thoroughly reviewed during the item development phase, have unforeseen content issues. These can range from missed double keys (hopefully rare) to possibly legitimate interpretations that were not considered during item development or to distracters that for some reason were simply too attractive or not attractive enough. Some portion of pretested items can be revised and re-pretested, whereas in other cases it is more practical just to drop the item from the pool.

A second reason why overage is needed is that it enables an item bank or pool to satisfy complex test specifications. An item bank might contain twice as many grammar items as are needed for a test form. Unless those items are evenly distributed with respect to other assembly rules or guidelines (for example, no more than three grammar items in a form can test the same grammatical structure, no more than four can be in the same content area, no more than three can have the same person as author, etc.), the item bank or pool might not contain enough items to create a form that satisfies all test specifications. Moreover, if an item meets a content specification but its statistical properties do not fall within the targeted statistical specifications for operational use, then that item should probably not

be counted in the operational item inventory. So, in order for an assemblage of items to satisfy all the test specifications for a form, an item bank must contain a broad combination of items.

Another important aspect of an item bank is tracking the forms in which each item has been used. If a testing program has a policy of using operational items only once, then it is essential to be able to identify items that have not yet been used. If there is a deliberate plan for the reuse of items (for example, a plan that allows items to be reused operationally only once, and only three years after their initial use), then the bank needs to track this information, and inventory information would need to be relevant for a specific point in time—as opposed to including “dormant” items that can only be used at some time in the future.

Counts of the numbers of items provided by individual item writers can help track item development costs and inform decisions about the need to train new item-writing consultants or about the need for increases or decreases in item acquisition. The number of new items being added to the bank needs to exceed the number of items that are administered, and this needs to be carefully monitored over time. Regular and detailed inventory information is essential to sustain a testing program. The inventory information should allow counts of items with any given content classification and with any given statistical value. If each form of a test needs to have a balanced number of items about males and females, then it is helpful if the entire item bank has a similar number of items about each gender. For each feature of an item that is reflected in the test specifications, there needs to be a sufficient number of items that have that feature, to supply forms with the number of required items.

Some inventory information may not be related to test specifications. For example, it might be helpful to track the cycle time for developing an item or a test form (say, the total number of hours it takes item writers to produce a final version of an item, or the total number of hours it takes reviewers to review an item). Knowing how long it typically takes to produce an item, from the initial authoring stage to the final stage prior to insertion into a test form, can help program managers develop an integrated schedule for the various stages of item and test development.

Item Banks for Classroom Assessments

Teachers who have been in the classroom for many years know that a variety of classroom assessments need to be given to students on a fairly regular basis. Before reusing an assessment, one would typically examine it to determine whether the items performed adequately and whether the assessment is serving current needs. An alternative approach to reusing assessments is to store the individual items of a test, with some basic information about each one, such as what the item is measuring and how it performed each time it was used. Then, when an assessment is needed for a specific unit of instruction, the teacher can select from the available items that assess that unit. If teachers who teach the same grade in a school or a district can combine their items, a larger bank can be created. These assessments can provide end-of-term summative information, or they can

be used in mid-term to obtain formative or diagnostic information. In the latter case, it is advisable to include as many metadata fields for each item and each possible incorrect response as possible, to make feedback to teachers and students more robust and more specific.

We need to mention that there are now countless commercially available item banks for English language learners. Many of them provide items in QTI (Question & Test Interoperability), a standard format for content, so the test can be administered in a variety of delivery modes—such as paper, computer, Web. When deciding whether to purchase an item bank, there are several criteria to consider. One is whether the items in the bank are classified in ways that will address your classroom needs. For example, for K-12 assessments, the items should be aligned to state standards, and this alignment should be clear for each item. Other criteria include ease of searching and selecting available items, the size of the item pool, the appropriateness of the available delivery mode(s), and the clarity and flexibility of the format of the items. Some banks have a feature whereby teachers can add their own items, which is helpful when one needs to assess more customized aspects of language learning.

Some banks allow the flexibility of tailoring an assessment to individual students. This type of bank, and the resulting test, can provide useful formative information for both students and teachers and can enable more individualized diagnostic information. Teachers of multiple classes, with English language learners at a variety of levels and with a variety of needs, may find such banks to be a helpful resource.

Appendix: Metadata Generally Contained in Item Banks

For Items

Item identification number

Item classifications

Content area

Skill tested (e.g., main idea, detail, inference)

Item format (e.g., sentence completion, graph, grid, multiple choice)

Names of item author and reviewers

Item development timeline

Copyright information

Delivery mode

Paper

Computer

Scoring information

Item key

Item point value

Topic notes (CR items)

Item use and history

Item versions

Pretesting

Operational
Anchor
Estimated item difficulty
Item statistics
Classical
IRT
DIF

For Reading Passages

Content area
Passage length (number of words)
Prose style (e.g., expository, narrative)
Abstract versus concrete
Readability level (e.g., Flesch–Kincaid)
Gender and/or race

For Oral Lectures

Content area
Lecture length (e.g., number of words, audio length)
Rate of speech
Number of speakers
Register (e.g., formal, informal)
Abstract versus concrete
Density of information
Gender and/or race

Adapting or Developing Source Material for Listening and Reading Tests

Anthony Green
University of Bedfordshire, England

Introduction

Because it is an essential aspect of using a language, assessing language learners' abilities in receptive skills—their ability to understand spoken and written language—has always been an important element in language tests. A major challenge for language assessors is that, unlike the ability to speak or to write, the ability to comprehend what is read or heard cannot be observed directly. Instead, evidence of comprehension has to be indirect. The learner draws on his or her competence in the target language to read a text or listen to a recording and is given a task of some kind to perform in order to convey how well he or she has understood. The score given to this performance is taken to represent the learner's ability to understand.

Language test batteries have for many years included components assessing test takers' ability to follow reading and listening texts or "passages," but the kinds of tasks used and the kinds of texts they are based on have changed along with shifting fashions in test design. This chapter will look at how different approaches and purposes for assessment have shaped the ways in which texts for use in tests of reading and listening skills have been chosen and adapted.

Whatever the testing technique employed, producing a test of comprehension must also involve either locating or creating appropriate source material to use as input: the obvious choice for the assessor lies between creating material specifically for use in a test and selecting material created for some other purpose and using it, with or without adaptation, as a basis for test tasks. This chapter will trace developments in advice given to assessors on how this choice should be made and in the practices employed in actual language tests over the past century.

Early Uses of Input Texts

The source materials chosen for use in language tests inevitably reflect underlying conceptions of the nature and purpose of language learning. A century ago, the 1913 Certificate of Proficiency in English, following earlier precedents in foreign language education, included a variety of input texts used as a basis for dictation (as an indication of listening abilities), reading aloud, and translation of English into other languages (as indicators of reading comprehension) (Weir & Milanovic, 2003). The oral test of foreign languages developed in the US by the New England Modern Language Association and used in college admissions (Barnwell, 1996) showed similar influences, supplementing the more widespread tests involving translation and the statement of grammatical rules with a ten-minute dictation, a written summary of an oral passage read by the examiner, and written answers to general classroom questions read by the examiner.

It is interesting to note that, although much has changed in the way we have thought about language tests since the beginning of the 20th century and such techniques have perhaps rather fallen out of favor, they have all remained in use in language tests throughout the period: reading aloud, retelling spoken texts, and dictation all appear in the Pearson Test of English (PTE) Academic launched in 2010.

During the early years of the 20th century, the dominant liberal educational paradigm in the teaching of foreign languages in Europe favored extending the supposed benefits of high culture to all sectors of society. Key objectives of language learning included accessing the classics of literature and history in the target language and, following the model set by the teaching of classical languages, puzzling out the complex grammar of literary works. In the 1913 Cambridge Certificate of Proficiency in English (CPE), test takers were asked to translate extracts from texts by recognized literary figures, including Thomas Arnold and Thomas Carlyle, and to “correct or justify” sentences such as: “Comparing Shakespeare with Æschylus, the former is by no means inferior to the latter” (Weir & Milanovic, 2003, appendix one). The reading of “set books”—literary works used as a basis for essays of critical appreciation—has continued in Cambridge tests as an option to the present day. As an example of this, in the 1984 Cambridge First Certificate in English (FCE), test takers were simply asked to “write on one of the following”: Austen’s *Sense and Sensibility*, Shaw’s *Arms and the Man* (both of which had also featured in the original 1939 test), and Greene’s *The Third Man*.

The liberal educational tradition, with its stress on literature, history, grammar, and translation, has continued to exert a strong influence on testing practices, although it was regularly and increasingly challenged by alternatives. In 1913 phonetics held central place in British linguistics, being allied with the oral method, which prioritized the spoken language in the teaching of modern foreign languages. Dictation and reading aloud were both favored teaching tools in the oral method, and their place in the 1913 CPE and in the 1915 Maryland tests reflects this.

Language teaching and linguistic theory have retained their influence, but another recurrent theme is reflected in early revisions to the CPE. Alongside the

liberal agenda of cultural enrichment, language learning has always embraced more utilitarian objectives. Learners themselves often wish to acquire a language not so much to access the cultural highlights as to facilitate travel, to access technical information, and to do business. During the 1930s the University of Cambridge came under pressure from CPE test users to address business uses of language, and a paper in “economic and commercial knowledge” was offered as an alternative to literature. This presages the later interest in target language use and performance or work sample approaches to testing in which future uses of the language become the basis for test design—in other words, the view that the reading and listening material used in tests should be taken from the real-world contexts in which learners would be expected to use the language.

Reading and Listening Comprehension

Short reading passages with accompanying questions were already firmly entrenched in tests of first language reading comprehension when Thorndike (1918) began to explore reading comprehension as a mental process. It was perhaps natural that such tasks should find their way into language tests, as indicators of how well learners could follow a written text. Barnwell (1996) described Hand-schin’s *Silent Reading Test in French and Spanish* (which appeared in 1919 and consisted of a written paragraph accompanied by 10 comprehension questions) as the first standardized modern language test. Barnwell recorded that the ambitious and highly influential Modern Foreign Language Study in the US in the 1920s viewed both reading and listening comprehension as core components of foreign language ability, but only produced tests of the former (paragraphs accompanied by “True/False” questions).

Early examples of listening tests tended to involve isolated words or questions spoken in the target language, with translation equivalents or appropriate responses presented as multiple choice options. According to Barnwell (1996), it was not until 1954 that the first test named “Listening Comprehension” appeared in the US. The College Board test of 1954 had clear work sample elements and involved a range of text types, from informal conversation to lectures and extracts from plays.

In Cambridge, although not elsewhere in the UK (see for example the language laboratory-based Association of Recognized English Language Schools [ARELS] Oral Examinations described by Hawkey, 2004), resistance to “objective type” multiple choice tests meant that listening comprehension tests did not appear until much later. The first listening comprehension papers were introduced to CPE and FCE in 1975 (Weir & Milanovic, 2003). Input for the latter took the form of extracts from written (literary) sources read out by the examiner.

In the 1950s, while the eclectic stew of linguistic theory, educational practice, and pragmatic influences continued to simmer in Cambridge, a fourth element was bubbling to the surface in the USA. Here educational testing had, since the 1920s, been more heavily influenced by psychometric theory, which attempts to extend to the social sciences the kinds of precise and consistent measurement that can be achieved in the physical sciences in the measurement of distance,

temperature, or time. For language testing, this would imply an emphasis on consistent, reliable results and componential theoretical models centered on the individual language learner. In what has become known as a discrete-point approach, Lado (1961) brought together psychometric theory, behaviorist psychology, and contrastive structural linguistics. For Lado, language tests ought to isolate and test the elements of a language—"distinct systems of pronunciation, stress, intonation, grammatical structure and vocabulary"—"that native speakers understand by the mere fact of being native speakers of the language" (p. 205).

Lado opposed established techniques such as reading aloud and dictation because of the uncertainty about exactly which aspects of language ability they were testing and on the grounds that presenting words in a context might give listeners clues as to their meaning that would allow them to guess a word without perceiving it accurately in the input. He also argued against the use of input texts taken from real-life settings on the grounds that this introduces "extraneous factors" such as technical knowledge, literary appreciation, or intelligence: "it is more economical and will result in more complete sampling to work from the language problems and then to seek situations in which particular problems can be tested" (p. 205).

Lado's approach implied the use of large numbers of very short input texts, especially constructed to target specific language points accompanied by "objective" multiple choice questions. This discrete-point approach to testing fitted quite comfortably with contemporary audiolingual approaches to language teaching. Valette's (1967) practical handbook for teachers reflects the traditional purposes of the high school language programme: "to enjoy the literature written in the target language, to appreciate the culture of the target country and especially to converse freely with its people" (p. 4). However, her recommendations on crafting scripts for use in a classroom test of listening comprehension reflect this discrete-point approach to language: "the teacher should, a couple of days in advance, prepare a first draft of the script . . . making sure that he has used all the structures and vocabulary used that week" (Valette 1967, p. 18). Although theories of language learning have moved on, the diagnostic appeal remains obvious: if the learners have failed to master one or more of the taught elements, this would be reflected in their test performance and they could be given remedial instruction.

In a highly influential paper written at around the same time as Lado's book, J. B. Carroll (1961) warned against over-reliance on discrete-point testing. He argued for the addition of "integrative" language tests with "less attention paid to specific structure points or lexicon than to the total communicative effect of an utterance" (p. 37). Such tests (the example he gave involved spoken sentences to be matched to pictures) would, he suggested, better reflect the pressures of real-time communication and focus attention on how well learners could function in the target language.

The influence of both points of view can be seen in early developments in the assessment of English for academic purposes, which is often (and for obvious reasons) a focus for academics specializing in language testing. The Test of English as a Foreign Language (TOEFL), first administered in 1964, was introduced to assess the language skills of the growing numbers of international students studying in US universities. From its launch, TOEFL, alongside more discrete tests of

“structure and written expression” and vocabulary, included tests of reading comprehension (five passages of 100–250 words from social science, fiction, and natural science texts, each with four to five questions) and listening (including recordings of 20 sentences with written response options, 15 dialogues with comprehension questions and a five-minute lecture with 15 questions) (Spolsky, 1995).

Harris (1969), one member in the TOEFL development team, dedicated two pages of his handbook to the selection of texts as reading passages. He specified four features to consider: *length*, *subject matter*, *style*, and *language*. Without distinguishing between intensive and extensive reading and the implications of different reading skills for text selection, Harris recommended the selection of passages of between 100 and 250 words, because these could support six or seven comprehension questions to accompany each text for trialing, but they would allow for a wide sampling of types of material within the time available for a typical reading test. *Subject matter* addresses the work sample element. In a test of English for foreign applicants to American universities, texts “should reflect the various kinds of reading material assigned in basic university courses” (p. 60) and should not require cultural knowledge.

Harris advised avoiding passages that focus on a single proposition, recommending instead those that “(a) deal chronologically with a series of events, (b) compare or contrast two or more people, objects, or events, or (c) present an author’s individualistic opinions on a familiar subject” (p. 61). He suggested that language could be used as a basis for grading texts; passages that included too many difficult words or were too complex should be simplified to take account of the level of the test takers.

A UK contemporary of TOEFL, the English Proficiency Testing Battery (EPTB), popularly known as the Davies test after its author, was developed for a similar purpose by the British Council. In this test, listening abilities were addressed through discrete-point tests of phonemic discrimination (deciding which, if any, of three words were the same: either heard as isolated words: *stipple—steeples—staple*, or in a brief context: *I like the old fashioned ports/ ports/ parts of England*) and intonation (recognizing attitudes in brief conversational exchanges). Alongside the testing of such language elements, the EPTB, like the TOEFL, also incorporated elements of a work sample approach. There was a listening comprehension component, which was based on a short lecture accompanied by multiple choice questions based on summarizing statements.

Echoing the concerns voiced by Lado (1961), Davies (2009) pointed to the tensions that emerged between the authenticity of the lecture content, the requirements of efficient testing, and the theoretical rationale for the lecture-listening component. Extracts from genuine lectures did not seem to provide enough detail to support the intended 15 to 20 questions on the test and gave rise to concerns about differences in learners’ levels of content knowledge. A compromise was arrived at by using a lecture given by a doctor about services available to students.

The reading texts were also chosen to reflect the kinds of material that students would encounter at university. Two texts were included: the first was a form of cloze text—a text with some words replaced by gaps—the first letter of each of the missing words being provided. The second was a lengthier passage, of around 1,200 words, with additional words inserted at random. In the former (testing

reading comprehension), test takers needed to insert the missing word; in the latter (testing reading speed), they needed to identify the intrusive words.

Published in 1975, Heaton, like Valette (1967), offered advice on testing both discrete elements such as phoneme discrimination or vocabulary knowledge and passage comprehension. In reading, Heaton distinguished between the kinds of text that can be used in testing the beginning stages of reading (matching of words and sentences) and higher levels (comprehension questions based on longer passages). He was critical of tests that were limited to brief extracts of a few sentences because these seemed to restrict the focus to intensive, word-by-word reading rather than involving skimming or scanning strategies.

In listening, Heaton was concerned with the distinctive features of spoken language, making the point that “impromptu speech is often easier to understand than carefully prepared (written) material when the latter is read aloud” (Heaton, 1975, p. 58). This is because of the more frequent occurrence of features like redundancy and restatements in the former and the greater information density of the latter. However, Heaton offered little advice on how to select reading texts beyond suggesting that these should be appropriate to the learners’ ability, that text difficulty depends on the structural and lexical complexity of the language used, and that longer passages are often associated with greater propositional complexity and hence are better suited to higher-level learners.

The increasing availability of good quality recording and playback equipment made the use of recordings for listening tests increasingly practical from the 1960s, and Heaton weighed up the advantages of employing recordings. On the one hand, a live (or videorecorded) presentation has the advantage that “it is helpful if the speaker can be seen by the listener . . . a disembodied voice is much more difficult for the foreign learner to follow,” while, on the other, recordings made by native speakers both “present perfect models of the spoken language, an important advantage in countries where native speakers are not available to administer the test” (p. 58) and make it possible to use authentic recordings of texts made for purposes other than testing. While the appropriateness of native speaker models has been increasingly questioned over the intervening years, authenticity was to emerge, as we shall see, as an increasingly important, if problematic, concern.

Influenced by the reaction during the 1970s against discrete-point approaches in applied linguistics more generally, Oller (1979) argued that language tests should be integrative, testing language elements in combination rather than attempting to separate them out. Oller favored dictation and cloze techniques as integrative task types engaging multiple elements of language at the same time, and so providing a good indication of general language proficiency. Oller was relatively unconcerned with issues of text selection, noting with regard to cloze tests that, as long as the source text is long enough to support around 50 deletions, the “procedure is probably appropriate to just about any text” and that “it has been demonstrated that for some purposes (e.g., testing ESL proficiency of university-level students) the level of difficulty of the task does not greatly affect the spread of scores that will be produced” (p. 364). He did, however, suggest that potentially disturbing or offensive material should be avoided and that esoteric or highly technical topics would not generally be suitable. His conclusion was that

“material intended for fifth grade geography students” (p. 365) might work well as a basis for cloze tests aimed at these university-level students—presumably because this kind of material seemed widely accessible, yet plausibly academic. He took a similar line on dictation, suggesting that “dictation at an appropriate rate, of kinds of material that learners are expected to cope with, is a promising way of investigating how well learners can handle a variety of school-related discourse processing tasks” (p. 269).

Harris, Heaton, and Oller all recognized some virtue in the “realism” afforded by incorporating into tests the kinds of texts that learners might expect to encounter in the real world. Such texts would supplement questions constructed to target linguistic elements. Advocates of “communicative testing” such as B. J. Carroll (1980) went much further and whole-heartedly embraced a work sample approach. Carroll dismissed discrete-point testing as a “monotonous series of linguistic manipulations only distantly related to real communicative tasks” (p. 37). He took a lead from the growing interest in teaching English for specific purposes and was influenced by the functional orientation of the Council of Europe Threshold Level (van Ek, 1975). His point was to test not the knowledge of a language, whether as discrete elements or as an integrated whole, but the ability to use that language to carry out real-world tasks.

Carroll’s approach to text selection was therefore based not on abstract linguistic analysis, but on how learners would be expected to use the target language in relevant contexts. Authenticity was prioritized: material for tests should be drawn directly from what Bachman and Palmer (2010) have subsequently termed the target language use (TLU) domain—the content classroom, the university, the workplace, the public sphere—for use in tasks that would simulate real-world behaviors. Carroll suggested that, “in a test of English for Life Sciences, a booklet may be prepared dealing with such topics as ‘Antibiotic therapy,’ ‘Inheritance,’ ‘Lipids,’ ‘Lactation curves,’ ‘Nutrition,’ ‘Correlation of Ecological studies,’ ‘Weights and Measures’ and appropriate ‘Contents,’ ‘Bibliography’ and ‘Index’” (pp. 37–8). The texts would be chosen and prepared “by an inter-disciplinary team of language and subject specialists” (p. 38) guided by the analysis of learner needs.

Where Lado (1961) used the phrase “integrated skills” to refer to listening or reading (as distinct from discrete elements such as vocabulary or intonation), B. J. Carroll used the same phrase to refer to the integration of modalities involved in carrying out tasks: listening and speaking integrated in conducting a conversation or discussion; reading, listening, and writing along with graphics or other supporting visual material in preparing a simulated academic assignment.

By the early 1980s the first communicative tests had begun to appear. Weir (1983) carried out an empirical analysis of the ways in which international students used English in pursuit of their studies and of the difficulties they encountered. The outcome of this needs analysis, the Test of English for Academic Purposes (TEAP), was a simulation of the cycle of assessment found in universities across academic disciplines. It involved responding to short answer questions based on a lengthy reading passage of around 1,000 words taken from an academic textbook or journal; responding to questions on a recording of a ten-minute lecture extract; and, finally, integrating information from both the listening and the reading sections to respond to an essay prompt. B. J. Carroll was involved in

the development of the English Language Testing System (ELTS, subsequently IELTS), which tested the use of reference material (in a component titled “Study Skills”), integrated reading and writing, and offered test takers a choice of modules linked to different disciplinary areas.

Enthusiasm for communicative testing was tempered by criticism from language-testing researchers. Echoing J. B. Carroll’s (1961) complaint that Lado’s use of contrastive linguistic analysis implied the need for a separate test for learners from each different language background, Alderson (1988) pointed out that the English for specific purposes orientation of communicative testing seemed to imply tests individually tailored to each learner to take account of their personal communication needs. Another key concern was the prioritization of content—the imperative that material be taken from the TLU domain—over theory—any account of the knowledge, skills, or abilities that language learners would require in order to process this material. Bachman (1990) showed that, without providing a coherent theory of an underlying language ability to replace Lado’s (1961) contrastive structuralist model or Oller’s (1971) pragmatic expectancy grammar, the appeal to “real-world” uses of language could not justify the assumption that test performance would predict performance on tasks beyond the test situation.

In short, the history of tests of second and foreign language reading and listening skills during the twentieth century saw a movement away from translation and toward the use of comprehension questions. In earlier tests, input texts were composed or chosen to exemplify aspects of the linguistic system. The selection of sources took on greater importance in later tests, as they came to represent the types of material that language learners might expect to encounter outside the test, when undertaking specified social roles. The authenticity of source material emerged both as a central consideration and as a matter for debate. There were differences between those who gave priority to task accomplishment—comprehension of material representing real-life language use—and those who looked for evidence of underlying abilities.

What Characteristics Count in Text Selection?

The period since 1989 has seen something of a compromise (or synthesis) between the cognitive and the contextual. In revisions made in 1989 and 1995, IELTS retreated from many of its more “communicative” features, including the testing of study skills, the integration of reading and writing, and the provision of alternative test modules for students in different disciplines (although test takers may still choose between “academic” and more vocationally oriented “general training” versions of the reading and writing papers). Moving in the opposite direction, the revision of TOEFL that led to the Internet-based test saw the incorporation of TLU analyses (Rosenfeld, Leung, & Oltman, 2001), introduced more extensive passages based on TLU sources for reading (700 words) and listening (3–5 minutes), and brought in integrated reading-into-writing or listening-into-writing tasks. The PTE Academic, a more recent entrant to this area of testing, also includes components-integrating skills such as reading and writing or speaking (summarizing written texts) or listening and speaking (retelling a lecture extract).

Handbooks published after 1985—such as Weir (1993), Alderson, Clapham, and Wall (1995), Davidson and Lynch (2002), and Hughes (2003)—although broadly preferring the use of authentic texts and recordings drawn from the TLU, advised flexibility according to test purpose—discrete points have greater diagnostic and therefore educative potential—and pointed to the importance of test specifications in guiding text selection. Hughes (2003) advised teachers preparing tests to “keep specifications constantly in mind” (p. 142) and offered guidance on length, variety, and topic. His conclusion was that “successful choice of texts depends ultimately on experience, judgement and a certain amount of common sense” (p. 142). Alderson, Clapham, and Wall (1995) offered similarly practical guidance: “for many tests, the item writer’s next task is to find appropriate texts. In this case, ‘appropriate’ means not only texts that match the specifications, but also texts that look as if they will yield suitable items” (p. 43). Such texts can be difficult to find, and readers were advised to build up collections of promising material against future needs. Weir stressed the need to consider learner level and purpose:

for lower-level general English students we need to look at the range of language forms candidates can be expected to handle. Does the text contain too many unknown lexical items? For higher-level ESP students we need to examine whether the lexical range is appropriate in terms of common core, technical and sub-technical vocabulary. (Weir, 1993, p. 67)

Grading text difficulty is, of course, a traditional educational concern dating back to Thorndike and beyond, but the debate over authenticity, together with developments in areas of applied linguistics such as discourse and genre analysis, raised new issues. Readability formulas like the Flesch Reading Ease index for English had already been used for many years to grade material for school children. These relied on word and sentence lengths to provide an indication of the difficulty of the vocabulary (longer words tend to be less common) and grammar (longer sentences tend to be more complex) of a text, and so they might be helpful in meeting Weir’s (1993) suggestions on grading. However, they provided no real guidance on what types of text learners at different levels of ability might be able to process and what kinds of information they might be able to obtain.

Views of difficulty can be more fully explored by looking at how test developers have specified their tests at different levels of proficiency, for example in the Cambridge suite of tests, the Common European Framework of Reference (Council of Europe, 2001), and in other frameworks used in national assessments of foreign language ability. One such characterization is contained in the ACTFL (American Council on the Teaching of Foreign Languages) Guidelines for Reading (Child, 1987: see Table 50.1). The ACTFL Guidelines divided reading proficiency into three areas—content, function, and accuracy—organized into two parallel hierarchies of difficulty level: one made up of text types and the other of reading skills. The evidential basis for these hierarchies has been questioned and not all text types readily fit the categories presented, but attempts to characterize textual features more fully have continued.

As noted above, Bachman (1990) and Bachman and Palmer (2010) argued that it is not sufficient simply to take material from the TLU domain and use it in a

Table 50.1 Child's (1987) typology of text modes

Level 1 orientation mode	Texts in this mode serve to orient the reader to situations and events. Examples include street signs, arrivals and departure notices, greetings. These are often abbreviated, assume conventional knowledge on the part of the recipient, and may be heavily reliant on context. Problems in comprehension for learners are more likely to result from a lack of vocabulary and relevant knowledge than from syntax.
Level 2 instructive mode	Texts in this mode involve extended discourse and straightforwardly convey facts and information (but not opinions) about situations and events. Examples of Level 2 texts given by Child include factual newspaper reports; assembly instructions; straightforward historical narratives; directions to and descriptions of geographical areas; technical descriptions of a chemical compound.
Level 3 evaluative mode	Texts in this mode do not simply report facts but select and marshal them for specific social purposes: to develop points of view, explain conduct, defend policy, etc. Examples include analytic and affective texts such as newspaper editorials disapproving or advocating some course of action; evaluative biographies; personal correspondence attempting to repair a breach. Child makes the point that such texts, reflecting their social character, are often governed by more or less explicit formal conventions or received practices, which make them more accessible to those who are familiar with the conventions.
Level 4 projective mode	This mode is "the natural realm of artistic creativity," as it involves individual responses, eschewing shared assumptions or conventional thinking, generating new approaches to a problem, or challenging received ideas. Reflecting the novelty of the writer's approach, texts may make use of abstract metaphors and symbolism and may be formally innovative. Child suggests as examples literary texts, philosophical discourse, and "think pieces" that advocate rethinking social, economic or political policy or that put forward a novel approach to a technical question.

test, as communicative testers had advocated, first because tests cannot provide sufficient space for all of the material that might be encountered in the real world and, second, because listening to a lecture in a lecture theater will inevitably be a different kind of experience from listening to the same lecture as part of a test. Instead, test developers will need to determine how the test taker's language knowledge is involved in reading or listening in the TLU domain and attempt in their tests to engage that knowledge in similar ways (Bachman & Palmer, 2010).

To help language testers to achieve this, Bachman and Palmer (2010) introduced frameworks for describing the key characteristics of TLU tasks that should be simulated or replicated in the form of test tasks. Similarly, Alderson et al. (2006) provided a framework for describing key features of reading and listening input texts (Table 50.2) that can be used in locating them in relation to the Common European Framework of Reference (Council of Europe 2001, 2009).

Table 50.2 Frameworks for describing text characteristics

Bachman and Palmer (2010, pp. 66–7)	Alderson et al. (2006), Council of Europe (2009)
A. Format	Listening/Reading comprehension in . . . (language) . . .
1. Channel (aural, visual, both)	1. Target level in the curriculum:
2. Form (language, non-language, both)	2. Item types
3. Language of input (native, target, both)	3. Source <i>Interviews, news broadcasts, public announcements, etc.</i>
4. Length/ time	4. Length <i>words for reading, duration for listening</i>
5. Vehicle (live, reproduced, both)	5. Authenticity <i>Genuine, adapted/simplified, pedagogic</i>
6. Degree of speededness	6. Discourse type
7. Type (item, prompt, input for interpretation)	7. Domain <i>Mainly argumentative, mainly descriptive, mainly expository, mainly instructive, mainly narrative, mainly phatic</i>
B. Language of input	7. Domain <i>Personal, public, occupational, educational</i>
1. Language characteristics	8. Topic <i>Personal identification; travel; shopping; house and home, environment etc.</i>
a) Organizational characteristics (rhetorical or conversational)	9. Curriculum linkage
1) Grammatical	9. Curriculum linkage <i>An optional category</i>
a. Vocabulary	10. Number of speakers
b. Syntax	11. Pronunciation
c. Phonology/ graphology	11. Pronunciation <i>Text speed: artificially slow, slow, normal, fast; Accent: standard accent, slight regional accent, strong regional accent, non-native accent; Clarity of articulation: artificially/ clearly/ normally/ sometimes unclearly articulated</i>
2) Textual	12. Content <i>Only concrete content, mostly concrete content, fairly abstract content, mainly abstract content.</i>
a. Cohesion	13. Grammar <i>Only simple structures. mostly simple structures. limited range of complex structures. wide range of complex structures</i>
b. Organization (rhetorical, conversational)	14. Vocabulary <i>Only frequent/ mostly frequent/ rather extended/ extended vocabulary</i>
b) Pragmatic characteristics	15. Number of listenings
3) Functional (ideational, manipulative, heuristic, imaginative)	16. Input text comprehensible at CEFR level <i>A1/ A2/ B1/ B2/ C1/ C2</i>
4) Sociolinguistic (genre, dialect/ variety, register, naturalness, cultural references, figures of speech)	17. Items comprehensible at CEFR level <i>A1/ A2/ B1/ B2/ C1/ C2</i>
2. Topical characteristics	

Recent work by Bejar, Douglas, Jamieson, Nissan, & Turner (2000) and by Weir (2005)—among others—went a step further in suggesting frameworks that bring together the contexts within which language tasks are undertaken and the different cognitive processes that are involved in carrying them out. Working from this sociocognitive perspective, Khalifa and Weir (2009) considered how cognitive processes are reflected in the texts employed as input for the Cambridge ESOL tests of reading. Studies using questionnaires, verbal protocols, and eye-tracking tools have been used to explore how purpose and context shape the reading and listening process in tests and in TLU domains and how closely these processes resemble each other in the different contexts (see for example Green, Ünalı, & Weir, 2010).

Current Issues and Future Trends

The degree of realism that can be achieved in the texts and recordings used in tests remains an intractable issue today. Buck (2001) called attention to the dilemma facing test writers. There is a balance to be struck between clear and detailed specification and textual authenticity. Found texts are unlikely to have the features that a test developer would like to see; but adapting texts in ways that are sympathetic both to the original writer's and the test developer's purposes is a very demanding task, even for the most experienced item writers. Where specifications set out in advance what reading or listening skills are to be tested but also call for the use of authentic input texts, practical compromises will need to be reached. The issue affects both reading and listening tests, but its impact is more obvious in listening, as any changes beyond minor edits will probably require a re-recording and so will substantially alter the nature of the material.

Increased awareness of the differences between spoken and written language means that readings of written source texts such as excerpts from novels are no longer very widely used in listening tests. On the other hand, many of the recordings that are used are based on scripts or outlines intended to approximate spoken language but prepared specifically for the test. These scripts may be modeled closely on source recordings of authentic speech (and so they claim a degree of authenticity), or they may be simply invented. Tests sometimes include recordings of scripted, semisc scripted, or rehearsed speech (which may or may not be edited) made for purposes other than testing: news broadcasts, lectures, interviews, dramas, or public announcements. In other cases, unrehearsed, unedited recordings may be used. While these are certainly more authentic, they are more likely to involve uncontrolled variations in content, rate of speech, articulation, and accent. As shown in Table 50.2, features of listening tests such as the number of participants in conversations and the number of opportunities to listen further add to the potential for differences across forms of a test.

Authentic texts rarely feature all of the characteristics that a test developer may wish to target in a format that will easily fit into testing templates, but substantially adapting texts may reduce their similarity to those found in the TLU domain, threatening the validity of the test. The growing availability of video resources, although it makes video-based tests increasingly practical, further limits the options for realistic adaptation.

The challenges involved in using authentic recordings is well illustrated by the account given by Brindley, Hood, McNaught, and Wigglesworth (1996) of the problems faced by developers of a test designed for migrants to Australia. Sometimes the recordings proved to be too long, but

at other times they contained either too much or too little information, or would have required extensive contextualization. Even some texts which were capable of generating a considerable number of items had to be edited when it was found, for example, that the items followed one another too closely and thus placed an overly demanding processing burden on candidates or that a text contained specific cultural references which would be difficult for some candidates to interpret. (Brindley et al., 1997, pp. 40–1)

Ultimately the recordings employed in the test were either entirely scripted or adapted from broadcast material and re-recorded using actors.

Buck (2001) dedicated a whole chapter (chap. 6) to the selection of recordings for tests of listening, noting the additional difficulties that this process involves by comparison with selecting and adapting reading texts. There can be no doubt that using scripted speech (including speech from broadcast sources) allows test developers to exert control over the recordings and to achieve greater consistency in test content—an important consideration when multiple forms must be produced. Scripted and controlled forms of speech may also be more suitable for beginners in language learning. On the other hand, Buck renewed the warning that scripted dialogue tends to be unrepresentative of spontaneous speech and that greater authenticity can be achieved when recordings are not crafted by the test developers. Buck suggested a range of strategies for obtaining more realistic spoken samples, while exercising some control over content. These strategies included semiscripted scenarios and directed interviews.

Khalifa and Weir (2009, p. 110) provided a list of the kinds of adaptation currently considered appropriate in Cambridge tests of reading:

- cutting to make the text an appropriate length;
- removing unsuitable content, to make the text inoffensive;
- cutting or amending the text, to avoid candidates being able to get the correct answer simply by word matching, rather than by understanding the text;
- glossing or removing cultural references if appropriate, especially where cultural assumptions might impede understanding;
- deleting confusing or redundant references to other parts of the source text;
- glossing, amending, or removing parts of the text that require experience or detailed understanding of a specific topic.

Recent research by Salisbury (2005) for listening and by Green and Hawkey (2012) for reading has provided direct insights into how item writers approach text selection. Salisbury found that expert writers were more aware of the test specifications, were quickly able to recognize texts with potential as test material, and could add contextualizing elements to a script to make it accessible to listeners. Writers often started from ideas for questions and then modified the script to make

it fit with them. For example, they might change words in the text to avoid giving direct clues to the correct answer, or they might add text to the script to introduce distraction and make answers less guessable. Green and Hawkey similarly found that questions of authenticity played relatively little part in item writers' editing processes. Writers focused instead on the relationship between the text and the tasks, including matters such as coherence and avoiding the repetition of key information. Both studies have illustrated the role that effective group moderation can play both in reviewing text selection and in editing processes.

A promising avenue for future developments is the use of automated text analysis tools for text selection. Recent approaches to measuring readability using automated text analysis have incorporated a wider range of textual features. The lexile approach is an example of this (see <http://www.lexile.com>), and lexile measures have been linked to test scores on tests such as TOEFL. However, lexiles are based on L1 readers of English and so may not be the optimal metric for L2 readers. It is also problematic that the proprietary nature of the tool makes it difficult for users to see exactly how lexile values are arrived at. Green (2011) used computational measures of features listed by Alderson et al. (2006) and by Khalifa and Weir (2009) to differentiate between texts used in educational materials targeting learners at different levels of proficiency and found that vocabulary range played a greater role in distinguishing between lower levels (up to level B2 of the Common European Framework of Reference), while syntax measures emerged as more salient at the higher levels. Sheehan, Kostin, and Futagi (2007) reported on a computer system that can be used to retrieve texts with characteristics that might make them suitable as reading input texts for a specific test: the Graduate Record Examinations (GRE). They reported that identifying texts in this way leads to dramatic improvement in the number of texts that item writers are able to locate to use on the test in a given time. In addition to aiding text selection, such tools can also help test developers evaluate how closely their texts reflect key texts from the TLU domain and the impact of editorial changes. Green and Hawkey (2012) were able to trace how changes made by item writers impact on the nature of the texts presented to test takers.

The Internet has provided the item writer with a hitherto unimaginable wealth of potential input material in all modes from which to choose. However, for the present, there is no doubt that finding suitable sources for use in tests of comprehension remains a subtle and challenging activity. Increasing use of integrated multimedia resources can only add to the complexity of the challenge, and it seems likely that we will see an expansion of research, building on Wagner (2008) and others, into the impact on comprehension of different combinations of textual, graphic, and auditory input.

This chapter has mainly been concerned with tests originating in the "Anglo-Saxon" countries and with the testing of English. However, recent years have seen increasing professionalism in the production of language tests globally, and it seems likely that future innovations in testing techniques may come from elsewhere. One issue for testers of English and other international languages that might perhaps be more easily tackled outside the historic center is the shift away from the perception of English as the expression of Anglo-Saxon cultural heritage towards its perception as *lingua franca* (Elder & Davies, 2006) or as an international

basic skill (Graddol, 2006), used more in interactions between second language speakers than between second and first language speakers. In the future, which non-native accents should be included on a test of listening? Which locally current expressions should be allowed on a test of reading? To what extent might it be desirable and acceptable to incorporate plurilingual competences (Lenz & Berthele, 2010) into comprehension tests? Validity concerns may argue for the inclusion of relevant non-native accents, but in tests with an international candidature the imperative to avoid bias argues for the use of standard native varieties, which are likely to be similarly familiar to a wider range of test-taker groups. The experience of test developers has also shown that learners themselves often favor “Inner Circle” varieties over locally more prevalent varieties (Elder & Davies, 2006).

Writing Scoring Criteria and Score Reports

Megan Montee

Center for Applied Linguistics, USA

Margaret E. Malone

Center for Applied Linguistics, USA

Introduction

A central purpose of any test is to convey information to stakeholders about examinees' performances. However, many tests do not lend themselves to straightforward interpretations of test results. Information about scoring criteria and the score reports that accompany test results must be communicated to both technical and nontechnical audiences in meaningful ways, which often means "translating" jargon and specific testing terms into comprehensible language. Test scorers and test users have different needs; test users, including students, teachers, administrators, and parents, are often unfamiliar with language testing. How, then, do test developers write scoring criteria and score reports that convey the information to test users in ways that are understandable and yet faithful to testing terms?

North (2000), in developing the Common European Framework of Reference, summarizes the process of developing scoring scales as "trying to describe complex phenomena in a small number of words using incomplete theory" (p. 13). North's conundrum is echoed throughout this chapter on developing scoring criteria and designing the format and content of score reports. For test developers, it is crucial to develop valid and reliable scoring criteria that scorers can apply to student performance to yield consistent results. However, test developers must also work to develop score reports that communicate test results to a variety of stakeholders transparently and clearly. Scoring criteria allow test scorers, also called raters, to score tests reliably and consistently with a test's purpose and uses. Score reports provide a bridge from the test results to the real-world decisions made on the basis of test results. As North has stated, developing the scoring scales alone is challenging, and developing accompanying score reports for a nontechnical audience presents an additional responsibility for test developers. This chapter provides an overview of research related to these two challenges, presents

considerations for developing scoring scales and reports, and discusses areas where future work is needed.

Both scoring and reporting practices are essential to test validity, which refers to the argument made for using a test in a particular context to make specific decisions (Messick, 1989). An argument for the use of a test means that the test developers show multiple types of evidence about the test to its users, including information about how the test is scored and what decisions are made based on these scores. Shaw and Weir (2007) describe scoring validity as “the extent to which test scores are based on appropriate criteria, exhibit consensual agreement in marking, are free as possible from measurement error, stable over time, consistent in terms of content sampling and engender confidence as reliable decision-making indicators” (p. 143). While many aspects of scoring, including how scorers are trained and the scoring conditions, contribute to a test’s validity argument, criteria and reporting practices are an essential starting point.

As Chapelle, Enright, and Jamieson (2008) point out, recent approaches to test validity have focused on integrated and holistic arguments. An integrated approach to test validity asserts that each aspect of the development, scoring, and implementation process is part of a single framework that creates a cohesive argument for the use of a test in a given context. In constructing a test’s validity argument, evidence must be provided to support the assumptions and inferences on which the test is based. In performance assessment, scoring criteria and rubrics link inferences made between the examinee’s performance and the score. Similarly, the score report must explain the score and the decisions that stakeholders make on the basis of test results. The scoring validity of a test has implications beyond the test developer and test scorer; the validity argument must also extend to the impact on test takers and other stakeholders and how results are explained.

Definitions: What Is Scoring and Score Reporting?

A test score is “the outcome of an interaction that involves not merely the test taker and the test, but the test taker, the prompt or task, the written text itself, the rater(s) and the rating scale” (Weigle, 2002, p. 108). In performance assessment, scoring refers to both how individual tasks or items are scored and the composite score comprised of scores across multiple test items. This means that a specific test may have multiple scores: item- or task-specific scores as well as one score for the test that encompasses all individual task scores.

This chapter focuses on developing scoring criteria and reports for performance tasks. Responses to these tasks may include written or spoken responses, or performances that integrate multiple skills such as reading a passage or listening to a short talk and then producing an oral or written response. For this chapter, the term “performance assessment” is used to describe tasks in which test takers are required to use the target language, either in writing or speaking, to respond to a specific task.

Because it is so complicated to develop scoring criteria for performance tasks, many scoring scales are developed for the scorers’ use rather than that of any

other stakeholder, with the scale geared toward ensuring ease of scoring rather than for use outside of the scoring context. Alderson (1991) has identified three main uses for scoring scales:

- User-oriented scales: used to report information about typical or likely behaviors of a test taker at a given level.
- Assessor-oriented scales: designed to guide the rating process, focusing on the quality of the performance expected.
- Constructor-oriented scales: produced to help the test constructor select tasks for inclusion in the test. (p. 89)

Each user group has different purposes and uses for the rating scale. Test users, including students and instructors, typically look for information about the real-world implications of the test score, such as what the student can do in the target language. Assessors or scorers need information that will help them reliably and efficiently score examinee performances, and test constructors or developers need a scale that provides information on eliciting examinee performances that exhibit the features specified in the scale. All stakeholders need this information to be presented and delivered via wording and media that are accessible and comprehensible to them.

Once a scoring scale is applied to actual examinee performances, test results are communicated through the process of score reporting, which involves providing information about test scores to test takers and other stakeholders. Score reporting includes the documentation of examinee test scores as well as how the scores are communicated, whether in writing or via computer. In addition to test takers, the audience for test scores may include parents, teachers, administrators and school officials, program funders, community members, and local or national government agencies. The groups that use the scores will need to consider the purpose of the test and the decisions that need to be made based on test results. Test developers have the responsibility of communicating information about the test to these groups in ways that are comprehensible and relevant to test users. While a great deal of research and discussion has focused on how to score performance assessments, score reporting has received less attention. Recently, however, the field of language testing has begun to focus on the real-world impact of tests (McNamara & Roever, 2006). Because they are a central part of communicating test results to stakeholders, score reports are the crucial link between test scores and how they are used in the real world. Score reports represent the test results to users, and users in turn make decisions based on how they understand these results. A better understanding of the needs of different stakeholder groups, and empirical research about how these groups interpret score reports and test information, are necessary in order to improve testing systems and for establishing a test's validity argument. Data about how users understand and apply test results can provide evidence that the results are being interpreted and used in appropriate ways. Regardless of the extent to which the validity argument is supported through research and resonates with testing experts, it is essential to communicate the results to stakeholders in ways that they understand and that represent the test construct.

Developing Scoring Criteria

Developing scoring criteria is a complex and iterative process, and developers must consider the framework for the test as a whole, meaning how individual tasks contribute to the whole test score, as well as how individual tasks are scored. The term “task” can be defined in a number of ways and is often related to specific, task-based approaches to teaching and testing (e.g., Ellis, 2003). However, in this chapter a general definition of task is used, taken from Bachman and Palmer (1996): “an activity that involves individuals using language for the purpose of achieving a particular goal or objective in a particular situation” (p. 44). Examples of written performance test tasks include writing an argumentative essay, writing a letter, or composing an e-mail. Luoma (2004, p. 32) defines speaking tasks as “activities that involve speakers in using language for the purpose of achieving a particular goal or objective in a particular speaking situation.” Examples of speaking tasks include giving oral directions based on a map, or participating in an interactive, spoken, role-play scenario. Thus, performance tasks result in evidence of an examinee’s language ability within a specific context. The evidence collected by performance tasks must be scored according to established criteria. These criteria, as well as how they are interpreted and applied by test scorers, mediate the examinee’s performance and the score.

In developing tasks, it is necessary to develop scoring criteria that align with the language elicited by the tasks. This facilitates scoring. As Luoma (2004) points out, “scores express *how well* the examinee can speak the language being tested”; this is equally true of writing. However, developing scoring criteria for performance tasks can be difficult, because, on the one hand, it is important to score a specific task and the extent to which an examinee has succeeded in responding to it. On the other hand, developing task-specific criteria can be unwieldy and time-consuming. Scorers may have difficulty reorienting themselves to new criteria for each individual task. Such reorientation takes up valuable scorer training and operational scoring time and can result in a longer time before scores can be reported.

Scoring scales are often difficult to develop because they need to summarize incomplete information about language learning in a way that scorers can internalize and apply quickly and accurately (Luoma, 2004). Shaw and Weir (2007) note that scoring levels are defined through established criteria as well as through training and particularly through exemplars of performances at different levels. These exemplars make scoring criteria concrete and meaningful to scorers, and help them to internalize the scoring criteria for efficient and consistent application to performances. The exemplars also establish the range of performances that can meet criteria at a particular level.

At the task level, scoring criteria describe how well an examinee’s performance meets the expectations of the task. Scoring criteria usually include information about whether or not the examinee completed the task and information about both the quality and quantity of language the examinee produced. Generally, scoring criteria are ordered in a scale that describes performances at various levels; often the highest level indicates a perfect performance and the lowest a

“zero” performance (Bachman, 1990). The scale may assign numeric values to different performances or it may use descriptors. In performance assessments, scoring scales are often referred to as rubrics, or short definitions of performances at each of the levels. These descriptions of different levels within a rubric or scoring scale are the scoring criteria against which examinee performances are compared.

Finally, scale development must reflect the purpose of the scale, and development may include the creation of several versions of the same scale. As discussed previously, scales may be developed or modified for use by test users, assessors (raters), or test constructors. The same set of scale descriptors or level of information may not be appropriate for each type of scale. For example, a constructor-oriented scale used to develop test tasks would most likely include technical language and specialized vocabulary that could be difficult for test users to interpret. As a result, a revised scale may be developed for test users so that scale descriptors are represented in clear, nontechnical language. When a scoring scale has different versions for different user groups, test developers need to think about how to align the results across scales so that information conveyed to each group is consistent. In other words, the language used to describe the scale might change, but developers should be careful that the changes are parallel to the test construct. In addition, any modifications made to one scale should be followed by a review, and the related scales may be revised. For example, raters may note that the language of a scale is too abstract or difficult to apply when scoring test responses. If feedback from test scorers results in modifications to an assessor-oriented scale, this may affect the test development process and lead to changes in the types of tasks that are developed. If appropriate, changes on the assessor-oriented scale would then be reflected in the constructor-oriented scale. Even when one scale is used for multiple purposes, scale development must consider how the scale functions across all user groups, including test developers and examinees.

Types of Scoring Scales

There are three types of scoring scales commonly used in performance assessment: holistic scales, analytic scales, and primary trait scales; each is described in this chapter. Holistic scales assign a single score to an overall performance. For example, a response to a speaking task might be scored according to a proficiency scale that describes the overall level of a response. In contrast, in analytic scales separate scores are assigned for various features of a performance (Weigle, 2002). For example, separate scores might be assigned for fluency, grammatical accuracy, and vocabulary use. Primary trait scales, the third type, are used to assign a single score based on one trait of the performance, such as fluency or vocabulary use. With primary trait scales, a separate scale must be developed for each test task, and when used, the assessment results are not generalizable to other tasks (Shaw & Weir, 2007). The trait for each task is chosen based on what aspect of the task is considered most important. Because of these limitations, “the primary trait approach is regarded as time-consuming and expensive to implement” (Shaw & Weir, 2007, p. 149).

Given the limitations of primary trait scoring, holistic and analytic scales are the main options for scoring performance tasks. The choice of scale type will depend on how test results will be used, as well as practical considerations. Holistic scales are typically easy to use and performances can be scored rapidly (Shaw & Weir, 2007). The use of holistic scales may be preferable when resources for scoring or for training scorers are limited. In addition, holistic scoring can provide results that are easy to interpret and that give a global picture of examinee ability. However, holistic scores can limit diagnostic feedback, and test results provide less specific information to examinees than analytic scores. Because analytic scales require scorers to attend to and score multiple features of a performance, they are more time-consuming to use but also have the potential to provide more useful information to examinees and other stakeholders. Analytic scales may be most appropriate when test results will be used to make decisions about classroom instruction or other issues when detailed feedback would be useful.

Approaches to Development

There are several methods for developing scoring criteria. This chapter presents four main approaches, including the use of a priori criteria, and three criteria described by Turner and Upshur (2002): theoretically based criteria, empirically derived criteria, and criteria based on a particular teaching context. Each approach has advantages and limitations, and may be used depending on the goals of a particular testing context. Additionally, these approaches may be combined in the process of developing scoring criteria. Such hybrid approaches are discussed briefly at the end of this section.

Scoring criteria may be developed or adapted from existing sets of descriptors. This type of scoring scale is often used in proficiency testing, which refers to tests that measure general communicative language ability. The goal of proficiency testing is to make a generalization about an examinee's ability to communicate in the target language based on performance on tasks that represent the target language use domain. Obviously, the target language use domain may differ greatly from one setting to another. For foreign language assessment in the United States, the *ACTFL Proficiency Guidelines—Speaking* (American Council on the Teaching of Foreign Languages [ACTFL], 1999), which describe five functional levels of language proficiency, form the basis for the scoring criteria of several standardized oral proficiency tests. These proficiency tests include the ACTFL Oral Proficiency Interview (OPI), the Standards-Based Measure of Proficiency (STAMP), and the Simulated Oral Proficiency Interview (SOPI), among others. When a general language scale is used, the scoring criteria represent an absolute scale in which performances are judged in relation to some external standard. On a scale derived from that of the Interagency Language Roundtable (ILR), the *ACTFL Guidelines* represent language ranging from no functional proficiency (Novice-Low) to a speaker who can function in professional settings (Distinguished). The original ILR scale was developed from a survey of language needs of professionals in the US foreign service and was neither developed according to any theory of language nor based on specific tasks to be performed in the target language.

There are several advantages to using such an a priori scale. Performances on a specific test are related to an external standard, which gives meaning to the performance outside the immediate context of the test. In addition, an externally developed language scale can facilitate interpretation and use of the test scores, particularly if the scale is widely used and understood by stakeholders. This is often the case with the *ACTFL Proficiency Guidelines—Speaking*, which are frequently used in US foreign language educational contexts to describe students' progress along a proficiency scale independent of any specific curriculum or textbook. However, although the *ACTFL Guidelines* are frequently used, they are not always well understood or consistently interpreted by users. Nonetheless, with training and familiarization, using such a scale can have positive washback on instruction and create opportunities for stakeholders to use the scale in classroom contexts.

There are several concerns with using an a priori language scale as a basis for scoring criteria. Such scales are often functional, meaning that they describe what interlocutors can do, rather than developmental, which describe the kind of language expected in a logical progression of acquisition. One reason for the focus on function rather than development is that research about the process of second language acquisition is often complex and not easily condensed into a developmental scale that can be used in teaching and testing contexts. Additionally, a truly developmental scale may be too general to be sufficient for constituting scoring criteria, and may not reflect the context of and performances elicited by test tasks.

In reflecting on one functional scale, the *ACTFL Proficiency Guidelines*, the advantages and disadvantages of a priori scales are clear. One advantage to this approach, of course, is that the scale may have currency outside of the local environment, and scores may be understandable from one context to another, for example from one university to another. However, there are a number of criticisms of the *ACTFL Guidelines* as a scoring scale. While claiming to be a functional scale, representing different levels of target language use, some critics claim that in practice the *Guidelines* represent a developmental hierarchy, even though there is no empirical basis for this use (Lantolf & Frawley, 1985; Bachman & Savignon, 1986). Therefore, although the *ACTFL Guidelines* are widely used in the United States and resonate with educators, as an a priori scale, they do not represent a theoretical construct for language learning.

Theoretically based scales are derived from theories of language acquisition and are intended to reflect language-learning progression. In the late 1980s, Pienemann, Johnston, and Brindley (1988) reported on the challenge of constructing such a theoretically based scale for assessing second language attainment. The specific criteria developed were based on a number of theoretical frameworks, current at the time, as well as research on German word order development. Pienemann et al. (1988) transformed a scale used for learners of German into a scale for learners of English as a second language (ESL). In applying the results of this scale development to actual scoring, the researchers found that training was crucial to inter-rater reliability and that such scoring criteria may differ from language to language. Bachman and Palmer (1982) conducted research on a theoretically based scale derived from research from Hymes (1972), and Canale and Swain (1980), among others. Bachman and Palmer (1982) also developed a

theoretically driven scoring scale to be applied to second language learning, administered oral proficiency tests and rated them, and conducted factor analyses to determine the factors most relevant to language proficiency. While the scale was theoretically based, the test could not always reflect all of the real-world tasks that speakers need to produce in real-life settings. Therefore, while theoretically based scales, in sharp contrast to a priori scales, reflect current knowledge of language acquisition, they may be difficult to convey to stakeholders and may not reflect all the real-world tasks an examinee needs to perform (Hudson, 2005). Bachman (2002) has noted that it is not sufficient for scales to be based on theory; assessments must also include relevant tasks.

A third approach to developing scoring criteria is to use empirically derived criteria. This approach attempts to address some of the criticisms of a priori scales as well as theoretically based scales (Turner & Upshur, 2002). In empirically derived approaches, scoring criteria are developed or selected by test developers by working with sample performances from the test. For example, test developers may group the samples into a predetermined number of levels, and then determine descriptors that distinguish the different levels. Alternatively, test developers might ask raters which criteria are most important in their decision-making processes and then use these to construct the scale. In this development process, the resulting descriptors are thus contextualized to the specific test. However, because they are derived from test performances rather than external criteria, the descriptors may not be generally applicable outside of the specific testing context. In other words, empirically derived scales represent a test-specific rather than a general theory of language use, and these descriptors may not be relevant to other testing contexts.

Critics have argued that empirically developed scoring scales are not theoretically grounded scales (Shohamy, Donitza-Schmidt, & Ferman, 1996; Brindley, 1998). For example, Brindley (1998) points out that practitioners may not have theoretical knowledge about language acquisition. If scale descriptors are derived from practitioner judgments, then the resulting descriptors will not be theoretically grounded and will not reflect what research says about how language is acquired. This means that empirical scales contrast with theoretically derived scales, because they emerge from how examinees respond to the test rather than from a framework for explaining language use and acquisition. In addition, empirically derived scales are not generalizable in the same way that theoretically based scales are, because they reflect only a specific linguistic universe—that of the test—and not a general theory of language acquisition. However, Turner and Upshur (2002) point out that “the lack of generality of these rating scales is not in dispute, but more general, theory-based rating scales have not been shown to be equally valid for the various task types that empirically derived scales are designed for. For performance testing, therefore, such scales are advocated, in part because of their content relevance” (p. 53). Therefore, empirically derived scales may be more relevant and easier to apply than theoretically based scoring criteria.

When developing empirically based scoring criteria, variables such as the samples used to develop the criteria and the developers themselves may affect the resultant criteria. Upshur and Turner (1999) found that the development team had a minor effect on the criteria while the essays used to develop criteria had a

major effect. In a follow-up to this study, qualitative results showed that the essays directly shaped the comments participants made and the criteria that they chose (Turner, 2000). A later study (Turner & Upshur, 2002) comparing teams of scale developers and performance samples confirmed the differences these variables can cause in resulting scale descriptors. The results particularly emphasized the important impact the selection of performance samples can have on resulting scale descriptors. Overall, the results of this line of research indicate that variables in how scales are developed can lead to important differences in the scales themselves, and that these variables should be systematically accounted for during the planning and development process.

A fourth and final model for developing scoring criteria is to use learning goals or outcomes as the basis for the criteria. This approach is best suited for achievement testing, and is not widely used in large-scale standardized testing. However, in cases where a test is used for program-specific decisions, this approach can be beneficial. Because the scoring criteria are tied to the goals of a program, the scores will provide useful information to instructors about how well students are learning material both within one classroom and across the language program, where students are expected to progress at similar rates. While such scales provide important information to instructors about student progress in a specific class or program, and similarly, to students about their progress in the same course, it is difficult or impossible to generalize results outside of the specific program. In addition, such scales may not be particularly reliable, as instructors are generally scoring their own students' responses and may be biased in their application of the scale. Such scales may conflate Alderson's (1991) three main uses for scoring scales and may therefore be too general in their purposes.

In addition to the four approaches to developing scoring criteria, any of the approaches may be combined to create a hybrid model. For example, a development team may use an a priori scale as a starting point for empirical scale development and then integrate aspects of both scales into the descriptors. Hybrid approaches combining both a priori and empirical approaches may address some of the limitations these methods demonstrate independently. By adapting theoretically grounded criteria to a specific context and testing situation, test developers can ensure that the criteria are meaningful and relevant to the context while still using criteria that are generalizable outside of that context.

On the other hand, a hybrid approach may allow for the inclusion of specific terminology from a classroom-based scale within the context of an a priori or empirically based scale and serve only to confuse users. When using a hybrid approach, it is essential that everyone using the scale understand and apply the descriptors consistently rather than transferring previous knowledge of one scale to the hybrid scale.

Developing Score Reports

It is not sufficient to develop scales and train scorers to use them consistently. While such applications are necessary for valid and reliable testing, it is also important to find ways to describe results to an audience less technical than

scorers and test developers. As stated earlier, scoring criteria are the essential link between a test score and the decisions made based on this score. In many cases, these decisions are made by stakeholders outside of the test developers, and the scores must be reported to these groups in ways that are both accurate and understandable. In many cases, test takers and other stakeholders may not be familiar with language testing or with principles of performance assessment. When developing score reports, test developers must consider how well stakeholders understand the test scores and more general principles of language and language assessment using the test scores. In cases where the test users are not language-testing experts, score-reporting documents and practices are particularly important in ensuring the valid use of test scores.

The International Language Testing Association (ILTA), a professional association of language testers, describes best practices for score reporting in its *Guidelines for Practice* (2007):

- The institution should provide all potential test takers with adequate information about the purposes of the test, the construct (or constructs) the test is attempting to measure and the extent to which that has been achieved. Information should also be provided as to how the scores/grades will be allocated and how the results will be reported.
- Reports of the test results should be presented in such a way that they can be easily understood by test takers and other stakeholders.

According to these guidelines, test takers have a right to know about the scoring processes of a test. Even before score reporting, the organization administering the test may want to distribute information about the test and how it will be scored. This information can help prepare stakeholders to understand test results later. Some testing organizations do not provide detailed rubrics to test takers, either for proprietary reasons or because the language of the rubrics may not be comprehensible to a nontechnical audience. Although it may not always be appropriate or possible to make scoring scales accessible to test users, they should be provided with adequate information about scoring processes.

The ILTA *Guidelines* also state that results should be understandable to stakeholders. In many cases, this may mean that separate scoring criteria and scoring scales are developed for test development and rating and for use by test takers. The detailed and technical information often included in rating materials may not be useful to test takers. Additionally, test takers may benefit from sample performances to help them understand scoring criteria.

The translation of test results and test information is another important consideration. For example, when young second language learners are tested in school contexts, parents may need translations of test results into the parents' first language. While translating score reports can present practical challenges and may be difficult when resources are limited, it is especially important when test results are high stakes and are tied to decisions about schooling and language support services. At the same time, such efforts are culturally difficult. For many cultures, the educational system of a new country alone may be bewildering. While translating score reports is a first step in communicating information to

such parents, the information contained may be devoid of meaning to newcomers who do not have a background in the testing practices or educational processes of that context.

At the core of issues related to score reporting is knowledge about the perceptions and needs of various stakeholder groups. While score reports are typically developed based on what language testers think stakeholders understand and need to know, there has been limited empirical research about stakeholder groups and their needs. The technical information and vocabulary that professional testers often use may not be accessible to groups of test users. In developing score reports, test developers may hold focus groups or interviews with test takers and other stakeholder groups to help determine how to best communicate scores and test information. Communicating with and seeking to understand the needs of stakeholder groups should be a part of the test development process. In addition, as scales are revised, score reports must also be revised to reflect any changes.

Conclusions

This chapter has described issues related to developing scoring criteria for performance assessment and then communicating test scores to stakeholders in meaningful ways. The development both of scoring criteria and of score reports presents several challenges to test validity, or the argument developed for the use of a test in a particular context and for certain decisions. Scoring criteria are where the test's construct is explicitly realized. Choices about the type of scale to use and the method for developing it can be difficult, and should be based on the needs and goals of the test. For example, using a priori criteria may be desirable if the test results need to be easily understandable to a wide group of stakeholders, or if the test results need to be easily transferrable across institutional contexts. However, empirically developed criteria may be desirable in cases where the performance task elicits language that is not easily captured by existing scales and theoretical frameworks. For example, a performance task that integrates reading and writing may be more accurately and easily rated using a scale developed specifically for this task.

Once the process for developing criteria has been established, these criteria must be implemented by scorers, and scorer training must be aligned with both the criteria and the ways that scorers apply the criteria. While a thorough discussion of scorer behavior and perceptions is outside the scope of this chapter, research related to this topic is of direct interest to scale developers and users. How do scorers interpret and apply scales to student performances? The criteria may be understood and applied in ways that were not intended by the test developers. Understanding how scorers use scales is also a crucial aspect of test validity.

Finally, there are several major challenges that test developers face related to score reporting. The main challenge is in understanding the needs of different stakeholder groups and how to best communicate results to these groups. A strong program of test validation should certainly include evidence about how stakeholders understand and use test results to make decisions. Such information may

lead to stronger scoring and reporting practices, and to making test results more useful for classroom teaching. In addition to such information contributing to the validity argument and adhering to the ILTA *Guidelines for Practice*, the process of including stakeholders in making decisions about the design and delivery of score reports demonstrates a respect for the stakeholders and a recognition that including stakeholders and promoting transparency in score reporting are essential not only to the development of score reports but to the test development process as a whole. While the process of including stakeholders as we have described may extend the time needed for test development, it may increase the trust that stakeholders place in test results, and may support testing as a collaboration between test developers and stakeholders to promote effective language testing for appropriate test use.

Response Formats

David D. Qian

Hong Kong Polytechnic University, Hong Kong

Mingwei Pan

Hong Kong Polytechnic University, Hong Kong

Introduction

A language test is normally composed of a number of tasks that are inherently linked with various characteristics (Bachman, 1990; Bachman & Palmer, 1996), among which *response format* is an indispensable ingredient, generally understood as “the way in which the candidate will be required to respond to the materials” (McNamara, 2000, p. 26). In the profession of test development, response format is often referred to as *item type*, indicative of the linguistic or nonlinguistic behavior a particular task aims to elicit based on the instructions (Bachman & Palmer, 2010). Response formats may include such extensively adopted methods as cloze test, gap-filling, multiple choice question, and sequencing (e.g., Alderson, 2000; Read, 2000; Buck, 2001; Purpura, 2004). How a response is expected to be constructed is usually stipulated in the test specifications, and determines the ultimate development of the test. Therefore, response format is deemed to be one of the variables that not only will help reflect the test construct to a certain extent but also may produce undesirable intervening effects on the test taker’s performance and impact the rating process (Bachman & Palmer, 1996; Alderson, 2000; Brantmeier, 2005).

This chapter will first elaborate on a plethora of taxonomies of response formats in language assessment, with exemplification from well-established tests. Other response formats based on discrete skills will be discussed later with a view to clarifying the reasons why particular formats are usually favored in measuring language skills in a certain content domain. The chapter will then align the existing response formats with current views and existing studies in the field of language assessment to provide a review of the status quo of response formats. An overview of challenges related to the use of various response formats in different

types of language tests will be offered toward the end of the chapter, with a view to identifying important issues for future research.

Taxonomies

The taxonomies of response formats naturally derive from the notion of task characteristics in language assessment. Bachman (1990) and Bachman and Palmer (1996) proposed an overall framework of task characteristics in which features of various aspects of test tasks are described, such as setting, test rubric, input, expected response, and relationship between input and response. In the category of expected response, the framework particularly elaborates on the classification of response formats from the perspectives of *type*, *channel*, *form*, *language*, *length*, and *degree of speededness*, all of which can be viewed as restrictions on what is produced by test takers in assessment settings. An in-depth analysis of these classifications points to the fact that *type* may be an overarching, though narrowly defined, division (Popham, 1978; McNamara, 2000). Therefore, the present discussion commences with an elaboration on *type*, followed by other classes of response formats.

Type

As mentioned, response formats can be categorized in a widely accepted fashion in terms of *type*. Popham (1978) broke them down into *selected* or *fixed response*, characterized by a number of given alternatives to choose from, and *constructed response*, which is an answer based on the testee's own response to the task input. The former, with the testee's own initiatives barred, is best represented by the format of multiple choice (MC) questions, in which there is usually a stem and three or more options to select from. Example 1 (ETS, 1998, p. 45) is a typical case in point. The item type features an unfinished stem followed by four alternatives.

Example 1

Geysers have often been compared to volcanoes ____ they both emit hot liquids from below the Earth's surface.

- (A) due to (B) because (C) in spite of (D) regardless of

As a variation, MC options can also be intrinsically embedded in the stem. As can be seen from another grammar item in Example 2 (ETS, 1998, p. 48), instead of having stems and options separately, there is no alternative detached from the stem per se. Test takers are to select only one of the underlined parts which is grammatically unacceptable.

Example 2

Guppies are sometimes call rainbow fish because of the males' bright colors.

- A B C D

In addition to the MC format which has traditionally been dominant in language tests, there are also other varieties of selected response formats, such as True/False and matching and sequencing. True/False statements, also known as Yes/No statements, are usually dichotomous, but sometimes there is also a third option of *Not Given* or *Not Available*. Example 3 is provided to illustrate matching tasks, where testees are asked to select from the box the most appropriate sub-heading to summarize the gist of the given paragraph. Although differing superficially from the mainstream MC format, the options provided in this MC variant are also always predetermined and usually numbered. Thus, test takers are left with no other choice but to select from the supplied options.

Example 3

- i. Wine Lovers Explore
- ii. Hiking in New Zealand
- iii. Four-wheel-drive South Island Extravaganza
- iv. The Traditional Culture of Rotorua

Tour A. Learn more about Maori culture, food, dance, performing arts and the internationally famous Haka. The tour involves lectures on Maori traditions and etiquette; particularly customs for welcoming to and visiting a marae—the meeting house of Maori tribes. Experience an authentic cultural show in one of the country’s best-known Maori performance venues. (IELTS, *n.d.*)

One somewhat limited response format is proofreading, also known as *error recognition*, in which testees are supposed to locate, identify, and sometimes correct errors. Example 4 presents a shortened version of such a format. In order to obtain a mark, testees are expected to follow two steps: (1) locating the erroneous element (*as*) in Line 1 based on the judgment of the error type (confusion between *as* and *like*), and (2) writing *like* in the blank provided. In this case, it can be perceived that the steps involving locating and identifying the error are predetermined and trialed by test developers, yet the final step leading to the correction of the error involves a constructed response. Therefore, proofreading tasks can be regarded as a mixture of selected and constructed responses, the latter of which will be discussed below.

Example 4

- _____ 1. The hunter-gatherer tribes that today live as our prehistoric
 2. human ancestors consume primarily a vegetable diet
 supplemented
 3. with animal foods.
 (from the 1998 paper of the Test for English Majors (Band 8) administered in China)

When it comes to constructed response, alternatively termed open-ended response (Davies et al., 1999), further divisions are needed to reflect the degree to which test takers’ freedom is restricted in constructing their responses. In

Table 52.1 Categorization of task types (Purpura, 2004, p. 127)

<i>Selected response tasks</i>	<i>Limited production tasks</i>	<i>Extended production tasks</i>
Multiple choice	Gap-filling	Summaries, essays
True/False	Cloze	Dialogues, interviews
Matching	Short answer	Role play, simulations
Discrimination	Dictation	Stories, reports
Lexical list	Information transfer	Some information gap
Grammaticality judgment	Some information gap	Problem solving
Noticing	Dialogue/discourse completion	Decision making

that context, Bachman (1990) and Bachman and Palmer (1996) proposed two categories, namely, limited and extended production responses. A limited production response is usually brief (Douglas, 2010). It can be as short as one word or phrase, or sometimes a short sentence is sufficient. Therefore, the prototypical examples of response formats falling into this category are gap-filling and short answer questions. In some cases, there is also a word limit to the response, such as *Answer the questions in no more than three words*. On the other hand, an extended production response normally involves a much lengthier response, with less restriction imposed on the test taker. Such a response format is often used in writing and speaking assessments in which the test taker is expected to produce an entire essay or monologue based on a given prompt.

Purpura (2004), also referring to Bachman's (1990) and Bachman and Palmer's (1996) framework of task characteristics, provides a synopsis of various expected responses with the most common task types attached (see Table 52.1). While it should not be deemed to be an exhaustive list of all the existing response formats, the table does present a list of widely adopted task types that can be classified under *type*. These tasks will be further evaluated when we consider the suitability of specific response formats with particular types of skill-based testing.

Given the above classification, the pros and cons of selected and constructed responses are naturally closely related to the tension between test reliability and validity. As constructed response can be thought of as more authentic, it can normally improve test validity convincingly. However, compared with the running cost for a test with mainly selected response items, a test containing predominantly constructed responses is usually expensive: The rating is demanding and complex and the constructed answers can be lengthy if a restriction on length is not firmly imposed. Comparatively speaking, since the options in selected response formats are predetermined, they facilitate the control of test reliability, and of scoring reliability in particular. Nonetheless, selected responses are not without limitations, as the issue again arises as to whether the response thus elicited can really be regarded as authentic content. Considering the fact that a majority of selected responses are based on MCs, there is always room for test-wiseness (Bachman, 1990), thus causing concern about response validity, as testees may "not approach the testing situation in the expected manner" (Henning, 1987, p. 92). Hughes (2003, pp. 75–8) has also listed a host of potential weaknesses in MC questions.

Channel

In addition to the most pervasive classification of response formats in the task characteristic framework (Bachman, 1990; Bachman & Palmer, 1996), there are also other methods to distinguish response formats, among which *channel* is one. A channel refers to the mode in which a response is provided, such as aural and visual channels.

Let us take paper-based language tests as an example. Almost all the responses in such tests are produced through the visual channel because the answers are produced on the paper and rated visually. When access to certain language tests is also provided to visually handicapped testees, Braille-based test papers are often utilized so that the tactile channel is available for these testees to make responses. In oral test settings, testees might have face-to-face interviews with examiners or interlocutors, when both aural and visual channels will be open for the response. However, if the test is administered in a semi-direct fashion, which means testees' responses will be assessed later by raters referring to the recorded materials, testees probably do not need to face an examiner on the spot. In this context, the visual channel is blocked when a response is being produced. There has been research (e.g., Stansfield & Kenyon, 1992; O'Loughlin, 2001; Qian, 2009) on the effects of utilizing different channels on test candidates' performances.

Form

The *form* of response can be either language or nonlanguage, or both. Undoubtedly, the most prevalent practice is to measure testees' language proficiency by assessing their language production. The response to be provided in the form of the target language, therefore, is typically conventional and manageable in language assessment. However, responses can also be achieved in a nonlinguistic form, such as drawing lines or coloring a picture based on the input material. This approach is more conspicuous in assessing young learners, whose levels of test performance can be attained by responding to nonlinguistic tasks, so as to minimize or even bypass their de facto constraints on language or verbal expression (McKay, 2006). In such contexts, the provision of relaxed assessment settings is also conducive and desirable (Hughes, 2003). Listening tests normally provide the best examples of such tasks. In the listening test of Cambridge Young Learners English (e.g., Cambridge ESOL, *n.d.*), for instance, young test candidates are often asked to link target objects with their corresponding locations by drawing a line between the object and the location in the picture. A more complicated task may involve not only drawing lines but also coloring the specified objects, as well as adding additional images to the given picture under instruction. Requirement for nonlinguistic production in a test may help arouse young learners' interest in the task, since tasks of such a nature would better accommodate young test takers' creativity and allow them to inject their passion into the assessment process.

In a similar vein, nonlinguistic response can also take the form of a physical response based on what is heard, and can thus be applied to assessing languages for specific purposes (Douglas, 2000). For example, in assessing testees' compre-

hension of military commands, such as “attention” and “at ease,” the most direct and effective way might be just asking testees to perform the actual actions expected by following these commands, instead of asking the candidate to describe the action in words. Performance-based assessment, used for both professional and educational purposes nowadays, often adopts this type of response format.

Language

The medium in which the response is conveyed can also be one of the bases for categorizing response formats. It is worth mentioning that the notion of *language* used to distinguish different response formats neither equates to the notion of *form* as outlined above, nor necessarily means the language in which the instructions or directions in the test are written. Instead, it is more concerned with which language is used in constructing the response to the question: the testee’s native language or the target language, or a combination of both.

Where feasible, most language proficiency tests instruct testees in the target language and also require them to produce responses to the test items in that language so that the testees’ proficiency in the target language can be measured. But sometimes a test, for example a translation test, may require the responses to be produced in the testees’ native language. In such cases, what is measured also includes translation skills, as testees will be expected to translate the target language version of a sentence or a longer discourse into their native language, so that not only the testees’ literal understanding of the original version but also their code-switching ability can be examined. Such tests may also assess testees’ intercultural awareness, if needed.

Length

The categorization of *length* can be viewed as an extension of classifying constructed responses. This is because when testees are supposed to produce an answer, the length can vary from task to task. In some cases, the length is limited to one word only, whereas the essay-writing task allows test takers to produce much longer responses. Brown (2005) made a further division of limited production, whose subcategories to some extent overlap with constructed responses in Bachman and Palmer’s (1996) framework. Brown treats fixed production as a twofold notion: “fill-in items” requiring one or several missing words, and “short-response items” expecting longer production. However, there is still the issue of identifying these two subtypes, as the concept of length may involve a subjective judgment and so can vary substantially. For example, using the length approach, which is based on comprehensible output (Swain, 1985), in formative assessment or writing coaching courses, a response can be of any length provided testees are able to complete the task within the time specified.

Degree of Speededness

Response formats can also be categorized in terms of how fast responses are expected to be produced. Degree of speededness, therefore, can be generally

understood as the duration allocated for a particular task or a certain section in language tests. However, a number of language tests break that limit into several specific time limits on individual sections, thus imposing a stricter time restriction on response construction. A typical case is speed reading, as shown in Example 5. From the perspective of response *type*, this task still takes the form of an MC question, yet the high degree of speededness (30 seconds) appears demanding.

Example 5

Finish the following speed reading task within 30 SECONDS.

The main purpose of the passage is to _____.

- A. explain how to contact the police B. discourage people to take wallets
C. describe how to catch thieves D. warn people of pickpockets

Pickpockets operate in crowded places in the hope of getting easy pickings. Don't make it easy for them. Keep wallets, purses and other valuables out of sight. If wearing a jacket, an inside pocket is the best place to use. If not, your possessions are safest in a pocket with a button-down flap. Please co-operate with the police by reporting any crime or suspicious activity immediately, either by dialing 999 or calling at your nearest police station.

(from the 2002 paper of the Test for English Majors (Band 4) administered in China)

Response Formats for Skill and Knowledge Testing

Following the review of various types of response format, this section considers the suitability of various formats for different purposes, in particular in discrete skill and integrated skills testing. For discrete skill testing, two dimensions regarding the nature of test tasks are considered, namely, language knowledge (grammar and vocabulary) and language skills (the receptive tasks of listening and reading, and the productive tasks of speaking and writing). For integrated skills testing, consideration is given to how receptive and productive tasks are orchestrated for the optimal formulation of desired response formats.

Response Formats and Language Knowledge

The language knowledge dealt with in this section consists of grammar and vocabulary, as both are considered to underpin all the four conventional language skills, namely, reading, writing, speaking, and listening. Almost all the above-mentioned response formats can probably be applied in grammar assessment tasks; thus, there might be no preferred format to speak of. However, in reality, MC still remains the prevailing response format in grammar assessment, even though it has been widely criticized because of its construct under-representativeness (Weir, 1990; Hughes, 2003) and decontextualization (Alderson, Clapham, & Wall, 1995). In defining grammatical ability, Purpura (2004, p. 91) divides this ability

into two dimensions: grammatical knowledge and pragmatic knowledge. The former is further broken down into grammatical form and grammatical meaning, and the latter is understood as pragmatic meaning, or the meaning of a grammatical form as realized in a specific context. Various types of selected response task, limited production task and extended production task may be useful for assessing different dimensions of grammatical ability (see Purpura, 2004, pp. 129–45 for detailed illustrations).

Unlike grammar assessment, which can be accommodated by almost all the response formats mentioned above, the choices available for vocabulary assessment seem to be relatively limited. Read (2000) summarizes the nature of existing vocabulary assessments in three categories: discrete versus embedded, selective versus comprehensive, and context dependent versus context independent (i.e., whether vocabulary is tested in context or without context). However, it seems that no matter how assessment dimensions may vary, as far as the existing vocabulary tests are concerned, the preferred response formats have been MC, Yes/No, matching, and gap-filling. What is worth mentioning is that the first three types are usually used to assess receptive vocabulary. As MC in vocabulary assessment can be relatively easily conjured up, the following examples are cited to illustrate other formats. Example 6 is an item type for measuring depth of vocabulary knowledge (Qian & Schedle, 2004, p. 50; see also: Read, 1998; Qian, 1999, 2002), and the format of Example 7 is used in the Yes/No vocabulary test (Meara, 1992). With the former format, test takers are supposed to select the predetermined associated words from the two boxes, with the left for semantic association and the right for collocation. To discourage wild guessing, while the number of correct words in a single box can vary from one to three, the sum of correct answers in the two boxes always totals four. In the Yes/No vocabulary test, testees need to indicate whether they know the words displayed. However, since the words are presented without any context, the test can only assess vocabulary size, or breadth of vocabulary knowledge.

Example 6

Minute

(A) tiny (B) timely	(E) adjustment (F) preconception
(C) incorrect (D) hard	(G) imperfection (H) particle

Example 7

Adair gumm cliff stream system

Example 8

I've had my eyes tested and the optician says my *vi*_____ is good.

(from <http://www.lex tutor.ca/tests/>)

Gap-filling is more favored in assessing productive vocabulary. As is illustrated in Example 8, which is a controlled gap-filling item, testees are supposed to fill the gaps given a few initial letters (*vi*) as hints. An advantage of this item type is that there is usually only one plausible answer and therefore the rating process is straightforward.

Response Formats and Language Skills

Conventionally, language skills include listening, reading, speaking, and writing, with the former two heavily dependent on the processing of supplied information prior to the production of response, and the latter two more concerned with the response production based on given prompts. What needs pointing out is that when an individual language skill is assessed, there might not be a particular test format accommodating all situations (Alderson, 2000; In'nami & Koizumi, 2009). Various response formats can only be deemed relatively suitable for assessing individual language skills.

Concerning listening skills, Buck (2001) argues that the response formats for listening assessment can range all the way from selected responses to constructed ones. Conspicuously, with their advantage of less consumption of rating time and higher scoring reliability, discrete-point formats such as MC, matching, and gap-filling are popular in large-scale, high stakes tests, such as the Test of English as a Foreign Language (TOEFL) and the International English Language Testing System (IELTS). However, there is also a list of possible constructed response formats for listening assessment; dictation, thought of as a sound measure of general listening skill yet with quite a time-consuming scoring process, can still be found in some language tests, such as the College English Test and the Test for English Majors in China. In addition, some other response formats are typical in listening assessment: information transfer, recall protocol, summary, and outline completion, all of which are possible formats for measuring testees' listening skills in gist distillation, detail comprehension, and text construction, particularly in the context of assessing English for academic purposes (e.g., listening to a lecture).

Alderson (2000) believes reading skills can be tested with either discrete-point formats or integrative techniques. In discrete-point testing, almost all response formats suitable for listening assessment can also be applied to reading assessment, such as MC, gap-filling, ordering, matching, True/False, and short answers, to name a few (see Alderson, 2000, pp. 207–56 for an illustration of various formats). For integrative testing, reading skills can be partially assessed in the cloze test format, where other language skills and knowledge cofunction with reading skills for task accomplishment.

The response formats used in speaking and writing assessment are fewer than their counterparts used in listening and reading assessment. This is because both skills are intended for prolonged production, and therefore extended responses are required in most cases. If the illustrative tests of writing reviewed by Weigle (2002, pp. 140–71) are all considered, the difference in their response formats really lies in the discrepancies in expected genres (such as argumentation and exposition), length and timing. Similarly, there are also a limited number of response formats for speaking assessment. The differences in response formats for assessing speaking usually consist in the environment where speaking tasks are fulfilled. For example, speaking assessment can take the form of interview, individual presentation, paired conversation, or group interaction (Luoma, 2004). However, whatever the form is, the response format does not change significantly, as the expected response is still a constructed one. The difference can only be identified

when the following factors are considered: (1) the nature of the utterance in the speaking assessment and (2) how the utterance is conveyed to the raters. For the former, Bygate's (1987) fine distinctions between types of speaking tasks, with two broad categories of fact-oriented talk and evaluative talk, can help differentiate the responses. The latter, as mentioned, touches upon the channel of responses. The aural and visual channels can differ (O'Loughlin, 2001), because testees tend to talk in a less oral-like manner when facing a recorder or computer, and their gestures and facial expression cannot be conveyed to the raters unless the speaking performance is videotaped.

Response Formats and Integrated Skills Testing

Integrated skills tasks are becoming increasingly popular with language testers, as authenticity is now regarded as an important feature of valid language tests. What should be noted is the difference between the integrative task and the integrated skills task. The former refers to a task designed to assess multidimensional subskills within a particular skill; the task is most typically a cloze, which usually involves knowledge of vocabulary and grammar as well as reading comprehension skills. The latter usually refers to the use of a combination of language skills in the assessment task. For example, the integrated writing task of the Internet-based TOEFL requires the testee first of all to read a passage within a given period of time, then to listen to a passage that likely casts doubt on the points outlined in the first passage, and finally to produce an extended response by synthesizing the listening and reading materials. Although the ultimate outcome of such writing task is still a lengthy written production, the basis on which the response is produced differs fundamentally from an independent writing task, which generally elicits the testee's output based on a writing prompt (such as a statement). What is more, the way the response is produced also ensures that academic English is inherent in the task itself (Swales & Feak, 2004; Cumming et al., 2006).

Current Studies on Response Formats

In the previous two sections of this chapter, a variety of response formats were introduced under different taxonomies. Item types usually adopted in discrete skill and integrated skills assessment were also highlighted. With such a diversity of response formats, it is natural to think that adopting different item types for a particular assessment may result in different test-taker performances, results generally known as format effects. In this section, therefore, recent studies pertaining to the effect of response formats, especially when certain formats were treated as a variable in the research, will be discussed.

Generally speaking, studies on format effects predominantly dwell on the comparisons between selected and constructed responses and among the effects of various responses on testees' performances. More specifically, there are two dimensions of comparison: whether different response formats measure different constructs and whether different response formats increase or decrease the difficulty level of targeted language tests.

With regard to the issue of whether different response formats tend to elicit more information than is necessary for the given construct, it should be noted that the different response formats usually refer to the most representative forms of response types, namely, MC and short answers. Researchers have come to realize that different formats tend to assess different constructs or traits (Ackerman & Smith, 1988; Bennett & Ward, 1993; Bridgeman & Rock, 1993; Thissen, Wainer, & Wang, 1994; Campbell, 1999; Buck, 2001). For instance, the literature on writing assessment indicates that MC and constructed responses measure different traits (Ackerman & Smith, 1988).

The counterargument claims that even though different response formats are adopted in language tests, the target construct to be measured can remain unchanged (e.g., Bennett, Rock, & Wang, 1991; Hancock, 1994; Lukhele, Thissen, & Wainer, 1994), as research findings suggest MC and constructed responses may be used for the same trait (for writing assessment: Bennet et al., 1991; for reading assessment: Ward, Dupree, & Carlson, 1987). Shizuka, Takeuchi, Yashima, and Yoshizawa (2006) also compared the effects of three-option and four-option MCs on testees' performances on reading assessment, and found that there was no significant change in the mean item difficulty and item discrimination. Therefore, no consensus seems to have been reached as to whether different response formats can measure the same construct. However, one possibility is that various response formats might measure the same construct only within a particular content domain. Kobayashi (2002) compared different response formats and text organizations in reading assessment and found both had a significant impact on the testee's performance.

The doubt as to whether various response formats give rise to variation in difficulty has also invited much attention. In particular, for the same construct, it has been controversial whether different formats will trigger a concomitant change in difficulty. Research in this area involves comparisons between various types of selected responses and of constructed responses. In reading assessment, Davey (1987) found that MCs were easier than constructed response items when the same assessment domains were specified, whereas results from other studies indicated no statistical difference between both formats (Pressley, Ghatala, Woloshyn, & Pirie, 1990). Bridgeman (1992) compared item difficulty of stem-equivalent MC and constructed response versions in the Graduate Record Examination (GRE), and found that some items can be tailored to be tougher if constructed responses are required. Yet the result of item response theory (IRT) analysis does not suggest that there would be a universal impact on all test items if they all took the form of constructed response. Research on this issue still seems inconclusive. Considering that a host of possible internal variables, such as test-taker factors, and external variables, such as the type of response data and other test-related variables, may cofunction with the variable of response format in affecting the test construct and test difficulty, caution must be exercised in claiming that a change in response format will have a significant impact on the testee's performance.

As research on language assessment largely centers upon reliability and validity, investigation into response formats also touches upon these two qualities, especially the comparison of the reliability and validity of various response

formats. When response formats are investigated from the perspective of cognitive processing, a number of studies also contribute to revealing possible format effects. For example, Martinez (1999) suggests that the cognitive processing requirements for selected and constructed responses differ. Specifically, it has been found that format effects can be more obvious for those items with cognition complexity in reading assessment (Ward et al., 1987), and that the construct of reading assessment can be heavily affected by the MC format design (Rupp, Ferne, & Choi, 2006).

In addition to the above, the effects of response formats have been studied with regard to how various formats cause test anxiety and motivation change (O'Neill & Brown, 1998), what formats testees prefer (Rocklin, 1992), how language knowledge is retained and measured by different response formats (Currie & Chirama-nee, 2010), and how the time allocated for preparing and making the response in the oral assessment can affect testees' performance (Malabonga, Kenyon, & Carpenter, 2005).

Challenges and Future Directions

Two issues deserve special attention from language-testing professionals, both involving the tension between selected and constructed response formats, from the perspectives of test design and the scoring of assessment performance.

Test design contributes directly to construct validity. While the existing literature is inconclusive regarding whether selected and constructed response formats can measure the same construct in a language test, there are at least two distinctive features that can set the two types of response format apart, namely, content authenticity and content representativeness. Tests taking the same time tend to be able to contain many more items if they are presented in a selected response format, because the test operation is simple. This certainly improves content representativeness, or content validity, as long as the items are carefully chosen. On the other hand, it is easier to make constructed response items simulate real-world use of the language, and therefore have higher authenticity. It would be challenging to achieve both desirable qualities at the same time in most cases. The test designer needs to consider the main purposes of the test and the resources available, and then decide how these purposes can be best attained through an optimal adoption of certain item types.

Traditionally, stakeholders favored selected response formats mainly because they believed that rating selected response items, or objective rating, was much more reliable than rating relying on subjective judgment, or rating constructed response items, especially when lengthy responses such as essays were involved. Therefore, on the one hand, constructed response tasks might be highly desirable in some contexts, but the dubious rating results deterred many stakeholders from adopting this format. The introduction in recent decades of IRT to managing and analyzing testing data has to some extent alleviated this concern by having effectively improved inter-rater reliability, but the problem has not been completely solved, since the initial rating processes still are time-consuming and demand large amounts of human and other resources. Therefore, how to strike a balance

between rating efficiency and rating reliability remains a great concern and challenge.

From another angle, the increasing popularity of integrated skills tasks implies a greater need for human rating, which tends to be slow and, to a great extent, still relies on the rater's subjective judgment under the guidance of test rubrics. It thus remains a major challenge to the wide adoption of such item types in language tests, even though integrated skills tasks are already recognized as a constructed response format capable of reflecting authentic language use to a great extent. Fortunately, the advent of automatic scoring, also known as e-rating or automated scoring, has shown promise for improving rating efficiency, with moderate inter-rater agreement with human raters (Burstein, 2002). However, automatic scoring also has its constraints because all the responses need to be computer-readable, which makes computer literacy and computer-based tests essential conditions for using this technique. Furthermore, there are certain aspects of writing which automated scoring cannot address as successfully as do human raters, such as organization and coherence (Weigle, 2010). These above issues are all worth further exploration.

Field Testing of Test Items and Tasks

Daniel J. Reed

Michigan State University, USA

Introduction: Basic Terms, and a Paradox

Definitions and Related Terms

The term “field testing” applies broadly to the trialing of a new product (e.g., a new car, a new tennis racket, a new computer, a new test) in the environment in which it is ultimately intended to be used, under conditions that are anticipated to occur, and with individuals that are representative of the user population. The implication is that the performance of even the most expertly designed product is not entirely predictable when that product is put to use outside of the tightly controlled conditions of the laboratory or factory or shop in which it was created. For example, new cars need to be driven on real roads (or at least on test tracks that simulate the most important features of real roads) and in all kinds of weather. Initial tests might be carried out by professional drivers, but ultimately ordinary people need to test-drive the cars and give their feedback to the manufacturer or dealer. Furthermore, even after the cars hit the market, reports of problems are issued, recorded, and responded to. Parts go bad or just do not work as expected, accidents happen, recalls are made, lawsuits are filed, and adjustments are made. The point is, products typically are tested before they are used, but testing and monitoring do not stop when people start using the product.

Test development is accompanied by and, in fact, guided by “validity arguments” which evaluate the rationale for test design and the veracity of related claims. Data collected from field testing provide valuable empirical checks on many of these claims. Even after a test is fully developed, new items and tasks may be embedded in operational forms so that empirical checks can be made at those levels. This connection between field testing and validity arguments is elaborated on below.

There are a number of terms that are sometimes used interchangeably with field testing, and sometimes used to make related distinctions. These terms include “pilot testing,” “pre testing,” “trialing,” “field trialing,” and simply “trying out.” These and other terms such as “beta testing” (small-scale tryout with intended users) are further explained in the following section in the context of what can be learned at different stages of language test development. All of these concepts can be thought of as types of “preoperational” testing, which is simply any testing that takes place before a test is made “live,” or put to use for real purposes (when the results “count”). It is also important to note that field testing is as much a part of ongoing testing programs as it is of test development. This is due to the fact that existing testing programs must continuously provide new forms of the same test (to prevent examinees from “sharing” remembered content) and therefore have an ongoing need to create and field test new items and tasks. Once created, the new items go into an item “pool” or “bank” but are not used on operational forms until their status is “active,” which is after field testing and analysis.

While the terms “pilot testing” and “field testing” are sometimes used interchangeably, pilot testing is most often viewed as relatively small-scale testing that serves to inform revisions to items and tasks, and sometimes to the test specifications themselves. Pilot tests are especially useful when developing novel item types, which typically involves several cycles of trialing and revision (and retrialing). Field testing is typically carried out on a larger scale, at a later test development stage, with more attention paid to obtaining a motivated, representative sample of the test-taking population and obtaining item statistics that can be used in the creation of multiple forms and in scoring.

The distinction between piloting and field testing in practice also depends on what the test developers have time to do. Sometimes a test is commissioned and the budget for piloting, development, and field testing is very limited, so one does whatever seems possible in terms of collecting data to support the validity of the test. This happens often in institutions that need in-house tests, or even within small departments or language programs that need something better than what they are currently using. Ethical decisions in these cases are not really difficult or complex since the choices are very limited. Perhaps a better way to think of preoperational testing, rather than as a two-stage process, is as a continuum from small-scale to large-scale activities that happens to correspond to one from low stakes to high stakes, with assessment development as a continuum of contexts from small classrooms to large organizations (with government contracts). It is also important to recognize that there is a range of testing contexts in between the extremes (e.g., testing at small and large educational institutions; testing at small and large companies with small and large contracts, etc.).

Field Testing and Test Types

Test types include placement tests, achievement tests, and proficiency tests. Given that all three types may contain multiple choice items or constructed response tasks, all three will benefit from many of the same field-testing techniques, such as estimation of item or task difficulty and evaluation of the degree to which an item or task successfully separates the stronger test takers from the weaker ones.

However, some aspects of field testing will be sensitive to differences in test type and purpose. For example, placement tests may be evaluated in terms of the accuracy of placements they generate where the criterion measure is current placement in an established program (which may be accomplished by an existing, trusted test in combination with promotion of some individuals from lower levels based on classroom performance). Placement accuracy can also be determined by the number of placement reconsideration requests that might be issued by teachers if it is felt that teachers are in a good position to judge placement appropriateness based on students' initial assignments. Similarly, performance on achievement tests can be compared with existing tests to establish "concurrent validity," or analyzed vis-à-vis what was taught in class. In contrast, proficiency testing is not concerned with any particular syllabus or with how the language was learned. Rather, proficiency is "forward looking," in the sense of being concerned with "predictive validity" in terms of how well a candidate will perform in future communicative language use situations (e.g., grades on future assignments or in courses that are communicatively based, or performance level on other proficiency tests taken later on).

The Paradox of Validating and Using Items and Tasks

Not unlike the case of automobiles cited in the last section, test items and tasks are subject to a "use" paradox: They need to be validated before they are used, and yet they need to be used to be adequately validated.

To illustrate this paradox, let us consider one hypothetical example. The following "prompt" is intended to elicit an oral response from young English language learners (ELLs):

Mary loves animals. Her brother, John, is afraid of animals. One day Mary and John's parents decided to adopt a pet for the family and brought home a really cute puppy. Who is happier, and why?

It is possible that this prompt would be partially validated by a content reviewer based on the fact that the content is age appropriate and interesting, and the phrasing elicits an opinion. However, the validity of the task may not hold up when the task is administered. For example, if the answer key required the child examinee to say that Mary would be happier, there could be a serious problem. One child might say that, but another child might have a reason to say that the parents are happier. Yet another child might see the situation from the animal's point of view and might say that the puppy would be happier. In other words, when the task is used with real examinees, the examinees might think of interpretations that had not occurred to the original reviewers, and the students might not receive credit the way the task was written and designed to be scored. In such a scenario, the task would have been partially prevalidated (evaluated and determined to be okay before use, based on "content validation"), but subsequently invalidated when actually used. The crucial problem with the latter evaluation is that it would have come too late: Either some students would have unfairly received low scores, or else the task would not have been scorable due to the multiple number of reasonable interpretations.

One might think that more detailed content and task specifications combined with better reviewer training would solve most problems. While this would be a step in the right direction, the inescapable conclusion is that some interpretations or flaws might elude a small, expert review committee but would be revealed later by at least a few examinees when the item or task was administered to hundreds (or thousands) of people.

A logical resolution is to conduct field-testing sessions in which items are used but do not “count.” But there are several complications. Small-scale pilot studies will not yield adequate data for validation. Larger-scale administrations are problematic in that the target population may not be available or adequately represented, and the levels of motivation for the candidates may be called into question. And so this is one of the main dilemmas of field testing: How do you obtain an adequately motivated, representative sample of the examinee population if the results do not count?

The problem is softened somewhat by the fact that items and tasks can be *partially* validated before they are used. For instance, since tests are based on “blueprints” that contain “content specifications” (see Bachman & Palmer, 1996, 2010; American Educational Research Association, American Psychological Association, & National Council on Measurement in Education [AERA, APA, & NCME], 1999; Fulcher & Davidson, 2007), the validity of the content can undergo a rigorous check by having content specialists compare the substance of each item with the content specifications. The difficulty level of items and tasks can also be dealt with to some extent before items are used by making reference to general frameworks such as the Interagency Language Roundtable (ILR), or the American Council on the Teaching of Foreign Languages (ACTFL) proficiency framework, or the Common European Framework of Reference (CEFR). For example, writers might be told to create one reading passage that would be classified as “Advanced” in the ACTFL framework (or “2” on the ILR scale), and another classified as “Intermediate” (or “1” on the ILR scale). Presumably, it would be harder to answer questions based on the “Advanced” passage than on the “Intermediate” passage. But this does not always turn out to be the case. Furthermore, it is often desirable to have questions ranging from easy to hard all based on the same passage (e.g., easy and hard questions based on an Advanced passage; easy and hard questions based on an Intermediate passage). Writers are not consistently good at this. Several studies have shown that judgments of item or task difficulty made by raters do not correspond well to what examinees actually find to be easy or difficult when they take tests containing those items and tasks (Alderson, 1993; Impara & Plake, 1998).

Thus, just as is the case with cars, test designers and test writers (like automotive engineers) can anticipate a lot regarding item and task characteristics (before field testing), but not everything. And what is *not* anticipated can be critical, as will be seen as the discussion of this paradox unfolds.

Field-Testing Considerations at Various Stages of Test Development

The following paragraphs explain the relevance of field-testing concerns at various stages in the life of a test. For readers interested in more details, Welch (2006)

provides a comprehensive summary of the process of developing questions, prompts, scoring rubrics, and scoring processes in accordance with the content standards and test specifications that define the knowledge and skills being assessed.

Planning and Design Stage

One might think that the planning or design stage of test development was logically unrelated to field testing. However, field testing itself has to be planned, and it is thus dependent on decisions made during the design stage in many respects. The target population has to be identified and defined, and the conditions of and constraints on field testing have to be anticipated. This raises an array of questions: Will the test developers have access to the population, and will individuals from that population be willing to come try out a test? Will the examinees really try their best to answer questions correctly and to perform well on tasks? Will giving a trial test risk exposing the items to potential candidates who attend future, operational administrations? Will the test developers have access to adequate facilities to give the tests? If the test is long, will the facilities be available for an adequate length of time, and will the examinees be able to stay that long? Will these be the same or similar to the facilities that will ultimately be used?

Some of these questions are addressed in the section below, "Large-Scale Testing Concerns," in the context of later test development stages. However, the key to success in those later stages is to anticipate those special concerns during the earliest stages of test development and to plan ways to accommodate them.

Test-Writing Stage

Test writing is an ongoing activity for many testing programs. That is, even once a test has been developed and used, there is a continuing need to develop new items and tasks that can be used to create new forms of the same test. This is because once items have been "exposed," examinees might reveal content to their friends or other potential, future examinees. Thus, there is an ongoing need to pilot these items, and again, there is a need to plan and prepare. The relevance of piloting and field testing to test writers is manifested in the item-writing specifications. The test designers conceive of categories for items (e.g., content areas and topics within these areas, classification on a scale in a proficiency framework, domains such as social vs. workplace vs. academic language, specific knowledge such as vocabulary or grammatical points, specific skills such as identifying examples in a reading passage that support or refute an argument, etc.). These categories are reflected in the item-writing guidelines or specifications that writers must adhere to. Data can then be collected in subsequent field-testing sessions to be analyzed in terms of whether the categories are tenable (e.g., Can each item type be replicated and consistently exhibit similar statistical properties? Does each item type "correlate" well with other items in the same section that are intended to target the same underlying construct or ability?). Put more simply, the relevance of the item-writing stage to field testing is that it produces the materials that will be tried out and analyzed in terms of examinee response data obtained through

field testing (including item and task parts, subparts, and features and classifications of items).

Piloting and Field-Testing Stage

The various types of data collected during field testing yield an evaluation of both test materials and examinees. Naturally, examinee performances reveal at least general levels of abilities. As will be seen in the discussion of item analysis, knowing examinee abilities even in general terms is extremely useful in evaluating the items and tasks that comprised that evaluation. In that sense, the items and tasks tell us something about examinees. Conversely, examinee response patterns may reveal problems with items such as “statistical ambiguity,” which may reflect problems with the test’s validity.

For example, suppose for a given item with four options, half of the examinees select option A and half choose option B, but no one selects C or D. In this case, the examinees are telling us something about an item (i.e., options C and D are not attractive and would not fool anybody, plus the item has two possible answers). However, it is also possible simply to ask examinees directly to comment on various aspects of a test or its parts. In fact, data collection during field test administrations often makes use of instruments other than the test itself (namely, background questionnaires and test-taker feedback questionnaires). These tools are useful to ensure test quality and the dependability of information provided by the test, which is essential if informed decisions are to be made on the basis of test scores. Taken together, these instruments provide multiple checks, or crosschecks, on the validity of many aspects of a test. Here is a list of some of the most commonly used instruments and activities associated with field testing, immediately followed by a discussion of each:

- examinee background questionnaires;
- self-assessment questionnaires;
- the test itself (containing the items and tasks being field tested);
- test-taker feedback questionnaires;
- test and item analysis;
- bias analysis;
- inter-rater agreement analysis;
- correlations with other measures (some administered at nearly the same point in time to assess “concurrent validity,” others administered at some future time to assess “predictive validity”); and
- test administration or operational testing stage.

Examinee Background Questionnaires In order to provide a meaningful analysis of field test data, it is very useful to collect other potentially relevant information from examinees. This is typically done by having examinees fill out a brief questionnaire just prior to taking the test being evaluated. Sometimes test developers ask examinees to respond to such questionnaires before the day of the field test administration. However it is done, care must be taken not to fatigue the examinees by asking them to do too much at one sitting.

The types of information collected with background questionnaires typically include gender, age, education, any other languages studied, how the target language was learned, whether it was spoken in the home, how many years the candidates studied it formally, how much time has been spent in a country where the language is spoken (and was this study-abroad or work-abroad experiences, or visiting or vacation), the purpose for learning the language, degree of motivation, and so on.

When analyzing the field test results, test developers will look for reasonable patterns to help support the validity of the test. These patterns include relationships such as higher test scores by examinees who had studied longer, or by examinees who had studied abroad, or by those with a higher degree of motivation to learn the language. Sometime examinees are asked to self-report either class grades or scores on other measures of their language ability, which introduces the possibility of examining “concurrent” validity. The more patterns that are examined with the expected result, the stronger the case for the validity of the test.

Self-Assessment Questionnaires Self-assessment has become an increasingly popular activity, partly because the ability to self-assess is thought by some to be central to learning (Alderson, 2005, p. 97), and partly because it provides yet another measure with which performance on new items and tasks can be correlated in the quest to amass validity evidence. Alderson (2005) discusses the role of self-assessment in the language diagnosis system DIALANG, including ways in which learners can improve their ability to self-assess through activities that allow them to compare self-appraisals of their language abilities with performance-based evaluations of the same abilities.

The Test Itself There are a number of decisions to make about what form the test itself will take. Will the field test forms contain only new items, or will they be mixed with old items (sometimes called “used items” or “common items” or “linking items”)? How will the test be “published”? Will it be computer delivered, or will it be a simple, paper-based test that is the same for all examinees, or will different forms with different “embedded” items have to be created? Practical matters also include test length, time available for administering the test, and the availability of trained exam administrators. If a lot of tasks are planned, such as the trialing of various writing or speaking prompts, how many can be included before problems with test fatigue start to become a factor, or until the available time is simply used up? Further considerations relate to logistics, scoring, and reporting (examinees typically want at least minimal feedback such as percentage correct and how it compares to the average score for the test).

More critically, steps have to be taken to maximize the similarity of conditions of the field testing to anticipated operational conditions, and the examinees selected have to be representative of the target population and adequately motivated.

Test-Taker Feedback Questionnaires Test-taker feedback questionnaires are very commonly used during the pilot stages, or early field-testing stages, of a test under development. These instruments can be a useful complement to the test-taker

background questionnaires. For example, if the background questionnaire contains items that ask about an examinee's motivation and purpose for learning the target language, the feedback questionnaire could follow up with related questions such as how motivated they were to take the test (perhaps asking separately about their motivation when they started and when they finished). More commonly, test-taker feedback questionnaires are used to collect data on practical questions such as whether the examinees felt that the test instructions for each section were clear and whether enough time was provided for responses (asked separately for each section or passage). Both the background questionnaire and feedback questionnaire are most efficiently completed if most possible answers are anticipated in multiple choice format. However, feedback questionnaires in particular also benefit from the inclusion of a few open-ended questions that might capture any ideas or insights that examinees might have for improving the test. In early, pilot stages of test development, it may even be possible to conduct individual interviews with students to better elicit their perspectives on various aspects of the test items and tasks they tried. Qualitative analysis of recall protocol data, or information obtained from other reflective techniques during early stages of test development, can have important implications for test design revisions and thereby prevent major problems from occurring in subsequent, large-scale field-testing stages.

Test and Item Analysis Summary statistics for a test as a whole or for individual items and tasks are readily obtainable through the utilization of software packages specifically designed for this purpose. While special expertise is required to use item response theory (IRT) applications such as BILOG-MG, XCALIBRE, and WINSTEPS, there are a number of programs that perform a classical item analysis and present the results in a very useful form (e.g., Iteman, Remark) based on classical test theory (CTT). Test summary statistics include the average score (reflecting how difficult the test was overall), range of scores, standard deviation (reflecting how widely or narrowly the scores were dispersed), and reliability. Item statistics also include difficulty estimates, referred to as "*p*-values" to indicate the proportion of examinees who responded correctly to the item, or the probability of a correct response to the item if you knew nothing about the candidate's ability. These values range from 0 to 1.0, and as a rule of thumb, test developers look for *p*-values in the .30 to .80 range (because anything lower likely reflects guessing, and anything higher contributes little information since very weak and very strong test takers alike will get the item right). Exceptions to this rule of thumb are made if reasons merit. For example, early in a test or test section it might be okay to have an easy item to help the examinee "warm up" and give their best performance on subsequent items (conversely, inordinately difficult items at the beginning of a test might be psychologically discouraging to a candidate to the point that they no longer try their best). Thus, information on the difficulty of items is useful for helping to determine the order of items (to the extent that the order is free to vary).

Another property that is important to know is the extent to which any item appears to measure the same construct targeted by other items in the test or test section. This can be measured in a couple of ways. One way is to simply correlate performance on a particular item with the sum of the number of correct responses

to other items in the test or test section. This statistic is referred to as a "point biserial." Like most correlation coefficients, it is expressed as a number from -1 to $+1$, and a statistically significant positive correlation is what is required. Another way to approximate this type of "internal consistency" is to compute the difference in the proportion of correct responses to an item by the top $x\%$ of examinees (top 25% or top 33% or some other figure) and the bottom $x\%$. This statistic is known as the "item discrimination index." If the value is well above zero, the item is functioning well in the sense that the stronger test takers are outperforming the weaker ones on that particular item. If the difference is near zero, then the item is not contributing to the separation of more able students from less able ones. If the difference is a negative number, then either the scale is inverted from the usual approach (e.g., the number of errors is counted as the score rather than the number of correct forms or answers) or else the item requires serious attention (i.e., the item writers or reviewers need to revisit it and try to identify and fix the problem).

Finally, item analysis also looks at the performance of each individual option in a multiple choice response set. Typically, the "correct" choice, or "key," should be the option that is chosen by the greatest number of high level examinees, and the remaining options ("incorrect" choices, also known as "distracters") should be roughly of equal popularity to one another (equally "distracting"). Most software programs "flag" items that function in unexpected ways. For example, if an item is correctly responded to by more low level test takers than by high level test takers (as defined by total score on the same test), the program will recommend that the answer key be checked for a possible error. Or it could be the case that the item functions well in most respects, but few or no test takers select a particular option. In this case, the item is referred to writers or content experts who try to determine the reason that the distracter is not functioning and revise it if possible. Similarly, if an item has a poor discrimination index or low (or negative) point biserial, then the content of the item has to be re-examined and edited (or replaced).

The information provided by the item difficulty and item discrimination (or point biserials) statistics of CTT have parallels in the item "parameters" of IRT. A major difference is that, in IRT, an estimate of examinee ability is factored in. In the case of item difficulty, for example, an item could have a difficulty index of $.50$ (as determined by a classical item analysis), reflecting the fact that 50% of a group of test takers responded correctly to the item. Thus, if nothing else was known about an examinee, one could predict that the examinee would have a probability of $.50$ of responding correctly to that item. Of course, it is clear that very weak candidates would have a much lower probability than $.50$ of getting the item right, and very strong candidates would have a much better chance of responding correctly to it. Rather than simply reporting a difficulty index, then, IRT-based programs generate item response functions that reflect this interaction.

In terms of task analysis, IRT makes it possible to evaluate rater harshness and relative task difficulty by placing difficulty estimates on the same scale as candidate ability and rater severity. McNamara (1996) provides a clear explanation of these concepts. In the case of test designs that provide ratings for multiple tasks, each task (with its associated prompt) can be evaluated in a way that is analogous to item discrimination. That is, given the ratings for all tasks plus an overall, average rating, performance on each task can be correlated with the overall

average to check for internal consistency (i.e., to answer the question, “To what extent does each task measure the same ability as the test as a whole?”).

Regardless of whether one uses CTT or IRT programs to analyze field test data, it is important to take the information back to the test writers to see whether the flagged items can be revised and improved. Taking the time to do this is an important way of increasing the reliability and validity of the test as a whole.

Bias Analysis Bias analysis can make use of a number of techniques that aim to determine whether certain subgroups of an examinee population might have an advantage or disadvantage in responding to certain items and tasks. Conducting such an analysis first requires an adequate knowledge of the target population and subgroups (e.g., male or female, young or old learners, examinees differing in educational background). For example, an English language placement test given at a university in North America might target a population that has subgroups varying in both cultural and educational traditions. Whenever possible, item content should be submitted for “cultural sensitivity” review to screen for potential problems before the content is published on field test forms. Much as in the case of other aspects of test writing, many problems will be caught in such reviews, but not everything can be anticipated. This is yet another area where the empirical benefits of field testing are clear. In this case, techniques such as differential item functioning (DIF) can be applied to determine whether an inordinate number of examinees from one group outperforms examinees in other groups. If the probability indicates a potential problem, then the culture or content experts would revisit the item to look for an explanation and a way to adjust (or, if repair fails, to recommend a replacement item).

Inter-Rater Agreement Analysis As mentioned earlier, the term “task” is often used to refer to test activities that involve language production. If the first part of a task involves a receptive skill (reading or listening) and then calls for an essay or spoken response, the term “integrated skills” task is often used. Unlike for most “items,” the grading or scoring of tasks requires human judgments. Those who judge or grade tasks are referred to as “raters” and must undergo training and certification procedures. For new tests, it must be demonstrated that raters are capable of applying scoring rules consistently. During training, consistency must be demonstrated between each trainee’s evaluation of “benchmark” performances and the “official” rating of each benchmark (determined by “master raters” or panels of raters who happened to agree on those samples). Some raters will tend to be “harsher” than others, and so limits will need to be set regarding the degree of “rater severity” that would be tolerable. During field testing, however, the emphasis is typically on inter-rater agreement levels. Sometimes this is evaluated with a correlational technique, and other times as a percentage of either exact agreements or agreements within adjacent scale points. If raters cannot agree, test developers must determine whether the problem was inadequate training, poorly chosen benchmarks, weaknesses in the rating rubric, or something else (or all of the above). As is the case in revising items based on information provided in an item analysis, any revisions necessitate another round of piloting or field testing to “prove” that the revisions were effective.

Correlations With Other Measures Scores obtained during field test administrations can also be used to provide evidence for both “concurrent validity” and “predictive validity.” Concurrent validity is supported when significant correlations with other measures of the same language abilities are obtained, while weaker correlations with measures of different language abilities are demonstrated. Of course data from these “other” concurrent measures would have to be provided somehow. Asking candidates to self-report scores from other tests when filling out the background questionnaire is one way to get the scores, but examinees are not always accurate in remembering scores (let alone the order of subscores) and not always willing to provide such scores even when they do remember them. Sometimes scores from other tests are available from another source such as a student’s academic record, but then access would typically require going through an institutional review board (in charge of research on human subjects and enforcement of confidentiality laws). However they are obtained, the scores need to be current enough to accurately reflect the level of a person’s ability at the time of the field test administration. If a score is more than a few months old, it may no longer be a valid indicator of a person’s ability. A simple example would be a Test of English as a Foreign Language (TOEFL) test score reported in March being used for comparison with a field test score in September of the same year, in the case where an international student spent the entire summer in his or her home country without having any contact with native English speakers and no reason to use English in the interim.

“Predictive validity” is similar to concurrent validity in the sense that it requires a correlational analysis, but with the difference that the “criterion measures” (established measures of the same abilities) are administered at some future point. For example, a field test of interpreting abilities could be used to select interpreters for particular jobs, and the results of the interpreter test could be correlated with job review data after a period of time.

Test Administration or Operational Testing Stage It was noted in the previous section that many important considerations for field testing and test validation emerge in the planning or design stage of test development and continue to be relevant on into the fully operational testing stage. In fact, field-testing and validation activities may go on until the product is no longer in use. This is one reason why field testing is as much a part of ongoing testing programs as it is a part of test development. A second reason in the case of language testing is the constant need to create new forms of the same test so that test content is not shared with examinees who will take the same test at a future point. Thus, there is an ongoing need to create and field test new items. In fact, one of the best ways of trying out an item is to place it on an operational test and simply not count it. If the examinees do not know which items are counted, they presumably will do their best. In fact, the use of “embedded” field test designs is one of the ways of resolving the “use paradox” outlined above. Embedded designs entail placing some new items on live test forms so that they may be evaluated in the context of an actual test (but typically not scored).

Thus, in the ways just described, field-testing data feed into the iterative, review-and-revision process of test development (inform revisions, leading to new

versions of items and tasks that need to be tried out in their new forms before being placed on operational test forms). That is, field testing makes a significant contribution through the twofold process of identifying validity problems and providing information that is useful to improve the validity of particular items and tasks (and thus the test as a whole). In short, data from field testing can be used for a variety of purposes including verification of the statistical properties an item was designed to have and calibration that enables an item to be used on test forms yet to be created. So conceived, field testing serves as an empirical check on both the past and the future of items and tasks.

Activities Related to Field Testing

Norming

Norming refers to the collection and tabulation of test scores for various groups of test takers whose differences are potentially relevant and important for score use. The participants in a norming study are referred to as the norm group. Norms typically include a breakdown of score distributions by gender and by age group or grade and other variables. For example, the *Modern Language Aptitude Test: Manual* (Carroll, Sapon, Reed, & Stansfield, 2010) has a table that contains raw scores corresponding to percentile values for grades 9–11 and college freshman, and male and female within those categories. Another table contains norms for college freshman and other adult groups (air-force-enlisted men, men in intensive language training at the Department of State, and students at the Army Language School).

It is fair to ask how well one can trust norming data if it comes from field tests. In fact, this is another example of a “use” paradox. The use of test scores requires reference to meaningful reference points. In the case of norm-referenced testing, the norms may be obtained from field tests, and again the question of examinee motivation comes to the forefront. In the case of the Modern Language Aptitude Test norming data, the participants were volunteers. Nonetheless, the publisher felt that the scores were trustworthy enough to be useful.

Calibration and Linking

If two tests are constructed from the same “blueprint” (and meet a fairly strict list of other requirements) they may be placed on a common scale through a process known as “equating” (thereby creating “alternate forms” of the same test). Field test data can also sometimes be used to estimate IRT parameters for the purpose of creating or refreshing a “calibrated item pool” which can also be used to generate alternate forms. In field testing, the practice of placing previously used items on a form with otherwise new items is known as “common item equating” (because an earlier field test or operational test shares items with the current field test form). Equating designs can be very complex (Kolen & Brennan, 2010) and require a great deal of expertise to implement, but the importance of having essentially “interchangeable” forms of the same test is generally thought to justify the costs.

Standard Setting

Standard-setting procedures are formal ways of deciding on “cut scores” or “passing scores” for particular uses of particular tests. For example, an English language test used for placement purposes will need as many “cut scores” as there are levels in the program. A panel of judges can speculate as to how many questions should be answered correctly to merit placement into each level, but their judgments are greatly aided by empirical information on item difficulty obtained through field testing. One approach, known as the “bookmark method,” arranges items from a field test in a book with one page per item in order of easiest to hardest in accordance with “logit” values expressing item difficulty. Panelists can then place bookmarks on the pages that represent the “minimally competent” candidate for each level. Participants then explain their rationale to other participants in attempting to persuade each other to adjust their marks. After two or three rounds of discussions (with independent bookmarking in between discussions), a close level of agreement is a common outcome because participants modify their original judgments in ways that are consistent with the argumentation (again, aided greatly by the data obtained on item difficulty from field test administrations). A number of other standard-setting methods also make use of field test data (Cizek & Bunch, 2007).

Large-Scale Testing Concerns

Special Requirements

Kirkpatrick and Way (2008) present a sobering number of challenges and solutions that test developers face in designing field tests for large-scale, high stakes tests. Here are just a few of those challenges that require carefully thought-out field test designs:

- a demand for immediate score reporting;
- a mandate to release all items on a form to the public after its operational administration;
- restricted time periods for field testing (e.g., 45-minute class periods, when the actual test is much longer than that); and
- passage-based tests with extended response formats (rendering an embedded design essentially impossible).

Solutions: Standalone and Embedded Designs

The solutions to the above challenges cited by Kirkpatrick and Way fall into two categories: standalone field test designs and embedded field test designs. In standalone administrations, results typically do not count (are not used for any high stakes purpose). Participation may be voluntary, or examinees may be paid a modest fee (which introduces questions about how motivated they are to do their best). Often all of the items on the forms are being tried out for the first

time, but standalone designs also allow for the inclusion of “common items” (previously used items whose statistical parameters are known and can be used to calibrate the new items if adequate data are obtained during the field test administration).

Embedded field test designs aim to solve the problem of examinee motivation by placing (embedding) items being tried out for the first time in actual operational forms. This exposes the item, but calibrates it dependably and allows it to be used with a fair amount of confidence after a certain period of time (typically after a year, and in a geographic region other than that of the field test site).

Relation Between Program Needs or Characteristics and Designs Chosen

While embedded designs may appear to be superior and always preferable to standalone designs, this is not the case. Completely new programs, for example, cannot use embedded designs simply because they have no operational forms in which to place new items. Also, for ongoing programs that have long-response formats, embedding is not feasible because it would lengthen the test unreasonably. On the other hand, for ongoing programs in which motivation is a well-documented problem, standalone designs are not a good choice. Thus, the needs of a program should be carefully weighed before making a final decision on what design would be most appropriate (Kirkpatrick & Way, 2008).

Field Testing and Validity Arguments

While most of this chapter has been devoted to practical matters of using field test data to improve items and tasks, it is important to emphasize that the evidence collected in connection with field testing can also be invaluable in supporting claims associated with the “validity argument” for a test as a whole. In recent years, much of the work on validity in language testing has focused on developing the work of Messick (1989, 1994) into practical frameworks to guide validation activities for testing programs. Kane (2006), for example, distinguishes “interpretative arguments,” which lay out the claims associated with tests, from “validity arguments,” which challenge or evaluate those interpretive arguments. Naturally, a test developer would start to develop an interpretive argument for a new test as early as the planning and design stage. The goals would be to design items and tasks that provided the information needed by the future users of the test. The design, rationale for the design, and associated claims would ideally all be made explicit. Evidence supporting the design and associated claims could be drawn from previous research and further supported by data collected during field test administrations of the new test. An interpretive argument could then be “backed” by this data, which would include the measures of internal consistency discussed earlier in this chapter, as well as patterns of correlations between field test scores and scores from external measures for the same examinees (reasonably strong, positive correlations with other measures of similar abilities, indicating some level of generalizability of results and concurrent validity; and lower

correlations with dissimilar abilities). In laying out the claims associated with this interpretive argument, the test developer makes a case for the validity of the new test. An important question then is who presents the “validity argument” that challenges the interpretive argument in Kane’s sense. One logical possibility is that the test (including data sets from field test administrations) could be made available for validation by independent researchers and organizations. This view might assume that the test developer is limited to the “advocacy” role implied by the interpretive argument (and has a conflict of interest), and that only outside agents could objectively and critically evaluate that interpretive argument. However, it clearly is in the best interest of test developers to develop their own validity arguments that vigorously challenge their own interpretive arguments so that their tests are as good as they can be before being subjected to validation from the outside.

Another influential validity framework in language testing is the assessment use argument (AUA) approach of Bachman and Palmer (2010). This framework explicitly acknowledges the importance of multiple levels of test use including examinee performance on items and tasks, the relation of that performance to test scores, the inferences that are associated with various scores, the decisions that are made based on these inferences, and the consequences of these decisions. As is the case with Kane’s framework, claims are made that require backing data. Some of the claims can be backed by results from published research, but a complete and convincing argument would require data generated from the test itself. An important point to note is that while the AUA levels are in a sense organized in order of increasing importance (from item-level or task-level performance up to consequences associated with decisions made based on test results), they are all connected. For example, field test data might generate scores that are reported in terms of “bands” (e.g., “B2” in the CEFR; “Advanced-High” in the ACTFL framework; or an arbitrary number such as “7” that is used for a small range of raw scores). Within such bands, there would be a range of ability, and so if the scores were used to hire someone for a position such as an international teaching assistant (ITA), it would be important to know whether all candidates in the band were equally likely to perform satisfactorily in that capacity, or whether one could be confident in hiring only those in the upper part of the band. In the latter case, it would not be a valid use of the test to select ITAs based on the scores as reported, and that conclusion could be made by conducting a study with data generated from field testing.

Conclusions

An important challenge for test developers who use standalone field test designs is to obtain the participation and cooperation of students, teachers, and school administrators in pilot testing and field testing, and to ensure that the students are motivated to do their best, or at least nearly their best, on what they may perceive to be mere “practice exercises.” A key question is: What can test developers give back to the students and schools to make it worthwhile for them to engage in the process? Depending on the context, the opportunity to practice may be

adequately motivating; but often it is not. Efforts should be made to offer systematic feedback to students and teachers. At the very least, students should receive scores in some form (e.g., raw score, or percentage correct) soon after the test, as well as the average score from an appropriate reference group (e.g., their class's average or grade-level average). In some contexts, it will be possible to also provide feedback in the form of profiles of strengths and weaknesses for a class or other group of students (a feature that is more feasible with computer-based testing, but possible even with paper and pencil tests, with planning). Ideally, this information could inform future instruction in useful ways. In the case of language-training programs that develop test forms on a regular basis, piloting or field-testing activities could be built into the regular semester schedule, perhaps near the beginning amid other diagnostic activities. The teachers themselves could take the tests and comment on them. Involving teachers is crucial to establishing testing as an integral part of a language program.

A major problem that was discussed was that field-testing conditions and operational testing conditions never do match perfectly, because a "practice test" is not a "real test," and therefore conditions will not be identical and examinee motivation will not be the same. This problem is somewhat analogous to the observation that the best, most authentic test task is never real life, because it is a test, and the examinee knows that (or should know that). Nonetheless, with a careful consideration of a testing program's needs and a thorough knowledge of available field test designs and of how test analysis results can be used to improve a test, the field testing of items and tasks is clearly among the most useful and important activities in language test development and validation.

Using Test-Wiseness Strategy Research in Task Development

Andrew D. Cohen
University of Minnesota, USA

Introduction

Strategic competence was perhaps first viewed theoretically as an integral part of communicative competence in the Canale and Swain model (1980), and was then incorporated into Bachman's (1990) model, which was further articulated in a volume by Bachman and Palmer, where they viewed metacognitive strategies as having an essential role in test taking (1996, pp. 70–5). Bachman and Palmer went on to note that whether strategic competence was included in the construct definition for a specific testing task depended on whether “the test developer had wanted to measure not only language knowledge but also the test takers’ flexibility in adapting their language use to different situations” (p. 120). This chapter takes a close look at just what strategic competence means with regard to language assessment. The approach taken here is to break down strategic competence into strategies that might contribute construct-relevant variance to test results, namely language strategies and test-management strategies, and strategies that in contrast are likely to produce construct-irrelevant variance.

The chapter will begin by briefly defining language strategies and distinguishing them from test-taking strategies. Then the two types of test-taking strategies, namely test-management and test-wiseness strategies, will be defined and illustrated. It will be argued that test-management strategies contribute to construct-relevant (i.e., desirable) variance, while the purpose of test-wiseness strategies is to assist test takers in responding to items and tasks without having to reveal competence in the targeted language skill area(s). Once these distinctions have been made, we will consider findings from the research literature, challenges for researchers, and future directions to ensure that respondents’ language skills are actually being assessed. The intent is to focus on how to

mobilize what we have learned from the research literature on test-taking strategies in order to improve item and task development. The ultimate challenge is to fashion items and tasks that cannot be responded to easily by means of test-wiseness strategies aimed at bypassing reasoned and informed means of producing responses.

Tests are increasingly assuming the role of gatekeepers in societies where access to programs depends on successful language test results (Shohamy, 2001). Especially in high stakes second language (L2) exams, those respondents who lack the requisite language skills may well enlist test-wiseness strategies in order to circumvent those skills in their responses. They certainly cannot be slighted for making this effort, and test preparation programs may, in fact, encourage the use of such strategies in the name of “guessing,” especially on tests where guessing is not penalized. In the interest of obtaining a true measure of respondents’ language skills as opposed to their ability to avoid displaying them, it is imperative for test designers to construct items and tasks that require respondents to display the target language skills, rather than their ability to avoid them.

The above is easier said than done. It entails tightening up the test construction process, which is not an easy matter. For example, it presupposes that the test constructors have a clear idea of the language skills that they wish to assess. This process is easier when the skills being tested are more specific, such as the meaning of a given word in a given context, or the retrieval of a fact from a reading passage. But the process may be murkier on a task where the information necessary for correctly responding to an item calls for inference. Furthermore, if the aim of a given item or task is to assess multiple skills in an integrated fashion, this poses a real challenge to somehow target the use of the desired language knowledge and skills, without allowing for circumvention of this knowledge and skills through test-wiseness strategies.

In order to attempt to guard against the successful use of test-wiseness strategies, it is imperative that test constructors be cognizant of just what the test item or task actually entails, which would call for piloting. This is where the collecting of verbal report (see below) on what a sampling of respondents do in their efforts to respond to items and tasks would be helpful. Once test constructors have this knowledge, they can make more informed choices in the construction of test items and procedures—choices that ideally will better assess the respondents’ requisite language skills, rather than their cleverness at circumventing an assessment of these skills.

Conceptualization of Strategies

It is important to be clear as to the three types of strategies that may be called into play when attempting to respond to language test items and tasks. The first types of strategies are not test-taking strategies at all, but rather language learner strategies. Then there are two types of test-taking strategies, namely test-management strategies and test-wiseness strategies. Below are definitions of these three types.

Language Learner Strategies

The following is a working definition of *language learner strategies*:

Thoughts and actions, consciously chosen and operationalized by language learners, to assist them in carrying out a multiplicity of tasks from the very onset of learning to the most advanced levels of target-language performance. (Cohen, 2011, p. 7)

In order to respond to tasks on language tests, learners may employ language strategies to assist them in operationalizing the targeted language skills. Respondents will use such strategies to a greater or lesser degree depending on their awareness of possible strategies and their ability to mobilize them.

So, for instance, as part of the assessment of listening skills, a listening comprehension item could call for inferencing strategies on the part of respondents while listening to a brief interchange. The listeners hear the following: "Well, we could probably have it ready by 4 pm today but best to let us keep it overnight just to make sure all the updates have been properly installed," and they need to select the situation in which that utterance was *most likely* to appear:

1. a bicycle store attendant to a patron,
2. a computer technician to the purchaser of a new computer,
3. a clerk at an auto repair service to a customer, or
4. a music store clerk to the owner of a trumpet.

The key word in this item is "updates," which refers to the readying of a new computer. Some level of inference is involved here since some may think that a computer is ready "out of the box," without the need for updating. It also calls for knowledge of vocabulary such as "patron." So we see that the processing of listening comprehension items of this kind is likely to prompt respondents to make use of language learner strategies in order to demonstrate their control over the targeted skill(s). Strategies apply to the receptive skills (listening and reading), the productive skills (speaking and writing), and the related skills (vocabulary learning, grammar learning, and translating) for starters, but also, and importantly, to the micro-skills in a skill area such as reading (e.g., inferencing, paraphrasing, and skimming). It is in operationalizing the micro-skills that informed and reasoned use of strategies can be crucial, such as in strategizing in order to correctly make an inference on a language test item.

Test-Management Strategies

Test-management strategies are strategies for responding meaningfully to test items and tasks. These are the processes consciously selected to assist in producing a correct answer responsibly. They include logistic issues such as weighing the importance of responding to different items or tasks, keeping track of the time, and determining where to look for answers.

Test-management strategies on a reading test could include:

- going back and forth between a passage and a given question in order to obtain more information about just what to be looking for;

- dealing with multiple choice options systematically so as to give careful consideration to all the alternative choices and to craft a plausible rationale for why one choice is better than the others; and
- strategies for managing the use of the allotted time, to ensure that sufficient attention is given to items and tasks, especially those with the highest point values on the test.

A test-management strategy on an essay-writing task could be to outline the essay before writing it in order to ensure that it responds effectively to the writing prompt. Assume, for instance, that the task is to write an essay requesting that the respondent take a stand, pro or con, on an issue such as this:

It is important to send text messages throughout the day, regardless of who you are with and what you are doing. Use specific reasons and details to support your answer.

Test-management strategies would include lining up arguments in outline form in advance—listing points in favor of a given position (e.g., in favor of text messaging), making note of some caveats, and including counterarguments and a response to each of them. With respect to essay writing on a test, good test-management strategies would help to ensure productive time planning the essay and a smooth and effective write-up phase.

Test-Wiseness Strategies

Test-wiseness strategies are defined here as using knowledge of testing formats and other peripheral information to obtain responses—very possibly the correct ones—on language tests without engaging the requisite L2 knowledge and performance ability. So, for example, there are test-wiseness strategies that respondents can apply to multiple choice items, such as the following (from Allan, 1992):

- stem-option cues, where matching is possible between the stem and an option;
- grammatical cues, where only one alternative matches the stem grammatically;
- similar options, where several distracters can be eliminated because they essentially say the same thing; and
- item giveaway, where another item already gives away the information.

With regard to a reading test, applying these strategies would mean using the process of elimination (i.e., selecting an option even though it is not understood, out of a vague sense that the other options could not be correct), using clues in other items to answer an item under consideration, and selecting the option because it appears to have a word or phrase from the passage in it—possibly a key word.

The following is an example of stem-option matching. Respondents did not have to look in the text for surface matches. They were able to match directly between the stem and the correct alternative:

Question: The increased foreign awareness of Filanthropia has . . .

- (a) resulted in its relative poverty.
- (b) led to a tourist bureau investigation.
- (c) created the main population centers.
- (d) caused its extreme isolation.

Students associated “foreign” in the stem with “tourist” in option (b), without understanding the test item (Cohen, 2011, p. 313).

Research on Test-Taking Strategies

Since several extensive reviews of the test-taking strategy research appear elsewhere (e.g., Cohen, 2006, 2007a), the focus here will be primarily on test-wiseness strategies. While the number of studies dealing with test-taking strategies on L2 language tests is itself limited, the number focusing specifically on the subcategory of test-wiseness strategies is far smaller. Let us look first at some of the studies involving test-wiseness strategies, with an eye to seeing how the results from such studies can be mobilized in the design of test items and procedures. Then we will consider a study where even though the respondents made little use of test-wiseness strategies, the collection of test-management-strategy data indicated that the cognitive processes deemed necessary for responding to so-called “innovative” items were not necessarily being used.

Research on Test-Wiseness Strategies

The truth is that most test-taking strategies studies do not look at the phenomenon of test-wiseness at all. Rather, it needs to be inferred from the findings. For example, an early study of test-taking strategies investigated test method effect in English as a foreign language (EFL) reading by 428 Israeli 10th grade students (Gordon, 1987). The researcher used four response formats:

- multiple choice questions in English,
- multiple choice questions in Hebrew,
- open-ended questions in English, and
- open-ended questions in Hebrew.

A subgroup of 30 respondents were asked to verbalize their thoughts while they sought answers to each question, which is a useful means of determining test-taking strategy use. Low proficiency students were found to process information at the local (sentence or word) level, without relating isolated bits of information to the whole text. They used individual word-centered strategies like matching alternative words to text, copying words out of the text, word-for-word translation, and formulating global impressions of text content on the basis of key words or isolated lexical items in the text or in the test questions. High proficiency students were seen to comprehend the text at the global (text) level—predicting information accurately in context and using lexical and structural knowledge to

cope with linguistic difficulties. As to performance, open-ended (rather than multiple choice) questions in the L2 (English) were found to be the most difficult and the best discriminator between the high and low proficiency students, since the latter had difficulty with them.

So, reading between the lines, as long as the low proficiency students in this study were given multiple choice items that they could correctly answer at the local, word, and sentence level, they were more likely to respond correctly than if they were given items taxing their comprehension at a more global level. Also, open-ended questions to be answered in the native language of the respondents (so that they could not simply lift material from the L2 passage) were more likely to reveal limitations in text comprehension experienced by the less proficient students.

In a study aimed directly at test-wiseness strategies, the focus was on the ease with which multiple choice questions on an EFL reading comprehension test could be guessed. The study investigated the success possible if respondents were not given more than the title and opening paragraph of a text (Israel, 1982). The respondents were 25 high proficiency and 32 intermediate proficiency students taking the 2-hour-per-week and 6-hour-per-week EFL course respectively. The exam used was the end-of-year one from the previous year. There were 12 questions, none about the included paragraph. There was also a questionnaire regarding the task itself. Students took up to 40 minutes to do the task. If students took less than 5 minutes, their tests were eliminated. The results were as follows on a test for which 60 was a passing score:

- 2-hour students: a mean of 49 without the text, and 77.3 two weeks later with the passage; and
- 6-hour students: a mean of 41.2 without the text, and 62.3 two weeks later with the text.

One of the 2-hour students got a 10 (out of 12) and another an 8, while four of the 6-hour students got an 8. The conclusion was that the test was assessing more than reading comprehension. When a closer look was taken at the item behavior for these 57 respondents, it was found that for 7 of the 12 items, one or more distracters did not attract responses at all. Five of the items referred respondents to lines in the text, but a careful analysis of these items revealed that it was unnecessary to go to the text in order to respond correctly. The respondents reported that the first paragraph gave them the meaning of the passage. Given their experience with this task, half of the respondents indicated that they preferred questions that were not multiple choice.

Since there were four choices for each item, the results from guessing alone should have produced a mean score of 25%. The results obtained showed that the more proficient students, in particular, did far too well on the items to have done so by chance. Even some of the less proficient students almost passed the test. The items were simply too guessable, with too many clues to the right answer, and did not necessarily require the respondents to understand the text at all.

A more recent study investigated the impact of test-wiseness—identifying and using the cues related to absurd options, similar options, and opposite options—in taking the (old) Test of English as a Foreign Language (TOEFL) (Yang, 2000). First,

390 Chinese TOEFL candidates responded to a modified version of Rogers and Bateson's (1991) Test of Test-Wiseness (TTW) (see Yang, 2000, pp. 58–61) and the TOEFL Practice Test B (Educational Testing Service, 1995). An item analysis of the TTW results for a subsample of 40 led to the selection of 23 respondents who were considered "test-wise" and another 17 who were deemed "test-naive." All students were asked to provide verbal reports about the strategies that they were using while responding to a series of test-wiseness-susceptible items selected from the TTW and TOEFL. It was found that 48–64% of the items across the Listening and Reading Comprehension subtests of the TOEFL Practice Test B were identified as susceptible to test-wiseness strategies. It was also found that the test-wise students had a more meaningful, thoughtful, logical, and less random approach to the items than did the test-naive students—which meant that they also had better test-management strategies. In addition, these students were more academically knowledgeable and used that knowledge to assist them in figuring out answers to questions. Finally, they expended greater effort and were more persistent in looking for test-wiseness cues, even when it involved subtle distinctions. This study serves as a reminder that we need to keep performing test-wiseness studies as a means of checking whether tests are giving away the answers to items.

Research on Test-Management Strategies

Now let us consider research demonstrating that even if respondents are using test-management strategies rather than test-wiseness strategies, they may still not be exercising the cognitive processes that the test constructors deemed "necessary" for obtaining correct answers on given items. This reality underscores the value of doing research to determine just what strategies the learners are, in fact, using in order to produce their responses. We will consider a study that had this finding.

The study was undertaken in order to describe the reading and test-taking strategies that test takers used with different item types on the Reading subtest of the LanguEdge courseware materials (Educational Testing Service, 2002), developed to familiarize prospective respondents with the TOEFL Internet-based test (iBT) (Cohen & Upton, 2007). The investigation focused on strategies used to respond to more traditional *single-selection* multiple choice formats (i.e., *basic comprehension* and *inferencing* questions) as opposed to what were considered to be more innovative *multiple selection* multiple choice formats. The latter were referred to as *reading-to-learn* items, involving selection of more than one alternative using a drag-and-drop procedure. The reading-to-learn items were designed to simulate the academic task of forming a comprehensive and coherent representation of an entire text, rather than focusing on discrete points in the text. One of the reading-to-learn formats had as its purpose to measure the extent to which L2 readers can complete a prose summary through questions that are referred to as multiple selection multiple choice responses. It entailed the dragging and dropping of the best three (out of five) descriptive statements about a text. The aim of the study was to determine whether the TOEFL iBT was actually measuring what it purported to measure, as revealed through verbal reports.

Verbal report data were collected from 32 students, representing four language groups (Chinese, Japanese, Korean, and Turkish), as they did tasks from the

Reading subtest in the LanguEdge courseware materials. Students were randomly assigned to complete two of the six reading tasks, each consisting of a 600–700 word text with 12 or 13 items, and subjects' verbal report accompanying items representing 10 different item formats was evaluated to determine strategy use.

The findings indicated that while in principle the reading-to-learn item types did require an understanding of the major ideas in longer texts, in reality the completion of these items was greatly facilitated by the fact that they were always the last items in the test. Since examinees had already read the passage—at least significant parts of it—several times in order to answer the preceding 11 or 12 items, they actually found the reading-to-learn items relatively easy. They had become quite familiar with the passage and the key ideas because of their efforts to answer all the other items that always came before them, and in addition, they merely selected statements that had been prepared for them rather than having to generate their own summary statements of the key ideas. Hence, whereas the aim may have been to construct academically demanding items (e.g., requiring strategies for retaining ideas in working memory, for identifying markers of cohesion, and for perceiving the overall meaning), the reality was that respondents rarely reported using the test-management strategy of “whole-passage processing” while working through these items. Subjects had no need to use the presumed reading-to-learn strategies of looking at the reading afresh, summarizing in their heads the key ideas and the text organization, and then moving to the test item to find the answer that matched the understanding they had in their heads.

So the findings from this study would, indeed, underscore the importance of finding out just what is entailed in responding to test items, beyond the assumed testing objectives.

Challenges for Researchers

Although it is difficult to determine for any given testing task, testing specialists would want there to be a meaningful link between reasoned, on-task strategy use and performance on the language measures in terms of outcomes. Research, then, would presumably monitor the extent to which items and procedures call for the use of test-management strategies in the response process, rather than being susceptible to the use of test-wiseness strategies that allow respondents to avoid processing the language material. In an effort to ensure the validity of their tests, assessment specialists would benefit from knowing just which strategies are likely to result in the correct answer, which depends in part on respondents' characteristics, the particular test involved, and the context for language assessment.

Test preparation courses aimed at improving test takers' scores on language tests are likely to promote (however inadvertently) the use of test-wiseness strategies, since their intent is to arm respondents with strategies for figuring out the right answer as effortlessly as possible. The worrying issue is whether this approach is encouraging respondents to circumvent the use of their language skills in favor of certain shortcuts that may still produce correct answers. In a study of 43 students at a coaching school in Taiwan, for example, it was found that low scorers on a standardized test tended to focus on word-level strategies

and to use this set of strategies as a way of answering reading comprehension questions, as well as by following the test-taking strategy instruction from the coaching school mechanically. It was only the high scorers who were able to focus on their understanding of the given reading passage, and to use the strategies taught by the coaching school only as an auxiliary to comprehension (Tian, 2000).

The high scorers were the ones who expressed a need to personalize their test-taking strategies. For example, they were the ones who tended to mobilize test-management strategies on occasion to support themselves in the response process, rather than relying on test-wiseness strategies as a crutch to substitute for the sound use of language skills. It is possible that test-taking strategy instruction may be conceived of as a means for a quick fix, and, in fact, some test preparation programs may promote the cutting of corners. The consequence could be that clever respondents are able to use test-wiseness strategies in moderation and consequently to get enough unknown items right to pass a language test without actually being able to function in the language.

Future Directions: Ensuring Assessment of Language Skills

The ultimate concern is not to give respondents high marks in language performance when in reality their grasp of the language skills is at best mixed. The consequence of inflated performance due to vulnerable tests is that people ill-prepared to tackle programs of study or jobs involving a use of the L2 are given a go-ahead, and then, when it is too late, their lack of language skills is subsequently noted. In such instances, the test has not performed its legitimate gatekeeping function.

Such inflated performance is more likely to show up in listening and reading tasks than in speaking or writing ones, since test-wiseness strategies are best applied to the former two types of items and not to the latter. The best way of guarding against having respondents avoid having to display their true language abilities would be to construct items and tasks that genuinely require the use of various language skills in order to produce correct responses; that is, that are not susceptible to test-wiseness strategies. So we need first to collect data that accurately reflect what respondents do to respond to items and tasks, and then to construct items and tasks that require the use of language skills in order to produce correct answers. Respondents could specifically be told to do what they normally do, including whatever test-wiseness strategies they may wish to use.

In this section, we will first look at data-collection procedures and then consider efforts to make items more resistant to test-wiseness strategies.

Data-Collection Procedures: The Use of Verbal Report

Verbal report became a primary research tool for collecting data on test-taking strategies in the early 1980s (see Cohen, 1984). Verbal reports include data reflecting one or more of the following approaches:

1. *self-report*: learners' descriptions of what they do, characterized by generalized statements, in this case about their test-taking strategies—for example, "On

- multiple choice items, I tend to scan the reading passage for possible surface matches between information in the text and that same information appearing in one of the alternative choices”;
2. *self-observation*: the inspection of specific, contextualized language behavior, either introspectively, that is, within 20 seconds of the mental event, or retrospectively—for instance, “What I just did was to skim through the reading passage for possible surface matches between information in the text and that same information appearing in one of the alternative choices”;
 3. *self-revelation*: “think-aloud,” stream-of-consciousness disclosure of thought processes while the information is being attended to—for example, “Hmm—I wonder if the information in one of these alternative choices also appears in the text.”

While verbal report continues to play a key role in test-taking strategy research, there have been changes in procedures for conducting such verbal report, aimed at improving the reliability and validity of the results. One change has been to provide a model for respondents as to the kinds of responses that are considered appropriate (e.g., Cohen & Upton, 2007), rather than to simply let them respond however they wish, which has often failed to produce enough relevant data. In addition, researchers now may intrude and ask probing questions during data collection (something that they tended not to do in the past), in order to make sure, for instance, that the respondents indicate not just their rationale for selecting “b” as the correct alternative in multiple choice, but also their reasons for rejecting “a,” “c,” and “d.” Respondents have also been asked to listen to a tape-recording or read a transcript of their verbal report session in order to complement those data with any further insights they may have (Nyhus, 1994). The bottom line is that verbal report does not constitute one approach, but rather is the vehicle for a number of different approaches.

Another innovation in research is the use of software that assists in data collection. Screen recordings were used to track the development of pragmatic strategies by learners of Spanish (Sykes & Cohen, 2008). In order to better understand learner strategies for participating in role plays involving L2 pragmatics in a three-dimensional, virtual environment created specifically for assessing Spanish L2 pragmatics, all online activity was recorded using Camtasia screen capture software (www.techsmith.com/camtasia.asp). In another study, to investigate the use of test-taking strategies on a practice test of English as a second language (ESL) listening comprehension (LanguEdge Listening Test 2), the performance of the participants was recorded on video using a software program, Morae (www.techsmith.com/morae.asp), that records and indexes both screen capture and video of students’ test-taking behavior (Douglas & Hegelheimer, 2007). Thus, while the participants were working on the test, the researchers were able to watch remotely what was happening on and offscreen and to insert comments (e.g., when students took notes, referred to notes, or hesitated). These observations helped the researchers gain insights into the verbal report data and begin to form a conceptualization of the eventual coding scheme. The verbal reports of the participants were transcribed by the research assistants.

More recent efforts at tracking have become more sophisticated. Seedhouse and Almutairi (2009) reported on an approach that combined task-tracking hardware and software, video recording, and transcription. According to the researchers, this holistic approach allows for numerous elements of behavior to be included in the analysis. Micro-analyses of multimodal data can then be undertaken, which can provide insights into the processes of task-based learning.

Clustering of Strategies and Challenges in Categorizing Them

An important finding from a study by Nikolov (2006) was that test-taking strategies tend to occur in combination with others and that verbal report is needed to better understand these strategy clusters. For example, in her study, “reading the text in English” and “translating” were often combined with “phonetic reading of unfamiliar vocabulary items.” Also, respondents varied as to how they used metacognitive strategies to approach the different tasks. For example, they tended to check the instructions for several tasks but neglected to do so for the others, or they read the example first in the first task and then proceeded to respond to the rest of the items without paying attention to the rubrics or the example in other tasks. Given the individual variation, Nikolov found that efforts to categorize the data were highly problematic, as many strategies overlapped and other strategies could actually be subdivided. Also with regard to strategy sequences or clusters, a survey of language learner strategy experts underscored the fact that strategies are often used in combination (Cohen, 2007b, pp. 35–6), even though they are often treated in the literature as if they occurred in isolation.

Design of Items Impervious to Test-Wiseness Strategies

It is a real challenge to design items and tasks that provide no clues as to how to respond. In fact, if the test constructor’s concern is to support respondents in doing the best they can on the assessment measure, in the spirit of *dynamic assessment*, then perhaps some clues should be given, but ideally without opening the door to the unbridled use of test-wiseness strategies.

It is possible to watch out for certain things in the design of the items and tasks. Since there is a multiplicity of different formats, it would be impossible to provide a one-size-fits-all, formulaic description of what test constructors need to guard against. But as a sampling, here are possible guidelines for the construction of multiple choice reading comprehension items so that respondents are less likely to use test-wiseness strategies to outsmart the items and tasks:

- Make sure that there are no giveaway clues in the wording of the question, in order that respondents need to go back to the passage itself in order to find relevant information.
- Check that words and phrases in the question prompts are contextual paraphrases of material in the text, rather than the same wording, in order to guard against surface matching of a word or phrase in one of the alternatives with the same word or phrase in the passage.

- Check that no question can be answered purely on the basis of knowledge of the world, ensuring instead that the respondents need to verify information from the text itself (e.g., the author's opinion on some issue, rather than what is common knowledge).

Here are some sample guidelines for the construction of multiple choice listening comprehension items:

- Verify that none of the alternatives have material (e.g., key words, specific details like names and dates) that is a direct match with material in the listening passage.
- Make sure that a prior question does not give away the correct response to a current item.
- Check that the level of detail provided in one or other alternative response does not serve as a clue to whether that alternative is correct, ensuring instead that the same amount of detail is given in all alternatives.
- Make sure that the alternative is not a giveaway based on knowledge of the world.

The reality is that items on a test are likely to be inter-related. So responding to one item may contribute to the correct response on another (see Chapter 48, Writing Items and Tasks). The issue here for a test constructor is to make sure that responses on subsequent items entail some language processing (e.g., the comprehension of certain vocabulary or grammar, or even their correct use pragmatically), rather than being susceptible to a test-wiseness strategy such as “the alternative I selected had the same difficult word in it as in the alternative I chose for the previous item, so that's why I chose it.”

Using Standards and Guidelines

Nick Saville

University of Cambridge, ESOL Examinations, England

Introduction

Practices related to *standards* have been with us since the emergence of trades and guilds in the Middle Ages. However, industrial and scientific advancements in the 20th century raised the importance of *maintaining* standards, and more recently the focus has shifted to *improving* standards and to the notion of *continual improvement*.

This chapter will discuss the notion of standards in the context of assessment in general and will consider in particular its relevance within the field of language testing since the 1980s. Starting with a historical overview of the development of standards in educational assessment and in psychological testing, it will give consideration to contemporary approaches related to language testing. In defining what is meant by *a standard* in this context, it will cover related notions, such as accountability and responsibility—both personal and institutional or in society at large. These considerations highlight the need for assessment systems to be based on sound ethical principles and for societal values related to fairness and justice to be effectively addressed by test developers and other interested parties (Messick, 1980; Davies, 2004).

There is another important dimension that also needs to be considered: this is the way in which explicitly stated standards can help guide professional practices and contribute to the effective management of organizations responsible for developing and validating assessment systems. In this sense, finer-grained interpretations are required in order to set out *explicit guidelines* and work instructions. This highlights the need for test developers to set out procedures that enable practitioners to carry out their work effectively and allow the stated standards to be met in practice. The recent application of *quality management systems* (QMS)

to assessment will be discussed in this context. It is argued that an approach to achieving standards based on QMS principles can contribute effectively to a *validation argument* (Kane, 2006) and also address the *fairness* considerations noted above (Kunnan, 2000).

In the USA in particular, there was a movement to develop common standards and related guidelines in the fields of educational and psychological testing, starting with a number of technical documents produced by the American Psychological Association (APA) in 1954 and then continuing with subsequent publications until the latest version of the *Standards for Educational and Psychological Testing* in 1999 (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999). The influence of this Standards document and its approach to setting standards is discussed below—including ways in which it has helped major testing agencies and examinations boards with a broad remit for educational assessment to develop their own standards in various educational contexts and assessment traditions. For example, leading agencies on both sides of the Atlantic, such as Educational Testing Service (ETS) in the USA and Cambridge Assessment in the UK, publish documents that take into account the APA Standards and draw on the approach in different ways, for example *ETS Standards for Quality and Fairness* (Educational Testing Service, 2002), *The Cambridge Approach* (Cambridge Assessment, 2009), and Cambridge ESOL's *Principles of Good Practice* (University of Cambridge, ESOL Examinations, 2011). In these cases the stated purpose in adopting standards and related principles is to support their *core values* (or mission) in delivering useful products and services.

Language testing, on the other hand, is relatively young as an academic discipline and only began to develop as a profession in the 1970s. Since then it has gradually expanded, and numerous language-testing organizations and professional associations have been formed in different parts of the world. As a result of their work, several *codes of ethics*, *codes practice*, and *guidelines* have been developed with specific reference to language assessment. Most have drawn on the APA Standards as well as on documents related to it, such as the *Code of Fair Testing Practices* (Joint Committee on Testing Practices, 1988/2004) and other approaches to establishing standards coming from different sources (e.g., quality management in education). Such approaches include the *Code of Ethics* and the *Guidelines for Practice* developed by the International Language Testing Association (ILTA) (International Language Testing Association, 2000 and 2007); the *ALTE Code of Practice* and the quality management system (QMS) developed by the Association of Language Testers in Europe (ALTE) (Association of Language Testers in Europe, 1994, 2003a, 2003b); the code of practice of the Japanese Language Testing Association (JLTA); and the *EALTA Guidelines for Good Practice in Language Testing and Assessment* developed by the European Association for Language Testing and Assessment (EALTA) (European Association for Language Testing and Assessment, 2006). These are discussed below, within a suggested framework for considering the issues that arise both in setting and in monitoring standards for language testing. The potential for using quality management systems is discussed in the course of our linking principles to practice and ensuring compliance with stated standards.

Definition of Terms: What Is a Standard?

For the purposes of this chapter, it is important to define from the outset what is meant by standards.

The following eight key points are based on information provided by the British Standards Institute (BSI), the world's oldest national standards body (NSB), established in London, 1901, and still an authoritative voice in this field. Standards, then,

- are agreed-upon ways of doing things;
- are based on shared knowledge within a community of practice;
- provide the basis for clear guidelines and instructions;
- form an authoritative publication;
- are updated periodically in line with changes in society;
- constitute the basis for monitoring practice;
- are regulated by self-/peer-monitoring to check compliance (usually on a voluntary basis);
- are used within regulatory systems where compliance is a legal requirement. (Information retrieved February 28, 2013 from the BSI website: www.bsigroup.co.uk/standards/Information-about-standards/what-is-a-standard/)

BSI defines a standard in the following way: "Put at its simplest, a standard is an agreed, repeatable way of doing something."

In practice, a standard is often written as a technical specification that makes reference to *precise criteria* and provides the basis for explicit *guidelines* and work instructions. These detailed documents help to ensure that activities are carried out consistently. When "ways of doing things" are collected and put together, they are often published in a *document* referred to as "the Standards" for a particular area of activity or expertise.

The BSI website makes it clear that standards are developed *within* a community of practice in order to make life simpler and should be considered as a collective work. Standards are created by bringing together the experience and expertise of all interested parties such as the producers, sellers, buyers, users and regulators of a particular material, product, process or service.

As the demands of society change over time, the interested parties need to review and change the standards they are working with (in other words standards are not set in tablets of stone). This is particularly relevant in *technical areas*, where advances in scientific knowledge or technology provide new ways of doing things, but changing *social practices* also need to be taken into account. It is therefore common to come across documentation that bears version numbers and dates indicating when the standards were written or updated.

Another important question that often recurs is: *Who regulates the standards?* The BSI suggests that standards are designed for voluntary use and do not impose any regulations. However, laws and regulations may refer to certain standards and make compliance with them compulsory.

As noted, the standards themselves usually arise from needs that have been identified *within* a community of practice. This community may be a single

institution (as in the case of examinations boards), but frequently it is formed by a wider group of interested parties with representation from different institutions or geographical locations or both (e.g., language-testing associations). Professional bodies often establish regulations related to standards as a requirement for membership, and monitoring may be carried out through self-evaluation, peer review, or *auditing*.

Within a country or region, legislators may introduce standards and seek to make compliance a legal requirement within their jurisdiction. In such cases the regulatory regime will depend on the political and legal framework in operation, and sometimes this will involve *inspections* and other formal mechanisms for checking on practice.

If compliance is compulsory, this usually happens because there is a concern for *public accountability* and a need to ensure that citizens are not put at risk as a result of inadequate standards. Public safety is a particular concern when a product or service is potentially dangerous, and hence many activities are carefully regulated; for example electricians need to be accredited to guarantee professional standards of competence; cycle helmets need to conform to manufacturing standards to ensure resistance to impact; and so on. Because language tests are now known to have serious consequences for users, accountability has become increasingly relevant for language testers.

The question of *who* carries out the regulation is an important consideration; it may be the case that only other members of the same community of practice are qualified to judge whether the standards are being met. This is often the case where advanced technical knowledge is required (e.g., in the medical profession). The dilemma that frequently arises is expressed in the age-old question formulated by Juvenal: “Who guards the guards themselves?” (*Quis custodiet ipsos custodes?*).

Specialized standards organizations like the BSI can also be used to audit and evaluate other bodies. In such cases compliance may be judged in relation to standards that are set internationally, by bodies such as the International Organization for Standardization. For example, as BSI point out: “Electrotechnical standards are harmonized internationally by the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC).”

This general discussion of standards sets the scene for considering issues that arise in educational assessment, and specifically for language testing. It is clear from what has been already said that the setting and monitoring of standards relates not only to technical issues, but also to social practices (including attitudes and behaviors)—adopted either across society as a whole or within particular communities or organizations. The importance of working with relevant communities of practice in order to identify specific needs and to define the necessary parameters for standards is also clear; in educational assessment there is a long history of doing this, but in language testing most developments have occurred only since the 1980s. This is reflected in the discussion that follows.

In summary, when one applies to assessment the concept of setting standards, one should be concerned with the exercise of judgment in defining and setting relevant criteria; the implementation of transparent processes and procedures to

produce useful testing systems; and the evaluation of practice to ensure that all stakeholders are treated fairly and are not put at risk.

Historical Overview and Conceptualization

Although the impetus for standards within educational assessment developed in the 20th century, the concept of setting educational standards can be traced back to the late 1800s. This was the period that saw the first public examinations within school-based education and for the selection of candidates qualified to enter the professions, for instance the civil service or the teaching profession (Roach, 1971). Early considerations of validity and reliability (Latham, 1887) led to the use of statistics to account for the uncertainty of outcomes in public examinations in England; good examples are Edgeworth's papers on "The Statistics of Examinations" (1888) and "The Element of Chance in Competitive Examinations" (1890).

In the 20th century the development of psychological testing for measuring intelligence, personality, aptitude, and the like saw a growing need for the *technical features* of assessment to be systematically controlled and monitored (Haney & Madaus, 1991). This kind of monitoring was already happening in the growing field of psychometrics by the 1950s, and it was a committee of the APA that produced an early version of the Standards, in a document entitled *Technical Recommendations for Psychological Tests and Diagnostic Techniques* (1954). Subsequent publications were largely the result of the collaboration between three sponsoring organizations that represented a wide community of practice in the USA: the APA itself, together with the American Educational Research Association (AERA) and the National Council on Measurement in Education (NCME). New versions were published periodically between 1955 and 1999, and in keeping with this trend the next revision is expected sometime after 2012 (see Camara & Lane, 2006).

The approach adopted by the APA and the development of its Standards over an extended period have been extremely influential in North America, and a wide range of participants in education and measurement have helped to develop the Standards as the field has advanced. Both the 1985 and the 1999 versions were extensively reviewed and discussed at conferences by the assessment community (e.g., Davidson, 2000). In some other parts of the world, professional bodies also took a lead from the USA and adapted the APA Standards for their own purposes. The latest version, of 1999, has probably been the most influential so far and has certainly had an impact on recent developments in language testing (e.g., on the codes of practice and guidelines mentioned above).

Advancements in educational measurement in the 1980s, as well as important changes in the legal and social contexts that determine how test scores are used, suggested that the 1985 Standards needed to be revised in order for some important innovative features to be implemented. In 1991 the sponsors decided to go ahead with the next revision and, after a wide-scale consultation process coordinated by their joint committee between 1993 and 1995, an updated and expanded version was published in 1999. The new version, although still written with assessment professionals in mind, also seeks to make the discussion of key

topics more accessible to other interested parties, who may not have specific training in measurement or psychometrics. This revised treatment reflected changing attitudes towards assessment, including a greater concern for the social and legal considerations surrounding the use of assessment in society, as reflected in the need to accommodate diversity—say, test takers with various disabilities or with different L1 backgrounds. The revision also accounted for new item and test types (e.g., computer-administered tests), as well as for innovative uses of tests and for important developments in validity theory, which were influenced in particular by the work of Messick. Without undermining the importance of technical standards, Messick (1989) shifted attention to important issues not included in earlier approaches, for instance the *social consequences of assessment*—especially the consequences of decisions made about individuals on the basis of their test scores.

Noteworthy changes and additions to the 1999 version are the addition of background material in each chapter, a larger number of standards overall, and an expanded glossary. All of these features helped make the 1999 *Standards* more accessible and extended the focus to a wider range of social concerns. These changes highlight the importance of communication and the need to explain assessment issues to an expanding range of stakeholders and participants. In the decade since the publication of this version, the social dimension of assessment has continued to be discussed in the literature. The challenge is now to set standards that deliver technical excellence and also meet societal expectations in the 21st century. Future versions of the Standards are likely to reflect this trend.

In the next section the 1999 *Standards* volume is outlined in greater detail, partly to exemplify the range of topics for which assessment standards can be set, and partly to illustrate how standards are worded if this approach is followed.

In the Preface and Introduction to the 1999 *Standards* (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999, pp. 1–5), the revisions and significant changes are highlighted. The main text is then divided into three main parts, comprising 15 chapters altogether. Each individual standard is set out in the form of a brief statement, usually in one or two succinct sentences supported by an explanatory comment. This approach was employed in the earlier versions and has been adopted by other organizations, which have developed their own standards on the basis of the APA/AREA/NCME model (see for example Educational Testing Service, 2002).

For example, Standard 1.2 in the 1999 *Standards* (p. 17) dealing with validity states:

The test developer should set forth clearly how test scores are intended to be interpreted and used. The population(s) for which a test is appropriate should be clearly delimited and the construct that the test is intended to assess should be clearly described.

The supporting comment in this case makes it clear that it is incorrect to use the unqualified phrase *the validity of the test* and that no test is valid for all purposes or in all situations.

Altogether there are 264 statements of this kind; this represents a significant increase by comparison with the 1985 version, which has only 167 standards.

Part 1 deals with test construction, evaluation, and documentation and covers the traditional technical standards in six chapters. The key concepts of measurement and the central issues of validity and reliability are dealt with in this part. By comparison with the 1985 version, this one includes additional information on test administration, scoring, and reporting. The six chapters are as follows:

- Validity: 24 standards;
- Reliability and Errors of Measurement: 20 standards;
- Test Development and Revision: 27 standards;
- Scales, Norms, and Score Comparability: 21 standards;
- Test Administration, Scoring, and Reporting: 16 standards;
- Supporting Documentation for Tests: 15 standards.

Part 2 deals with fairness in testing in four chapters, as follows:

- Fairness in Testing and Test Use: 12 standards;
- The Rights and Responsibilities of Test Takers: 13 standards;
- Testing Individuals of Diverse Linguistic Backgrounds: 11 standards;
- Testing Individuals with Disabilities: 12 standards.

This part is noteworthy for its extensive discussion of fairness in relation to the *use* of test scores—not present in earlier versions—and for the discourse used to discuss *diversity issues* in relation to individual characteristics of test takers. For example, the focus on widening test takers' participation by providing adequate accommodation for those with special requirements (such as physical disabilities) reflects changing social attitudes generally and takes into account civil rights legislation specifically designed to reduce unfair discrimination (e.g., in the USA, the Americans with Disabilities Act, 1990).

Part 3 deals with testing applications in five chapters, as follows:

- The Responsibilities of Test Users: 24 standards;
- Psychological Testing and Assessment: 20 standards;
- Educational Testing and Assessment: 19 standards;
- Testing in Employment and Credentialing: 17 standards;
- Testing in Program Evaluation and Public Policy: 13 standards.

This part discusses the specific standards that need to be set when developing and using tests for specific contexts and purposes (an increasingly important trend). Chapter 11, on the responsibilities of test users (pp. 111–18) is a particularly important innovation; unlike most other chapters in the volume, which place emphasis on the responsibilities of those who instigate assessment programs and develop tests, this one sets out standards related to the *use of test scores* and to the responsibilities of those who make decisions on the basis of these scores. This reflects a widely held view, partly in response to Messick (1989), that the responsibility for fair outcomes in testing must be shared by a wide range of participants in

education and in society. The *Code of Fair Testing Practices in Education* (Joint Committee on Testing Practices, 1988/2004), first developed on the basis on the 1985 *Standards* by the Washington, DC Joint Committee on Testing Practices, illustrates this shared responsibility. This code addresses the *roles of different participants* in assessment processes and highlights their *joint responsibility in striving for fairness*. The key participants identified here are test developers, sponsors, and test users. Test *developers* are examinations boards or testing companies and their staff (e.g., test designers, item writers, administrators, raters, examiners); *sponsors* consist of government departments and similar bodies, which mandate and sometimes finance the development of assessment systems. Test users are categorized as *primary and secondary users*: the primary users are the test takers themselves; secondary users include the sponsors of the test takers (teachers, parents, employers, etc.) and test score users such as schools, universities, companies, government departments, immigration agencies, and so on.

The JCTP *Code* has also been influential in the development of other codes of practice, for instance *The ALTE Code of Practice* (Association of Language Testers in Europe, 1994).

A Framework for Setting Standards in Language Assessment

Our discussion of standards in educational assessment provides a backdrop for considering the same issues in contexts in which language tests are being developed and used. The example of the 1999 *Standards* shows how a wide community of assessment professionals considered the issues over a long period during the 20th century and how standards have been set out and used in practical ways following that approach. That example shows how developments in measurement theories and changes in the world around us have impacted the kinds of standard that are needed in 21st-century contexts. In addition, a central consideration in setting language-testing standards is the extent to which the knowledge or skill being assessed can be defined with precision for the purposes of assessment. In this respect, the nature of language itself and the definition of the core language constructs pose significant challenges.

While standards ideally represent agreed upon ways of doing things in specific contexts, they are often associated with controversies and debates over key concepts. So, for example, while construct validity was adopted in the 1999 *Standards* as a replacement for the traditional three-way distinction of *criterion-related validity*, *content validity*, and *construct validity*, the unitary conceptualization has been challenged and is not universally accepted (Embretson, 2007). A discussion of validity theory is beyond the scope of this chapter, and readers are referred to other entries in this volume; the point here is that a community of practice must develop a well-argued case for adopting a particular approach with reference to the relevant literature and must be able to demonstrate how and why standards based on that approach are suitable for their intended context and purpose.

A possible framework for considering the relevant issues is summarized under the following five bullet points:

- ethical considerations;
- principles of good practice and related guidelines;
- quality management and auditing of processes;
- setting and monitoring standards;
- compliance and regulation.

These points reflect the development of the field of language testing over a period of 30 years and move from general to specific considerations—in other words, from broad ethical considerations, which underpin professional behavior, to specific and auditable activities in the development and use of language tests. It is the latter that can be scrutinized and judged to be adequate (or not) for a given purpose.

It can be argued that standards for language testing have only emerged since language testing became recognized as a subfield of applied linguistics in its own right. The formation of the Language Testing Research Colloquium (LTRC) in 1979 was particularly relevant. The first Colloquium was formed by a group of applied linguists from several countries, with varied perspectives on language testing; and it occurred at a time when important questions were being raised about the nature of language ability and how it could be assessed effectively. Since then, LTRC has provided a forum for the discussion of language constructs and how to set professional standards in assessing them. In particular, it led directly to the setting up of the International Language Testing Association (ILTA) in Vancouver in 1992, and it strongly influenced other national and regional associations around the world. These communities of practice have been instrumental in developing codes of practice and guidelines.

Soon after the ILTA was formed, a task force was established to carry out an international survey of language-testing standards and to produce a report that would provide for exchange of information on standards and for development of a code of practice for ILTA. Members of the task force made contact with individuals involved both in language testing and in the broader domain of educational assessment in countries around the world, and this resulted in the collection of over 100 documents on standards from about 25 countries. These documents were described in an ILTA report of 1995, entitled *Task Force on Testing Standards* (TFTS) and presented in bibliographic format; this report is available online from the Educational Resources Information Centre (ERIC). In its conclusions, the task force recommended that a TFTS group pursue the idea of “setting world standards in language testing,” beginning with a definition of the term “standard” and the compilation of a dynamic and ongoing database. While this ambition has yet to be fulfilled, it has led to the adoption of a *Code of Ethics* (International Language Testing Association, 2000) and *Guidelines for Practice* (International Language Testing Association 2007) by ILTA’s members and institutional affiliates (see also www.ilta.org).

ILTA’s *Code of Ethics* was extensively discussed in the 1990s by the association’s members under Alan Davies’ guidance and was eventually published in the *Language Testing Update* in 2000. This document outlines the broad principles of professional behavior expected of those involved in language assessment and addresses actions that should be taken in order to achieve social justice and

fairness for all. The aim was to encourage ethical standards among members and to promote an ethical milieu among language assessment professionals around the world.

The *Code of Ethics* presents “the morals and ideals” of language testing as a profession in the form of *nine principles with annotations*, mainly addressed to *individuals* who consider themselves to be professional language testers, whether they work for language-testing agencies, as academics, or as other professionals in the field of assessment. The principles are intended to guide *good professional conduct* and professional language testers are encouraged to strive for fairness, to act in good faith, and to avoid negative impacts. In summary, language testers should:

- 1 show respect for humanity and dignity;
- 2 use judgment in sharing confidential information;
- 3 adhere to ethical principles in research;
- 4 avoid the misuse of their professional knowledge and skills;
- 5 continue to develop their knowledge and to share this with others;
- 6 share responsibility for upholding the integrity of the profession;
- 7 strive to improve the quality of language testing and awareness of issues related to language learning;
- 8 be mindful of obligations to society;
- 9 consider the effects of their work on other stakeholders.

JCTP’s *Code of Fair Testing Practices in Education* (1988/2004) and other guidelines derived from it bear similarities to ILTA’s *Code of Ethics* in being very general and aimed at a broad audience. For example, *The ALTE Code of Practice* (Association of Language Testers in Europe, 1994) is similar in sentiment to the *Code of Ethics*; it differs, however, in that it focuses more specifically on the *processes* of developing and using language tests. This is appropriate for an international association with its own community of practice (institutions and individuals), which represents specified language-testing constituencies in a regional context. The *ALTE Code* is based around 18 broad statements covering the development of exams, the issue of results, fairness, and the relationship with test takers. The focus, as in the *JCTP Code*, is on the role of various stakeholder groups in *striving for fairness*.

Neither ILTA’s *Code of Ethics* nor ALTE’s *Code of Practice* was, however, designed to assist language-testing practitioners in carrying out their day-to-day work of writing and administering tests, or in agreeing as to what might be acceptable in terms of standards of quality in their work.

As interest in language testing grew in the 1990s, the need to provide more detailed guidance to aspiring practitioners increased as well, and many textbooks dealing with the basic concepts have been written since then (e.g., Hughes, 2003; Bachman & Palmer, 1996, 2010; Weir, 2005; etc.). In particular, the work of Messick (1989) impacted on construct definition in language assessment and was widely taken up through the influence of Bachman (1990). Understanding *what* should be tested and how to ensure that valid measures are produced was therefore at the heart of the movement to establish standards, and the key *principles of validity* are included in most codes of practice that have been developed. In most cases

these codes follow the example set by the 1985/1999 *Standards* in how the principles are worded and exemplified; see for example ILTA's *Guidelines for Practice* (International Language Testing Association, 2007):

B. Responsibilities of test designers and test writers

1. Test design should include a determination and explicit statement of the test's intended purpose(s).
2. A test designer must decide on the construct to be measured and state explicitly how that construct is to be operationalized.
3. The specifications of the test and the test tasks should be spelled out in detail.

In the *EALTA Guidelines* (European Association for Language Testing and Assessment, 2006), which are specifically designed for use by language teachers, the statements are rephrased as questions, in order to communicate more effectively with the target audience, as in the following example:

TEST PURPOSE AND SPECIFICATION

1. How clearly is/are test purpose(s) specified?
2. How is potential test misuse addressed?
3. Are all stakeholders specifically identified?
4. Are there test specifications?
5. Are the specifications for the various audiences differentiated?
6. Is there a description of the test taker?
7. Are the constructs intended to underlie the test/subtest(s) specified?
8. Are test methods/tasks described and exemplified?

The tone of these questions comes across as more "user-friendly" and less prescriptive. In this format, therefore, the standards are deemed suitable for a less specialized audience and can be used for reflective purposes such as to develop assessment literacy among teachers.

The ALTE and EALTA documents are also available in many languages, as they are designed to be used in multilingual contexts.

Although such codes and guidelines indicate *what* the test designer should do, the ways in which it should be done and the criteria for acceptable quality are not given. For the *how* and the *how well*, practitioners have to look elsewhere for guidance.

A common feature of the textbooks on assessment is that the *process* of designing and delivering tests is conceived of as series of logical steps. Bachman and Palmer (1996), for example, set out to "enable the reader to become competent in the design, development and use of language tests" (p. 3). In his introductory chapter to Downing and Haladyna (2006, pp. 3–25), Downing similarly discusses "a systematic test development model organized into twelve discrete tasks or activities." This suggests that standards that account for the *processes of assessment and the quality of the outcomes* are also needed.

It can be argued that *quality management systems*, by moving beyond ethical concerns and fundamental principles of validity, offer an established paradigm to extend the framework for language testing in order to set and monitor standards. In other words quality management (QM) provides a basis for defining, controlling, and evaluating what gets done in practice. In the next section this topic is developed further. The case is made for adopting a QM approach to help ensure that appropriate professional standards are met. While this is being done, the section discusses the *core processes* required in developing and administering language tests and introduces the kinds of guidelines that are needed in order to implement quality assured systems.

Standards and Quality Management

Quality management is an overarching concept, which is concerned with the management of *processes* within an organization responsible for developing a product or service. It therefore subsumes detailed procedures for checking and assuring quality (i.e., *quality control* and *quality assurance*, which have related but discrete functions). By adopting a QM approach, it is possible to ensure that processes are not only maintained, but also improved, so that standards are raised over time.

In taking this view, language test developers need to adopt the kind of managerial practices that enable successful organizations to implement error-free processes by ensuring that appropriate guidelines and working practices are followed. However, although QM systems are often deployed within larger organizations, the principles can be applied in many different assessment contexts with the aim of *improving* quality, whether the test development team is a group of teachers in a school or specialized staff within a major testing agency. What differs across different contexts is the complexity of the organizational structure within which the assessment activities take place, and also the available resources.

The “quality movement” originated in manufacturing in the early 20th century (Taylor, 1911; Shewhart, 1931), but the approach is now widely employed across many types of organization incorporating concepts such as total quality management (Deming, 1986). It has been extended to the service sector, and recently to educational systems—specifically to educational assessment (Wild & Ramaswamy, 2008; Saville, 2012).

Along with the development of quality in management processes, the notion of *quality standards* has emerged as a mechanism of accountability and as a guarantee for consumers. One of the earliest examples was the BSI (noted above) and its quality “kite mark,” which was introduced in 1903. More recently the most important international influence in this field has come from the International Organization for Standardization (ISO) and its quality standards.

The International Organization for Standardization itself is a nongovernmental organization (NGO) founded in 1947, with headquarters in Switzerland (www.iso.org). It is composed of representatives from national organizations concerned with standards of the kind noted above. The standards are maintained centrally

by ISO but are administered by the accreditation and certification bodies at a national or regional level—for instance BSI; American National Standards Institute (ANSI); Deutsches Institut für Normung (DIN). The “ISO 9000” standards are relevant to educational systems, including test development and administration processes. These are updated periodically so that each standard has the most recent date added to it. “ISO 9001” is now the world’s most widely used standard, which can be applied to all types of organization, no matter what its size is, and 2008 is the most recent update (hence the name of the standard is ISO 9001: 2008).

While regulatory compliance may be a benefit that derives from its use, the main focus of ISO is on “getting the job done properly.” Its purpose is to enable an organization to control its processes, deliver client satisfaction, and focus on continual improvement. Organizations can apply to be independently audited and certified in conformance with the ISO standard in question (such as ISO 9001: 2008 noted above), and, once accredited, they can claim to be “ISO 9001 certified” or “registered.” Accreditation offered by ISO is designed to certify that *processes are being applied consistently and meet the stated objectives of an organization effectively*. This approach to quality management, combined with an appropriate implementation of language assessment principles, has the potential to give a sound basis for the achievement of professional standards (such as those set out in the various codes of practice and guidelines). When adopted and implemented in conjunction with each other, these two elements—quality management and principles of good practice in assessment—can help ensure that assessment systems deliver fair testing practices which meet the needs of users and at the same time meet the regulatory requirements, as set by external regulatory bodies such as a government agency.

Before moving on to consider ways in which principles of assessment can be linked to good practice in order to meet quality standards, it is important to note that the application of the quality management model in education is not without some controversy. Several commentators have flagged up important differences between commercial institutions that strive for standardization and efficiency and educational systems that place higher value on creativity, diversity, and interpersonal relationships. They suggest that there are potential dangers in using the model and that the latter may be at odds with sound educational objectives (Capper & Jamison, 1993).

It is certainly true that care needs to be taken in applying standardized procedures within schools and classrooms. However, if a QM approach is introduced sensitively, the aim should be to empower practitioners to carry out their own roles more effectively rather than to introduce inappropriate conformity and regulation. In the case of language assessment, explicit processes and guidelines of the kind which are central to QM can help any test developer to achieve greater transparency in deciding what to test and how to go about it. In all cases processes need to be developed to meet the specific context and purpose of the test; it is possible therefore to apply aspects of the QM approach to classroom-based assessments, which are designed to have formative purposes and to support individualized learning, without sacrificing the features that are central to the validity of such tests.

Linking Principles to Practice to Meet Quality Standards

An important point for this chapter is that the principles that are laid out in the codes of practice and related guidelines need to be put into practice so that they underpin the day-to-day processes of developing and using tests. The QM model is helpful in that the activities of any organization can be seen as a collection of processes that deliver products or services. In the case of language testing, this would be tests or other forms of assessment. Each process transforms inputs into outputs, and organizations must control the processes, so that the final products/services consistently satisfy the needs of clients (in our case, test users) and other interested parties, including regulatory authorities.

It is necessary to check that processes work as intended and that they are as effective and efficient as possible. Figure 55.1 provides a graphic representation of a generic process showing how inputs are transformed into the required outputs by using the relevant resources and control mechanisms.

If the processes are adequately defined and appropriately documented, the necessary *quality control* and *quality assurance* procedures can be carried out.

In handbooks on language testing, five main stages are commonly found that typically form an assessment cycle as the following:

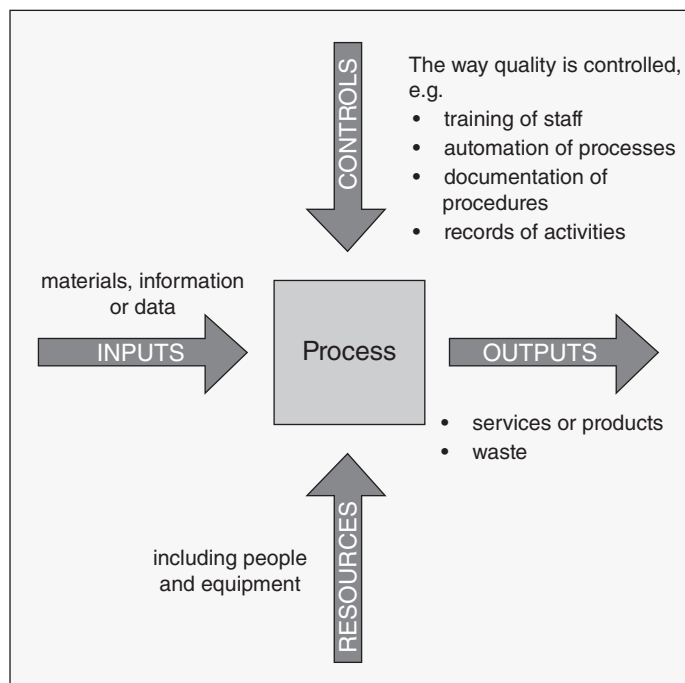

Figure 55.1 A graphical representation of a generic process © Cambridge ESOL Examinations

- planning and design;
- development;
- delivery, including routine test assembly and administration;
- processing, including the issue of results;
- review and evaluation.

These can be considered the *core processes* in a QM approach, and the *outputs* generated include:

- test specifications;
- assessment materials and rating procedures;
- test takers' responses;
- results and interpretive information.

To meet the stipulated standards, *each stage* of the overall process must be controlled for quality by carrying out systematic checks on the work flow. In QM terminology, each process should be described in a *standard operating procedure* (SOP), and specific tasks should be described in detailed *work instructions*. *Quality control* (QC) procedures must focus on the quality of the test materials themselves, including the test items and the rating procedures; the quality of the information and support provided to users; the quality of the documentation needed to administer the tests at the testing venues; the quality of the data collected; and so on. The routine checks are essential to ensure that mistakes are not made that could threaten validity, disrupt test administration, or impact negatively on test takers. These checks must be carried out by qualified people who bear responsibility for the processes, and not by a QC department; and senior members of the organization have the responsibility of *coordinating the links* among individual processes. They must also ensure that the staff are adequately trained in carrying out their tasks effectively.

Quality assurance (QA) activities differ from these checks in that they are carried out to monitor, evaluate, and improve the processes themselves; it is crucial that relevant evidence (data and information) can be collected (e.g., through audits, inspections, formal reviews), so that the evaluation can take place. Taken together, QC and QA procedures ensure that the defined processes are being followed; such procedures provide the necessary information to make improvements.

Saville (2012) discusses quality control and assurance processes in language test development and administration. At the development stage, test specifications and instructions for item writers need to be produced to enable tests to be written and assembled effectively and controlled for quality. Standardized quality control processes include editing and pretesting to ensure that the technical characteristics conform to the specifications. In larger organizations item-banking techniques are needed in order to track progress through the system and to monitor decisions taken about the quality of the material and the work of item writers. Similarly, test developers must ensure that the assessments are administered in a standardized way, as inconsistency and uncontrolled variation pose threats to validity. It is important to ensure standardization between testing venues and to control for quality the administrative procedures under operational conditions. Saville (2012) identifies the following areas to be covered: the physical setting, including the

safety and security of the premises; the storage and handling of confidential materials; the type and number of personnel needed to oversee the administration on the day; the training and management of invigilators/proctors and local examiners; the seating arrangements and the provision of accommodation designed to meet special needs or requirements; the management of the assessment procedures themselves; the handling of unforeseen eventualities. Quality assurance techniques might include *inspections* carried out across a range of venues. Large-scale testing agencies can also employ forensic techniques to identify possible cases of malpractice such as cheating. The continuous improvement cycle central to QM is often characterized as a “plan, do, check, act” model (Deming, 1986). This emphasizes the need for action to be taken after the checking and monitoring has taken place, in order to ensure that improvements are made to operational systems.

In this section we have seen how the QM approach can be incorporated into language assessment to monitor and improve practice with a view to meeting external standards, which in turn can be scrutinized through an audit or inspection. The standards themselves may be based on a code of practice for language assessment, or they may be specified by a standards organization such as ISO.

The codes of ethics and codes of practice now available in the language-testing community set out the specific areas of concern that need to be attended to by practitioners. The focus has been on ethical concerns and on the underlying principles of assessment, which provide necessary conditions for developing high quality tests that meet the expected standards of fairness and accountability. Language-testing practitioners also need to ensure that their assessment systems and underlying processes, which support the day-to-day work of writing and administering tests, can be managed effectively. If one adopts a quality management approach that is itself subject to external scrutiny, the principles of language assessment can be successfully incorporated into operational procedures.

The experience of ALTE illustrates an attempt to do this. On the basis of ALTE’s 1994 *Code of Practice* and 2001 *Principles of Good Practice* (Association of Language Testers in Europe 1994 and 2001), which drew on the 1999 *Standards*, a series of developments were implemented by members of the association to create an explicit basis for agreeing on the standards and on how they would be monitored on the basis of a quality management approach (van Avermaet, Kuijper, & Saville, 2004). In a QM system, standards are not imposed from the “outside” but are established *through the system itself*, and the procedures to monitor standards start with awareness raising and self-assessment in the first instance, in keeping with the BSI view (noted above) that standards are developed *within* a community. However, while the monitoring of standards begins with self-evaluation, such monitoring needs to be supplemented by external inspections or audits. In the case of ALTE, 17 *minimum standards* were established, which are externally scrutinized by an auditing system.

The auditing system was the culmination of a process of establishing a “quality profile” for an examination and it now enables ALTE members to make a ratified claim that a particular test or examination has a quality profile that is appropriate to its context and uses. These claims, together with the supporting evidence, can also be inspected by the competent authorities in order to ensure compliance will legal requirements.

Conclusion

In the future, language test providers will experience increasing demands to offer high quality tests and to account for the quality of their assessment systems with reference to acceptable standards, by adhering to guidelines that are in keeping with good practice. However, the nature of regulation and the problem of *who* is best qualified to set and monitor professional standards still need to be addressed; and it remains an open question to what extent these matters can—or should—lie within the language-testing profession itself. The present chapter has suggested that, whatever the legal jurisdiction, accountability needs to be based on a shared understanding of language-testing principles among the interested parties. The development of an ethical milieu and of higher levels of *assessment literacy* among user groups will therefore become increasingly important. This needs to be coupled with the capacity to develop and maintain high quality processes within organizations; and here the responsibility lies with test providers to develop the specialist knowledge and skills and to employ appropriate quality management techniques to meet the needs of their clients—the test users. As Saville (2012) suggests, a realistic way forward is to ensure that “best practice” models that employ QM techniques are identified and shared in order to help all test providers raise their standards.

Finally, the recent focus on diversity and the growing concerns about the effects and consequences of assessment within society mean that more attention should be given to standards as they apply to different *contexts* and *purposes* of assessment around the world (e.g., geographical variations; classroom vs. external assessment). It can be expected that international language-testing associations and regional forums will continue to play an important role in enhancing awareness and in sharing expertise and know-how. Through discussion and collaboration of this kind, improved mechanisms will emerge for agreeing on how standards should be set and monitored.

Statistics and Software for Test Revisions

Yo In'nami

Shibaura Institute of Technology, Japan

Rie Koizumi

Juntendo University, Japan

Introduction

Statistical analysis plays an important role in language assessment because quantified information available from tests, tasks, and questionnaires helps test developers and users to provide a clear and defensible interpretation of test scores. Statistical analysis is widely used in many disciplines in the humanities and social sciences, as well as in science and technology. Therefore it is not surprising that language testers have taken advantage of statistical analysis to examine the factor structure of tests (e.g., Kunnan, 1992), pre–post changes of variables of interest (e.g., Elder, Knoch, Barkhuizen, & von Randow, 2005), and variables related to test performance (e.g., Ockey, 2011), to name just a few. Although statistical analysis itself is a topic of interest in psychometrics, language testers must embed it in the validity argument of test interpretation and use, specifically in relation to the four bridges of inferences: evaluation, generalization, explanation, and utilization (Bachman, 2005; Chapelle, Enright, & Jamieson, 2008). This chapter mainly focuses on the evaluation stage—a key stage from which the remaining three inferences can evolve and in which tests are revised iteratively.

Evaluation and Test Revision

Evaluation concerns the appropriateness of the processes through which an examinee's performance is converted into test scores (Chapelle et al., 2008; Kunnan & Carr, 2013). Test performance should be appropriately handled so that the resulting scores are representative of the examinee's performance. This process is simpler for multiple choice tests, which can be scored dichotomously (as right or

wrong). Here, responses are machine scored or scored by hand according to a set of answer keys or a list of acceptable answers, or both. The situation becomes more complex for performance testing of speaking and writing skills. These skills are scored polytomously (for example, on a scale of 0 to 2) by raters according to rating scales describing a typical response or ability for each level. Compared to machine scoring, use of human judges can bring in irrelevant factors that may affect score judgments, undermining the score-based validity.

During the evaluation process, language testers should understand the distributions of examinee scores; evaluate the statistical characteristics of items, tasks, and tests; and analyze the rating scales and raters. The analysis of rating scales and raters is a more advanced topic, but is addressed as it is essential for performance assessment. The following sections examine each of these issues in turn, and are intended to serve as an introduction to relevant other chapters. Readers are referred to the “SEE ALSO” list near the end of this chapter for further details.

Understanding the Distributions of Examinee Scores

The distributions of examinee scores can be examined using measures of central tendency, which describe the location of most scores in the distribution. Measures of central tendency include the mean, median, and mode. The mean is the average, and is the most used of the three measures. It is calculated by summing all responses and dividing the number by the number of responses. The median is the middle value of a list. It is calculated by first ranking all responses in order (e.g., from small to large), and then identifying the middle value. If the list contains an even number of items, then the median is the average of the middle two. The mode is the most frequently observed number. The median and mode are particularly useful for small samples, non-normally distributed data, or both. In this case, the mean can be influenced by extreme scores and so is less likely to represent the distribution of data well. For example, when responses of 10 students in a 5-scale questionnaire item are 1, 1, 2, 2, 2, 3, 3, 4, 5, and 5, the mean is 2.8 $([1 + 1 + 2 + 2 + 2 + 3 + 3 + 4 + 5 + 5]/10)$. The median is 2.5 $([2 + 3]/2)$ and the mode is 2, as the number 2 appears most frequently.

In addition to the above measures of central tendency, it is useful to study measures of dispersion, which show the degree of variation in the distribution of scores. They provide a richer understanding of the data distribution than the measures of central tendency achieve alone. Further, because many statistical methods are based on score variability, it is important to report and interpret measures of dispersion. One of the most widely used measures is the standard deviation, a measure of the degree to which test scores deviate from the mean, expressed in terms of the original metric unit. This is obtained by first calculating the variance: Calculate the difference between each individual score and the mean, square the results, aggregate them, and divide the answer by the sample size minus 1. The standard deviation is defined to be the square root of the variance. The formula is shown in Equation 1, where X represents individual scores, M is the mean, and N is the sample size. The Greek letter sigma Σ is a summation sign and indicates the sum of the values $(X - M)^2$.

$$\text{Standard deviation} = \sqrt{\frac{\sum(X - M)^2}{N - 1}} \quad (\text{Equation 1})$$

Another useful distribution measure is the skewness of the data, which shows the degree to which the distribution is asymmetrical. A distribution with few low test scores and many high test scores is negatively skewed, whereas a distribution with many low test scores and few high test scores is positively skewed.

The shape of the distribution is further described by its kurtosis, which can be interpreted as measuring how peaked the distribution is. Peaked distributions result from many examinees achieving similar scores. A distribution with a flat-topped curve has negative kurtosis, and is called a platykurtic distribution. In contrast, a distribution with a high peak has positive kurtosis, and is called a leptokurtic distribution. A distribution somewhere between these two has zero kurtosis and is called a mesokurtic distribution.

An example of a distribution with zero skewness and kurtosis is the normal distribution. One way to judge whether the distribution is normal is to conduct statistical significance tests for skewness and kurtosis (e.g., Tabachnick & Fidell, 2007). The statistical significance of the skewness is examined using z-values (Equation 2), which show the degree to which the distributions are skewed in terms of the units of standard error of skewness, s_s , defined in Equation 3 (N is the sample size).

$$z = \frac{\text{skewness}}{s_s} \quad (\text{Equation 2})$$

$$s_s = \sqrt{\frac{6}{N}} \quad (\text{Equation 3})$$

The statistical significance of kurtosis is again examined using z-values (Equation 4), but this time showing the degree to which the distributions are peaked compared with the units of standard error of kurtosis, s_k . See Equation 5 for the definition of s_k (N is again the sample size).

$$z = \frac{\text{kurtosis}}{s_k} \quad (\text{Equation 4})$$

$$s_k = \sqrt{\frac{24}{N}} \quad (\text{Equation 5})$$

If the z-values exceed 2.58 ($p < .01$) or 3.29 ($p < .001$), the data are considered to be non-normally distributed. However, as stressed by Tabachnick and Fidell (2007), the standard errors of skewness and kurtosis shrink in large sample sizes, which can produce statistically significant skewness and kurtosis values, even though the distribution looks normal. Thus, with large samples, making substantive decisions based on the visual inspection of the data, using histograms or box plots, for example (see the “Reporting Practice and Examples” section below), is preferred.

Evaluating the Statistical Characteristics of Items, Tasks, and Tests

Along with the score distribution of examinee scores, we should also be concerned with statistical properties of items, tasks, and tests. This is important, particularly in pilot testing, because such analysis (called item analysis) shows whether items, tasks, and tests are functioning as expected. Some items may be too easy or too difficult, or some distracters (i.e., any incorrect options in a multiple choice item) may not be working properly. Thus, item analysis contributes to revising and improving test items so that the test measures what it claims to measure.

Item analysis can be conducted in terms of item facility, item discrimination, and distracter analysis. First, item facility (or item difficulty) shows the proportion of examinees who responded to an item correctly. It ranges from .00 to 1.00, with a high value suggesting that the item was easy. In norm-referenced tests (NRTs), we compare an examinee's performance against that of other examinees. Here, item facility should be around .50 to maximally differentiate examinees (e.g., Brown & Hudson, 2002; Bachman, 2004), with values between .30 and .70 generally considered permissible. In criterion-referenced tests (CRTs), we want to know whether an examinee has reached a certain level of skill or ability, as judged by a predetermined criterion (e.g., mastery or nonmastery). However, there are no guidelines on the standard of item facility. This is because, in CRTs such as achievement tests, everyone should ideally master the skills taught in the course, so item facility should be close to 1.00. Items with high facility values show that examinees have mastered a particular skill, whereas items with low facility values show that examinees need more time to master such a skill.

Second, item discrimination is a measure of how well an item distinguishes between groups of examinees with different proficiency levels. For NRTs, one measure is the item discrimination index. This is calculated by subtracting the item facility for the lower group from that of the higher group. Upper and lower groups can be the upper and lower 50% of the examinee group, based on the total test score, or the upper and lower 27% or 33%. For example, if everyone in the higher group answered an item correctly (item facility is 1.00) and everyone in the lower group answered it incorrectly (item facility is .00), the item discrimination has a perfect value of 1.00 ($1.00 - .00$). Values over .40 are generally considered adequate, but more detailed guidelines are also available (see Ebel, 1965). For CRTs, Brown and Hudson (2002) explain two statistics. First, the difference index is calculated by subtracting the item facility for the nonmastery group from that of the mastery group. This is similar to the item discrimination index for NRTs, the difference being that we focus here on the mastery and nonmastery groups rather than higher and lower groups. For example, two groups of students—one masters and the other nonmasters—take a test, and the difference index is calculated based on the results. Alternatively, in a pre-post, repeated measures design, students take a pretest, receive instruction in the interim, and then take a post-test. Here, we obtain the difference index by subtracting the item facility of the students before instruction (the nonmastery group) from that after instruction (the mastery group). However, it is not always possible to calculate the difference index, because it requires that two different groups, identified by experts, complete a test or that the same group completes the test on two different occasions. Another useful

method for CRTs is the B index, which is the difference between examinees who passed and those who failed a test. The logic is the same as for the difference index above, but the B index compares mastery and nonmastery groups after a single administration of a test. This requires determining the cut-off score for passing or failing the test before analyzing the data. In general, values over .40 are considered adequate for CRTs.

Another measure of item discrimination is based on the correlation between the item (a dichotomous variable) and the total score (a continuous variable). One example for NRTs is the point biserial correlation, a type of Pearson correlation ranging from -1.00 to $+1.00$. Another is the biserial correlation, which assumes underlying continuity for a dichotomous variable, in contrast with the point biserial correlation, which does not. The biserial correlation generally shows higher values than the point biserial one and can lie outside the range -1.00 to $+1.00$. Positive values show that high-scoring examinees performed better on a given item than low-scoring examinees, whereas negative values show the opposite. Values over .30 are considered adequate for both correlations, and the point biserial correlation is usually used in test analysis. For CRTs, item discrimination is based on the correlation between the item and mastery or nonmastery. A coefficient for ϕ (phi) over .30 is considered adequate. Item discrimination indices for NRTs may not work well for CRTs, because CRTs do not often have sufficient variance in test scores.

Analysis can also be conducted on distracters. Recall that item facility is the proportion of correct responses given to a certain item. In addition, item discrimination is the difference in item facility values between groups of examinees with different proficiencies, or is the correlation between an item and the total score (or between an item and mastery or nonmastery). Therefore, it follows that item facility and item discrimination are not related to whether or not distracters are working properly. It is possible that an item has adequate facility and high discrimination, but that its distracters perform poorly as they are obviously wrong and so not selected by the examinees. Thus, investigating item quality requires distracter analysis in addition to item facility and discrimination.

Analyzing Rating Scales and Raters

Rating scales refer to a set of level descriptions on behavior against which an examinee's ability is judged (e.g., Linacre, 1989). Well-known examples include the speaking rating scale of the Internet-based Test of English as a Foreign Language (TOEFL iBT), which judges performance on a five-point scale in terms of delivery, language use, and topic development (Educational Testing Service, 2004). In teacher-made classroom tests of speaking or writing, or even in tests of listening or reading in an open-ended format, some kinds of rating scales are used. Thus, unless scoring is dichotomous, as in conventional multiple choice tests, rating scales play an essential role in assessment.

There are a few issues surrounding rating scales and raters. First, rating scales, both holistic and analytic, must be developed carefully to eliminate ambiguity and ensure consistent scoring. A well-constructed scale articulates the construct being measured, signaling to the raters what aspects they should focus on in

performance and to the examinees what skill they are expected to demonstrate and how the skill is evaluated.

Second, raters must be trained to familiarize themselves with tasks and rating criteria. Newly hired raters are presented with previously scored exemplar performances and are required to rate a different set of performances at a predetermined level of consistency. Rater consistency or rater variability can be checked using *inter-rater* reliability or *intra-rater* reliability. Inter-rater reliability is the degree of the correlation of ratings between different raters on the same task, while intra-rater reliability is the degree of the correlation of ratings by a single rater on the same task on different occasions. Although these two reliability indices—particularly inter-rater reliability—are used in language assessment, it should be remembered that correlations are not sensitive to differences in the mean between ratings, and even a perfect correlation of 1 can be achieved with zero agreement (Kaftandjieva, 2004, p. 22). This underlines the importance of reporting agreement percentages (exact and adjacent). Further, for a scale with a small number of categories, exact agreement could occur by chance alone. Kappa statistics corrects for this and should also be reported (Cook, 2005).

A broader tool that can be employed for analyzing rater variability is generalizability (G-) theory. G-theory is a flexible, statistical framework for systematically investigating the reliability of instruments under specific conditions by considering multiple sources of error (Shavelson & Webb, 1991). G-theory allows us to investigate, in a single analysis, the relative and interactive effects of various factors, such as examinees (persons), raters, items or tasks, and occasions, on reliability (e.g., Kunnan, 1992; Schoonen, 2005). For example, it is possible to know what percentage of the variance of test scores is due to factors associated with rater or rater-by-task interaction. This analysis is referred to as a G study. Further, we can determine optimum measurement designs by systematically simulating how a change in factors would affect reliability. For example, would four raters rating once be more reliable than two raters rating twice? This type of question can be answered in the optimization phase, called a decision (D) study.

Additionally, valuable information on rating scales and raters can be gained by using many-facet Rasch measurement (Linacre, 1989). It is particularly well suited to analyzing judge-involved performance assessments. Many-facet Rasch measurement can model the characteristics of rating scales, raters, and other aspects of performance assessment settings (e.g., task, interviewer) and consider those (and interactive) effects on examinees' ability and task difficulty estimates. The results indicate, for example, rater severity or leniency, rater consistency, interaction between rater and item (called rater-by-item bias), and the difficulty level of each task. Such information is useful in rater training and item or task revision (e.g., McNamara, 1996). It should be noted that, although G-theory indicates various sources of error separately, it does not help us correct such errors in the calibration of ratings (Linacre, 2012). For example, even if we know some raters are too harsh, we cannot take that into consideration in rating calibration using G-theory. However, this is possible in many-facet Rasch measurement, which presents examinees' ability and task difficulty estimates that are statistically adjusted if raters are found to be consistently severe or lenient, although this is only possible if rater behavior is consistent and does not fluctuate considerably.

Software for Test Revision

Many computer programs, such as R, SAS, and SPSS, can deal with the statistics described in this chapter, and can compute the distributions of examinee scores (mean, median, mode, standard deviation, skewness, and kurtosis), item characteristics (item facility and item discrimination), and rater consistency (inter-rater and intra-rater reliability). For R and SPSS, see Larson-Hall (2010, 2012), and for SAS, see Field and Miles (2010). If rater consistency is not a primary concern, ITEMAN—software tailored for item analysis—will suffice, and may be preferable in this case as it is easy to use and has been written particularly for the purpose of item analysis. Its output is particularly lucid, giving a detailed figure and table of statistics for each item. It also allows users to specify criteria for an acceptable range for item facility, item mean, and point biserial and biserial values. For example, one can specify that a point biserial correlation be between .30 and 1.00, and any items outside this range (e.g., items with negative point biserials) are flagged and presented in a list. Particularly useful for item analysis and revision are quantile plots, which graphically show the behavior of each item. Plots are created by dividing the examinees into subgroups (the number of which we can decide) based on the total test score and by examining the proportion of examinees in each subgroup that selected each option. Quantile plots are a feature added to ITEMAN version 4. For video tutorials on how to use ITEMAN, see ASCpsychometrics (2011a, 2011b).

However, ITEMAN, SAS, and SPSS are all commercial programs, and statistics for CRTs are usually not available. Using Microsoft Excel is another possibility. Although this is a general-purpose software, Excel is widely available and provides a range of basic statistics in a friendly graphic user interface. To the best of our knowledge, the most useful resource for Excel currently available for language testers is Carr (2011), which comes with Excel worksheets for hands-on practice and three hours of video tutorials that demonstrate the procedures used in the worksheets. The worksheets and tutorials cover the issues of item analysis comprehensively, ranging from creating a class grade book in Excel, calculating descriptive statistics and correlations, constructing a histogram and a frequency polygon, performing item analysis for NRTs and CRTs, to calculating Cronbach's alpha and standard error of measurement. Step-by-step procedures for completing the worksheets are also offered in the book. However, Carr cautions that Excel would be adequate and useful for item analysis for low stakes tests, but that specialized software is recommended for high stakes tests.

Further, although R, SAS, and SPSS can be used for G-theory analysis, GENOVA and mGENOVA offer a variety of analytical options and are fast and efficient, as they are written specifically with G-theory analyses in mind. GENOVA is used for univariate analysis, and mGENOVA for multivariate analysis. A multivariate analysis includes multiple sections or subtests, and one can investigate the reliability of each section or the whole test.

For many-facet Rasch measurement, FACETS has often been used among language testers. It is designed to construct measures from judge-mediated ratings and complex data. FACETS can simultaneously manage heterogeneous tests, such

as those consisting of a mixture of dichotomous responses and judge-awarding polytomous ratings, with a complete rating design, in which all raters rate all examinees. FACETS can also analyze data with a partial rating design, in which some rate a group of examinees and others rate a partially overlapping different group of examinees. ConQuest, RUMM, PARSCALE, LPCM-WIN, and eRm all offer many-facet Rasch measurement analysis. These programs differ in their parameter estimation methods, although this may make little difference in practice. For details and further comparison of programs, see Eckes (2011, pp. 128–30) and Sick (2009).

Reporting Practice and Examples

Distribution of Examinee Scores

Box plots provide a good way to report statistics showing the distributions of examinee scores. Larson-Hall and Herrington (2010) strongly recommend reporting box plots (box-and-whisker plots) over bar graphs. Although bar graphs are the most basic graph and have been conventionally used, they are far less informative than box plots, because box plots also show the distributions of groups, including the degree of dispersion and outliers in the data. Figure 56.1 shows an example of a bar graph and a box plot for four groups of examinees ($n = 140$ each) taking the Test of English for International Communication (TOEIC). In Figure 56.1(b), the bold line in the box shows the median value. The length from the bottom to the top of the box shows the range between the first quartile (where 25% of the data occur) and the third quartile (where 75% of the data occur), which describes the middle 50% of the score distribution. This is also called the interquartile range. There are two whiskers above and below the box: The bottom bar of the whisker shows the minimum value or the median minus ($1.5 \times$ interquartile range); the top bar of the whisker shows the maximum value or the median plus ($1.5 \times$ interquartile range). Values outside the whiskers are outliers. For example, group 1 had a median of approximately 360, first and third quartile scores of 300 and 400, a

Figure 56.1 A bar graph (left) and a box plot (right) applied to the same data. Error bars in the bar graph represent 95% confidence intervals for means

minimum value of 180 (as shown by the bottom bar of the whisker), and a score of 510, calculated as $360 + 1.5 \cdot [400 - 300]$ (see the top bar). In actual data interpretation, one needs to refer to descriptive statistics to know the exact values of boxes and bars. While the means and the 95% confidence intervals in the bar graph in Figure 56.1(a) seem to be essentially the same across the groups, the box plot in Figure 56.1(b) shows in addition that the range of scores was equally wide (based on the upper and lower bars), and that groups 2 to 4 had more outliers than group 1. Outliers were found across all score ranges in group 3, whereas they were clustered around the 600 to 800 range in groups 2 and 4. These results suggest that, even if confidence intervals are reported along with means in a bar graph, the score distributions are better depicted in a box plot. However, box plots do not show mean scores. Therefore, since means are widely used, not only in primary studies but also in secondary studies (such as meta-analysis), the mean and other descriptive statistics (e.g., standard deviation, skewness, and kurtosis) should be reported along with box plots. The SPSS syntax for the bar graphs and box plots described here is included in Appendixes A and B.

Item Analysis

To report statistics showing item characteristics, a quantile plot for each item is recommended. For example, Figure 56.2(a) shows a three-option, multiple choice grammar item with five ability groups in an NRT (1 being low, 5 being high, and $n = 10$ in each case). A good item has an upward trend in the line for the correct answer, with a downward trend for the incorrect answers. For item 5 (see below), the line for the correct answer (option 1) was generally upward, whereas the lines for the two distracters (2 and 3) were generally downward across the five ability groups. This shows that examinees with higher ability were more likely to perform well on this item, while those with less ability were less likely to do so. In fact, approximately 70% of the lowest ability examinees chose the correct answer, whereas almost all of the highest ability examinees chose the correct answer. These results show that the item discriminated well between examinees. Table 56.1 shows that the facility value was .820 (i.e., 82% of the examinees scored correctly) and that the point biserial discrimination value was .370. Both values were above .300, so are considered acceptable. Note that the point biserials for the distracters

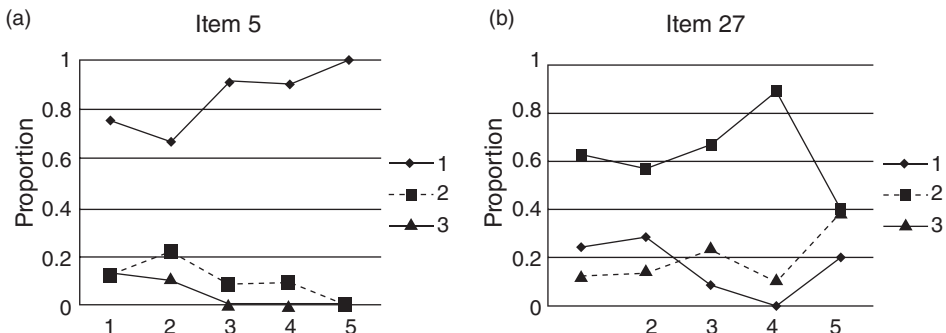

Figure 56.2 Quantile plots for well-functioning and poorly functioning items

Table 56.1 Item statistics for well-functioning and poorly functioning items

Option	N	Prop.	r_{pbis}	r_{bis}	Mean	SD	
<i>Good item</i>							
1	41	.820	.370	0.541	38.780	9.532	**KEY**
2	5	.100	-.184	-0.315	30.400	9.607	
3	2	.040	-.181	-0.412	27.000	2.828	
Omit	2	.040	-.138	-0.313	23.000	22.627	
<i>Poor item</i>							
1	7	.140	-.143	-0.224	33.000	13.166	
2	29	.580	.101	0.127	37.517	8.971	**KEY**
3	10	.200	.144	0.206	40.600	9.524	
Omit	4	.080	-.134	-0.245	29.250	16.661	

Note. Prop. = Item facility. r_{pbis} = Point biserial correlation. r_{bis} = Biserial correlation.

were negative (-.184 and -.181 for distracters 2 and 3, respectively). This is desirable because it shows that those who got the item wrong were likely to have a lower total score than those who got the item right.

Item 5: What are you () about?
 1. talking* 2. saying 3. telling

In contrast, Figure 56.2(b) shows an example of an item that does not function well. For item 27 (see below), although the slope for the correct answer (2) went up overall as proficiency increased from groups 1 to 4, group 5 performed worse than group 4. More problematic was that distracter 3 was selected as often as the correct answer in group 5. There was clearly something wrong with the options, and a closer scrutiny of the content of the item is warranted. Item 27 tests the knowledge of the phrase “not + comparative + than.” Although the intended correct answer was option 2, option 3 also makes sense, and group 5 examinees seemed to be confused. The item asks not only grammatical ability but also value judgment, and clearly needs revision. Table 56.1 shows that the facility value was .580 and the point biserial value was .101. The point biserial was far below .300, and therefore unacceptable. Note that the point biserial value for distracter 3 was positive (.144), which (weakly) suggests that those who scored incorrectly by choosing distracter 3 were likely to have a higher total score.

Item 27: Good sleep is not () important than good food.
 1. better 2. less* 3. more

Three issues are particularly crucial in item analysis. First, having too many items with high/low facility and negative/low discrimination values is problematic, particularly for NRTs, since such items cannot separate proficient from less proficient examinees. However, this does not necessarily mean these items should be discarded. They may be statistically flawed, but still represent the construct being assessed well. Including such items could make the test look more

trustworthy, and prompt examinees to be more motivated and better prepared to complete the test. It is more sensible to keep the items if the item statistics are not conspicuously unfavorable, or to revise them rather than to delete them. Second, item statistics tend to fluctuate particularly with small sample sizes. It would be advisable to pilot items to a reasonably large number of examinees to investigate whether the items function as intended. Readers may be interested to know how these items were revised and how effective the revision was, so one should provide pre- and post-revision statistics for the items in question. Third, quantile plots in ITEMAN do not appear if the output is opened in WordPad or Excel. It must be opened in Microsoft Word.

Analysis of Rating Scales and Raters

To report statistics showing characteristics of rating scales and raters in performance assessment, it is useful to report outputs from GENOVA and FACETS. Among GENOVA outputs, it is advisable to report G study estimates of variance components and D study results. Table 56.2 shows analysis of variance (ANOVA) estimates of variance components for a two-facet crossed design. The data included speaking scores of 145 respondents for four tasks rated by two raters, with no missing values. The design was fully crossed, meaning all respondents completed all tasks and these were rated by all raters using a holistic rating scale of 1 to 5. The tasks and raters were both random facets. Of great interest is the percentage of variance components, which shows the relative contribution of the sources of variation in this speaking test. Half the variation was attributable to persons (52.642%), indicating that examinee scores were spread well. The non-negligible variance components of the interactions between persons and tasks (19.667%) and between persons and raters (10.372%) suggest that the relative standing of examinees differed somewhat across tasks and across raters. For example, regarding the person-by-rater interaction, rater 1 may have judged that examinee 1 was more proficient than examinee 2 and that examinee 2 was more proficient than examinee 3. In contrast, rater 2 may have judged that examinee 3 was the most proficient,

Table 56.2 G study ANOVA estimates of variance components for a two-facet crossed design for the speaking test ($p \times t \times r$)

<i>Source of variation</i>	<i>Sum of squares</i>	<i>Degree of freedom</i>	<i>Estimated mean square</i>	<i>Estimated variance component</i>	<i>Percentage of variance component</i>
Persons (p)	763.232	144	5.300	0.538	52.642
Task (t)	2.217	3	0.739	0.000	0.000
Rater (r)	3.986	1	3.986	0.005	0.489
pt	246.532	432	0.570	0.201	19.667
pr	85.263	144	0.592	0.106	10.372
tr	1.889	3	0.629	0.003	0.294
ptr, e (residual)	72.860	432	0.168	0.169	16.536
Total				1.022	100.000

Table 56.3 D study for the speaking test ($p \times T \times R$)

	1 task	2 tasks	3 tasks	4 tasks
1 rater	.530 (.526)	.649 (.644)	.701 (.695)	.730 (.725)
2 raters	.614 (.611)	.733 (.730)	.784 (.780)	.812 (.808)
3 raters	.647 (.645)	.766 (.764)	.816 (.813)	.843 (.841)
4 raters	.666 (.664)	.784 (.782)	.833 (.831)	.860 (.858)

Note. Values outside parentheses are generalizability coefficients for NRTs. Values in parentheses are phi coefficients for CRTs.

followed by examinee 2 and then examinee 1. Approximately 16% of the variation was due to residual effects, indicating that a somewhat small proportion of the variance was due to the three-way interaction between persons, tasks, and raters, and measurement error that was not captured in this analysis. Further, D study results in Table 56.3 show predicted reliability (generalizability and phi) coefficients as a function of the number of tasks and raters. The current speaking test is, in general, considered reliable, with a generalizability coefficient for four tasks with two raters of .812. However, the relatively large person-by-task and the person-by-rater interactions compromise the generalizability of test performance. If the test needs to be shorter, we can still expect a similar level of reliability with three tasks and three raters (.816). These changes are often effectively reported as a graph. The GENOVA control card for this analysis is included in Appendix C.

Next, although FACETS generates numerous, useful outputs, those particularly beneficial to test revision are discussed (FACETS syntax was omitted from the appendixes due to space limitations). First, it is advisable to report a facets map, as presented in Figure 56.3. Results were derived using the same data as used in the G and D studies above. The map shows the relative abilities of examinees (column 2), the relative severity of raters (column 3), and the relative difficulty of tasks (column 4). Column 1 shows a ruler of a logit scale, and column 5 shows the ranges of each level of the rating scale. The examinees were relatively normally distributed, the raters rated similarly in terms of severity, as they clustered around zero, and the tasks were of similar difficulty. If tasks are found to be too easy or too difficult relative to the distribution of examinees' ability for NRTs, they should be replaced by tasks of reasonable difficulty.

A second instructive statistic to report from FACETS is the bias analysis, which examines systematic patterns of interaction between variables of interest (e.g., Kondo-Brown, 2002). For example, the aforementioned G study person-by-rater interaction from GENOVA can be further analyzed through bias analysis in FACETS. Three significant interactions were found, as shown in Table 56.4. Column 4 shows the average difference between the observed (column 1) and expected (column 2) scores. On average, this student (number 59 [column 10]; ability measure of -0.93 [column 11]) was being rated 1.17 score-points higher than expected by rater 1 ($[16 - 11.3]/4$). This corresponded to a change in rater severity of 3.35 logits (less severe). The standard error was 1.05 logits, and the t -value was 3.20, $df = 3$, $p = .049$. The rater was significantly less severe (more lenient) in rating student 59 at the .05 level (two-tailed). In contrast, rater 2 was more severe for the

Figure 56.3 Facets map for person ability, task difficulty, and rater severity/leniency

same student, assigning him scores (-1.17 score-points) lower than expected. Rater 1 was also more severe for student 68, giving her lower scores (-0.79 score-points) than expected. To summarize, significant bias of rater behavior was found for only 3 of the 290 cases (145 examinees rated by two raters), and the degree of bias was relatively small with similarly severe and consistent ratings of the raters (rater severity measures for raters 1 and 2 = -0.17, 0.17). This suggests that the person-by-rater interaction, which was non-negligible in the G study, was adjusted in many-facet Rasch analysis when examinees' ability was estimated. If many cases of rater-related bias are found, problematic rater behavior should be examined by inspecting the actual examinee performance and ratings; or interviewing raters to identify factors causing the disturbance, such as rater fatigue or failure to understand the rating criteria; or both. Information on the sources of rater divergence can be incorporated into rater training. Further, pre-post training data can be

Table 56.4 Bias analysis: person-by-rater interaction

Observed score	Expected score	Observed count	Observed – expected average	Bias size*	Standard error	t	df	p	Student Measure	Rater	Measure	
16	11.3	4	1.17	3.35	1.05	3.20	3	.049	59	–0.93	Rater1	–0.17
6	10.7	4	–1.17	–2.86	0.88	–3.23	3	.048	59	–0.93	Rater2	0.17
14	17.2	4	–0.79	–2.99	0.83	–3.62	3	.036	68	3.65	Rater1	–0.17

Note. *Positive bias size shows less severity (more leniency) of raters, whereas negative bias size shows more severity (less leniency) of raters.

examined through a pre- and post-facets map, similar to Figure 56.3, and bias analyses (e.g., Elder et al., 2005).

FACETS also produces statistics for evaluating the fit of examinee, rater, and task with the Rasch model, although these statistics are not shown in Table 56.4. A model fit shows whether the data patterns of examinee, rater, and task are similar to the one expected from the Rasch model, and can be examined by infit and outfit mean square fit statistics of 0.4 to 1.2 for judged ratings, and 0.8 to 1.2 for high stakes multiple choice questions (Wright & Linacre, 1994). Depending on the type and stake of test, different ranges might be acceptable (see Wright & Linacre, 1994). A model fit can also be evaluated with standardized infit and outfit mean squares. Values within ± 2 indicate conformity to the Rasch model. For raters 1 and 2 above, the infit mean squares were, respectively, 0.90 and 1.09, and the outfit mean squares were 0.88 and 1.10. The standardized infit mean squares were -1.7 and 1.5 , and the standardized outfit mean squares were -1.9 and 1.6 . These results together indicate that both raters' ratings fit the model.

Other relevant outputs are the category statistics (Table 56.5) and probability curve (Figure 56.4) of the rating scale. Bond and Fox (2007, pp. 222–6) summarize four types of the properties of appropriate rating scales. First, difficulty estimates in reaching a certain band level (category) should increase steadily as levels get higher, with at least 10 ratings at each level. Results in columns 2 and 3 in Table 56.5 indicate that difficulty estimates gradually increased from levels 1 to 5 (-3.29 to 3.56), with more than 10 rating at each level (e.g., $n = 62$ for level 5). Second, thresholds or step calibrations are difficulty estimates for selecting one level over another (e.g., -3.73 from levels 1 to 2 in column 4). The degree of distances between thresholds between adjacent levels should be at least 1.4 logits, but less than 5.0 logits. Results suggest all distances satisfied this criterion (2.05 to 3.92). Third, a probability curve shows the probability of examinees obtaining a rating at a certain level of a rating scale (e.g., examinees with ability of -2.0 logits have an approximately 50% chance of obtaining level 2). Each level should have its own distinctive peak, as seen in Figure 56.4. Further, the intersection of level probabilities equals the threshold estimate in Table 56.5. For example, the intersection of levels 1 and 2 in Figure 56.4 is -3.73 , as also observed in Table 56.5. Fourth, level fit statistics, as seen in column 5 in Table 56.5, have an average of 1.0. If the value is more than 2.0, ratings are considered to depart from rating patterns predicted from the Rasch model and are thus problematic. Results show that all the ratings

Table 56.5 Category statistics for the rating scale

<i>Level</i>	<i>Number of observations and percentage</i>	<i>Average measure for all examinees who selected the level</i>	<i>Rasch–Andrich thresholds measure (distance), Standard error</i>	<i>Outfit mean square</i>
1	63 (6%)	-3.29		1.2
2	203 (18%)	-1.82	-3.73 (3.73), .17	1.0
3	369 (32%)	0.05	-1.43 (2.30), .10	0.9
4	447 (39%)	1.64	0.62 (2.05), .08	1.0
5	62 (5%)	3.56	4.54 (3.92), .15	1.0

Figure 56.4 Probability curve for the rating scale

for each level fit the model well. Therefore, we can conclude that this rating scale functioned well and requires no revision. However, if results do not satisfy these criteria, test developers should consider collapsing adjacent levels, rewording descriptors in the levels, or both. The developers should then analyze rescored or newly collected data.

Finally, regardless of the statistics used, reporting commands, scripts, or syntax whenever possible and appropriate is highly recommended. Although readers peruse the method section of a journal article to try to understand how the analysis was conducted, method sections often do not include all the information that should be reported. This may be due to word limits or authors not being familiar with data-reporting practices. In these cases, reporting commands, scripts, or syntax (with annotated comments) make data analysis more transparent, so readers can see exactly how the data were analyzed. For example, for G-theory analysis, GENOVA requires specifying whether variables are considered random or fixed. For variables to be considered random, they must be considered to be randomly drawn from the universe (population) of examinees, raters, or tasks and exchangeable with any other samples of variables in the population. If such exchangeability is not assured, variables are considered fixed. Since the random/fixed specification affects results and, more importantly, any generalizations we

make, this should be clearly reported with the syntax. Long syntax can be snipped and reported. Reporting syntax helps readers become familiar with different analyses and helps them apply these methods to their own data.

Challenges and Future Directions

To further promote the use of statistics addressed in this chapter in actual data analyses among language testers, an important challenge is to ensure that statistical analyses are reported so that readers can understand how items, tests, and tasks have been revised based on those analyses, and how this has improved the validity argument for a particular instrument. In their seminal book on building a validity argument for the TOEFL, Chapelle et al. (2008) report unique and important studies that contributed to the revision of one of the world's most high stakes tests. For example, Chapelle (2008) reviews studies investigating various aspects of the TOEFL and synthesizes them into one validity argument for TOEFL score interpretation and use. Chapelle organizes studies according to (1) the appropriateness of scoring rubrics (e.g., whether scoring rubrics for writing should be holistic or analytic; how various factors are addressed, such as copying verbatim material from the reading text in an integrated writing task); (2) task administration conditions (e.g., whether note taking is allowed for a listening task); and (3) the psychometric quality of tests (e.g., whether tasks have the appropriate difficulties and discriminations). An iterative process of revision through these three phases led to an improvement in the validity of interpretation and use of TOEFL scores. Therefore, a revision of the items, tests, and tasks in relation to the inferences that language testers intend to draw from tests would make the whole process of test development and validation more valuable and meaningful. Statistics discussed in this chapter will put language testers in a better position to revise items, tests, and tasks and, eventually, to hone arguments for interpretation and use based on the test scores.

Standard Setting in Language Testing

Dorry M. Kenyon

Center for Applied Linguistics, USA

Anja Römhild

University of Nebraska, USA

Introduction

Standard setting refers to the application of socially moderated methodological approaches that link performances on tests to more generalizable interpretations of those performances. It is a process by which qualified panelists, following carefully developed and documented procedures that mitigate against arbitrariness, assign interpretative meaning to performances on tests. As such, standard setting plays a critical role in the development of an assessment use argument (Bachman, 2005) that provides validity evidence for the use of test scores.

Standard setting had its origin in certification testing, in particular, in determining cut scores on professional licensure tests. Indeed, in the psychometric literature, standard setting “refers to the process of establishing one or more cut scores on tests . . . [that] function to separate a test score scale into two or more regions, creating categories of performance or classifications of examinees” (Cizek & Bunch, 2007, p. 13). In the context of certification testing, standard setting is a process for clarifying the relationship between examinee performances on a test and real-life decisions that would be made about the examinee. Could the examinee be certified to join this profession? Does the examinee demonstrate mastery needed in this occupation? In Bachman’s assessment use argument terms, such an application would be part of the assessment *utilization* argument; that is, evidence supporting the use of test scores in making decisions about individuals.

More recently, however, standard setting has been used as part of Bachman’s assessment *validity* argument, a prior step in the assessment use argument that connects performances on an assessment to the assessment-based interpretation of the test scores. An increasingly common example of this, particularly in language testing, is when standard-setting methodology is used to link performances on an assessment to verbally defined levels of language proficiency. Thus, for

example, standard setting is used to link performances on language tests to the levels of the Common European Framework of Reference (CEFR) (Council of Europe, 2001). In such cases, the *interpretation* of the performance on a language test in terms of verbally defined proficiency levels is made separately from the *decision*, for example, to accept a certain level of proficiency as a qualification to do a certain job or for entrance to higher education.

Although the process of standard setting relies on psychometric and statistical tools, the process itself is a socially moderated one. Typically, an organizational or policy-making body in a high stakes setting needs the results of a standard-setting process in order to enact defensible decisions about individuals (e.g., certification) or to justify interpretations about test performances (e.g., linking test performances to defined proficiency levels). This body calls for a standard-setting study to be conducted. In the study, qualified panelists make judgments about examinee performances on tests. The outcomes of the study are typically seen as recommendations until ratified (or amended) by the policy board or policy-making procedures of the body that called for the study.

Despite the highly social aspect of a process that ultimately depends on human judgments, researchers and professionals who work in standard setting propose, develop, and investigate technical approaches both to conducting such studies and to analyzing the outcomes. They hope to limit arbitrariness and randomness, to estimate arbitrary and nonsystematic effects on the outcome, and to ensure that the final recommendations are determined by a justifiable and principled methodological approach.

Historical Background

In the USA, current approaches to standard setting have their origin in the field of certification testing, in which it is critical to set a legally defensible cut score to distinguish those candidates who can be certified as possessing the required knowledge, skills, and/or abilities from those who do not possess them. In the educational realm, distinguishing between students who “pass” and students who “fail,” or students who get top grades, middle grades, or bottom grades, is an age-old issue that faces every educator. However, as the US educational system increasingly began to recognize public accountability for education, the issues of distinguishing levels of educational achievement no longer had repercussions only on individual students, but passing rates and student achievement levels shed light on the capability and adequacy of local teachers, schools, school districts, and communities as well. For example, under the “No Child Left Behind” legislation of 2002, each state has to define performance expectations for its students and then to test its students to determine attainment of those performance expectations. In addition, national comparative student testing, such as the US National Assessment of Educational Progress (NAEP), known as “the Nation’s Report Card,” and international comparisons of student achievement, such as the Programme for International Student Assessment (PISA) and Trends in International Mathematics and Science Study (TIMSS), reveal that the defining of educational achievement levels can have societal repercussions. With so many

stakeholders involved, how can levels of student achievement in education be appropriately and defensibly set?

Increased needs for defensible standard-setting procedures have generated and continue to generate a growing body of basic research (see, for example, Philips, 2001), research on comparing and developing standard-setting methodologies (see, for example, Loomis & Bourque, 2001), and several practical resources (see, for example, Cizek & Bunch, 2007). A historical perspective can be had in the four editions of *Educational Measurement*, a definitive source of current knowledge and practice in the field since it was originally published by the American Council on Education in 1951. No mention of approaches to standard setting as currently understood appears in the first edition. In the second edition, an important footnote in Angoff's (1971) chapter, "Scales, Norms, and Equivalent Scores," became the impetus to what has become one of the most widely used methods, the Angoff method. The third edition discusses the topic in some depth in Jaeger's (1989) chapter, "Certification of Student Competence." The fourth edition, however, contains a dedicated chapter, "Setting Performance Standards" (Hambleton & Pitoniak, 2006).

Although performances on many language tests are often interpreted as performance levels (for example, the levels of "Novice," "Intermediate," "Advanced," or "Superior" on assessments based on the Proficiency Guidelines of the American Council on the Teaching of Foreign Languages [ACTFL]), the application of psychometrically based standard-setting procedures in language testing has been a relatively late phenomenon. Language tests have generally not been part of the US accountability system. Some long-established language tests, such as the Test of English as a Foreign Language (TOEFL), provide scale scores but no interpretive labels designating proficiency levels. (The TOEFL program, however, provides materials, such as the *TOEFL iBT® Test Standard-Setting CD-ROM*, that give guidance to local programs on how to set local standards [Educational Testing Service, 2005]. In doing so, the test publisher implies that the authority to make such decisions, and subsequent interpretations and consequences, is local only.)

In the context of the US "No Child Left Behind" legislation, the application of psychometrically based approaches to setting standards to link defined proficiency levels to performances on a K-12 English language proficiency test is provided by Kenyon (2006). More recently, the Council of Europe produced a manual for relating language examinations to the Common European Framework of Reference for Languages (CEFR) and reference supplement (Council of Europe, 2009) that advocates and explains psychometrically based methodologies for linking performances on assessments to the levels of the CEFR. Finally, the US government is exploring the use of such approaches for setting proficiency levels in its foreign language proficiency testing program. These are only a few examples of the increasing use of standard-setting approaches in language testing.

Current Approaches

Common Features

In order to produce defensible, valid outcomes, standard-setting methodologies pay careful attention to several key aspects of the standard-setting process. These

aspects include the selection and training of panels of judges, the incorporation of consensus-building processes and feedback information, and the collection and documentation of evidence on the procedural validity of the standard setting. Although standard-setting methods may differ in the details of implementing these procedural steps, there is general consensus that these elements constitute important measures toward strengthening the validity of the standard-setting outcomes.

Common to all methods is the utilization of panels of judges who provide the individual judgments from which final cut scores or cut score recommendations are derived. Selecting appropriate judges is a crucial step with considerable import for the perceived validity of the resulting cut scores by the various stakeholder constituencies and for the generalizability of the cut scores. Three main considerations generally guide the selection of panelists. First, appropriate qualification criteria must be specified in order to identify eligible standard-setting participants. Basic requirements are typically subject matter expertise in the content domain(s) of the assessment and familiarity with the characteristics and abilities of the examinee population. In addition, it is often desirable that panelists are familiar with the assessment itself, the test items, and the standard-setting context, since such knowledge can be helpful in understanding and executing the requirements of the standard-setting task. Such knowledge also places fewer demands on the training of panelists at the beginning of the standard setting. A second consideration for the selection of panelists concerns the representation of relevant demographic and stakeholder groups. The goal is to achieve generalizability of the standard-setting outcomes to a larger population of eligible panelists as an effort to strengthen the validity of the outcomes. Usually, attempts are made for panels to show a balance of gender, ethnic, and regional groups. In some contexts, political considerations may also play a role in that representation of diverse stakeholder groups will likely generate support among these groups for the cut scores. The third consideration for panel selection regards the number of panelists needed in order to produce cut score results whose associated standard errors—used as indicators of the replicability of results—are within acceptable ranges. A common recommendation is that panels include between 10 and 20 participants (Brandon, 2004), though more may be needed depending on the diversity of the population of panelists and if the standard-setting design includes an internal replication of the process using subpanels that independently complete the standard-setting tasks.

Most standard-setting participants have little or no familiarity with the standard-setting process and therefore require training to ensure that they understand the tasks and perform them correctly. In general, training in standard setting focuses on four major areas (Mills, 1995): developing an understanding of the standard-setting process, providing a context for the standard-setting activity, establishing a conceptualization of the target examinees who serve as the reference group during the judgment process, and providing instruction and opportunities to practice the judgment task. The first two training components include information about the development and purpose of the assessment, the purpose of the standard-setting study and its outcomes, as well as an overview and discussion of the consequences that the resulting performance standards may have on examinees. One of the most crucial aspects of training concerns the development of a

common conceptualization of the target examinee as a frame of reference with which panelists operationalize their expectations of examinee performance within the different performance categories. This step is essential for achieving valid and consistent translations of the performance categories into cut scores. Most standard-setting methods define target examinees as those who just barely belong to a particular performance category; that is, examinees who are “minimally acceptable,” “minimally competent,” or “borderline.” Building a common understanding of this reference group is usually accomplished by reviewing clear and detailed descriptions of the knowledge, skills, and abilities that define each performance category. In some instances, those descriptions are prepared in advance of the standard-setting meeting and panelists are asked to review and expand on them during training. For the fourth training component, panelists practice the steps of making judgments according to the conditions and specifications of the standard-setting method, so they can practice applying the process, become accustomed to the cognitive complexity of the required tasks, and clarify and correct misunderstandings.

Standard settings are based on the judgments of multiple individuals, so variability in judgments is an expected outcome. However, too much variability conflicts with the notion that cut scores should be replicable and may indicate that panelists are not addressing the task of making judgments in a consistent manner. To address this issue, the standard-setting process is often conducted in iterations so panelists can discuss and revise their judgments and consider various forms of feedback information. In this way, panelists identify and correct misconceptions about the standard-setting process, judgment task, and examinee performance before final cut score recommendations are made. The iterative process can also bring about convergence of panelists’ judgments. Because judgments are to be independent, however, some concerns exist that panel discussions and feedback information may exert undue influence on how panelists revise their judgments. It is usually the task of the standard-setting facilitator to recognize and intervene when individual panelists dominate the exchange between judges, though ultimately it is difficult to know to what extent panel interactions may be biasing, rather than facilitating, standard-setting outcomes.

Other concerns are in relation to the selection and presentation of specific types of feedback information. Cizek and Bunch (2007) distinguish three general categories of feedback information: normative information, which allows panelists to compare their own judgments to those of other panelists and the panel as a whole; reality information, which includes various forms of empirical performance data of examinees or items, or both; and impact information, which consists of classification rates that would result from applying the panel’s cut score recommendations. For some panelists, the presented information may not be straightforward and could lead them to adjust their judgments in erroneous ways, reflecting an inadequate or inappropriate understanding of the feedback data. Therefore, care should be taken in how the information is presented, interpreted, and used. Again, the facilitator plays a critical role in ensuring that all panelists properly understand and use the feedback data.

Standard-setting outcomes generally rely on procedural evidence to demonstrate their defensibility and validity. Procedural evidence is also one of the

easiest forms of evidence to obtain, for example through detailed documentation of the steps in a standard-setting study. An important source of procedural evidence is panelist evaluations of the standard-setting process. Common elements of these evaluations are questions about panelists' level of understanding of specific training elements; their perception of the quality of training and appropriateness of the amount of time allowed for specific activities; and their level of comfort and confidence in their own judgments as well as the panel's overall cut score recommendations. The evaluations are usually collected at the end of a standard setting, but they are sometimes also obtained after specific standard-setting steps in order to ask panelists about their understanding of the process up to that point. Panelists who indicate a lack of understanding may then be given additional training.

Angoff Methods

One of the most widely used and researched methods in standard setting is the *Angoff* method named after William Angoff, who famously proposed it in a footnote of his chapter in the second edition of *Educational Measurement* (Angoff, 1971). Angoff's original description of the method was brief with little substantive guidance on how to implement it. Therefore, most implementations of the process are *modified Angoff* versions that incorporate additional features not part of the original method.

At the heart of the Angoff method is a judgment process by which a panel of expert judges provides estimates of the probability that a "minimally acceptable" (Angoff, 1971, p. 515) examinee would be able to answer a test item correctly. Instructions often direct panelists to estimate the percentage of target examinees who would answer the item correctly. Summing these probabilities or percentages across items yields the cut score proposed by an individual judge, and averaging the sums across judges produces the panel's overall cut score. A modification of the judgment task—most commonly referred to as the *Yes/No* method (Impara & Plake, 1997)—is to ask panelists to estimate whether the target examinee would answer an item correctly or incorrectly. This version is thought to simplify the task of estimating a probability. Another variation—the *extended Angoff* procedure—extends the Angoff method to tests composed of polytomously scored items (Hambleton and Plake, 1995). Judges provide estimates of the expected item score that a target examinee would receive on the polytomously scored item. The *Yes/No* method and the *extended Angoff* method can be combined to perform standard settings on tests with mixed item formats, which is not possible with the standard Angoff procedure.

The majority of Angoff standard settings today are modified. Although there is no clear consensus on what constitutes a modified Angoff process (Cizek & Bunch, 2007), there are several features that many implementations share. These include a common conceptualization of the target examinee, an iterative judgment process allowing panelists to revise their judgments, and the provision of empirical feedback information. Various other modifications have been proposed and tested in the research literature. In general, modifications aim to improve the consistency of judgments within and across panelists (Hurtz & Auerbach, 2003) and to make

the standard-setting process more efficient. An overview of the research literature on Angoff methods can be found in Brandon (2004).

Although the Angoff method continues to be a popular choice in standard setting, it has been subject to sometimes harsh and controversial criticism. In their review of standard-setting research for NAEP, Shepard, Glaser, Linn, and Bohrnstedt (1993) concluded that the judgment process of estimating the response probability of a hypothetical borderline examinee was “a nearly impossible cognitive task.” Although panelists generally report confidence in their judgments and understanding of the process (Hambleton, Brennan, et al., 2000), evidence from the field of cognitive psychology suggests that human judgments of probabilities may not be very accurate (Tversky & Kahneman, 1993). Findings from the standard-setting literature are more mixed. In general, panelists seem to be able to judge the relative difficulty of an item reasonably well, but they tend to overestimate the difficulty of easy items and underestimate difficult items (Brandon, 2004). These distortions, however, may be mitigated through the incorporation of standard-setting features such as providing empirical item data as feedback and permitting between-rounds panel discussions (Brandon, 2004).

Bookmark Methods

The *Bookmark* method belongs to a family of standard-setting approaches that utilize item-mapping techniques as a key component. The purpose of item maps in standard setting is to convey through spatial representations the relationship between item content, item difficulty, and the measurement scale on which cut scores are set. The Bookmark method is the most commonly used approach in this family and is one of the most widely used standard-setting methods in K-12 education.

The method was first introduced in 1996 by Lewis, Mitzel, and Green, who developed it to address several perceived limitations in the Angoff and other judgmental standard-setting methods. The goal of the developers was to reduce the cognitive complexity of the judgment task and to make the overall process more efficient, especially for setting multiple cut scores. They also wanted the method to be appropriate for different item formats in order to accommodate assessments with both dichotomously and polytomously scored items (Lewis et al., 1996; Mitzel, Lewis, Patz, & Green, 2001).

A key feature of the Bookmark method is the ordered item booklet (OIB), which presents test items in rank order of their difficulty starting from easiest to most difficult. Polytomous items appear multiple times in the OIB and are arranged according to the difficulty scoring in each individual response category.

It is characteristic for the Bookmark method to use item response theory (IRT) models to estimate item difficulty. The use of IRT is advantageous in that items representing different item formats can be mapped onto the same proficiency scale on which cut scores are set. This item mapping also provides an illustration of the kinds of test content and associated knowledge, skills, and abilities that typify specific scale locations, thereby connecting test content to the score scale and cut scores. Of the various IRT models, the 3-parameter logistic model is most commonly used in Bookmark standard settings to scale dichotomous

items, and the 2-parameter partial credit model with polytomous items (Mitzel et al., 2001).

The task of panelists in a Bookmark standard setting is to review the items in the OIB and to place a “bookmark” at the location that, in their judgment, divides items into those representing test content likely mastered by the target examinee of a given performance level and those items representing test content not yet mastered. Multiple iterations of the judgment round occur with panel discussions and various forms of empirical feedback in between rounds. Such feedback tends to also include additional item maps. To define mastery as a criterion, panelists are instructed to consider a specific response probability (RP), typically 0.67, such that the target examinee would have a two in three probability to correctly answer an item at the cut score location. For items below the cut score, the response probability would be higher, while for items above the cut score, the response probability would be lower.

The choice of RP value is important because it can affect the rank ordering of items in the OIB depending on the IRT model chosen (Beretvas, 2004). Mitzel et al. (2001) proposed an RP value of 0.67, claiming that psychologically it corresponds more closely to the concept of mastery and is therefore more easily understood by panelists. Mitzel et al. (2001) also argued that it is the concept of mastery, not the RP value itself, that should drive panelists’ judgment. Alternative RP values have been tested in conjunction with standard settings using the Bookmark and the related Mapmark method (Schultz & Mitzel, 2005). This research (e.g., National Research Council, 2005) found that different cut scores were obtained with different RP values, although theoretically they should be identical (Hambleton & Pitoniak, 2006). Wyse (2011) pointed out that practical challenges related to gaps in the item difficulty distribution make it impossible for cut scores derived from different RP applications to be equivalent. Given these differences in cut score outcomes, Schultz and Mitzel (2005) recommended to treat the choice of RP value as a policy decision that is made prior to standard setting.

Body of Work Methods

The *Body of Work* method was developed for complex assessments that consist primarily of constructed response item types such as those found in portfolio, essay writing, or alternate assessments (Cizek & Bunch, 2007). Unlike the Bookmark or Angoff methods, where the focus of the judgment process is on the item, the Body of Work method focuses on the evaluation of complete response sets from examinees. The method is sometimes referred to as the *Holistic* method (Hambleton, Jaeger, Plake, & Mills, 2000), a term that also summarily describes the family of approaches to which the Body of Work method belongs (Hambleton & Pitoniak, 2006). The main characteristic of the family of holistic approaches is the evaluation of whole or subsets of examinee work (Cizek & Bunch, 2007).

The judgment task in the Body of Work method is to identify the knowledge, skills, and abilities evident in the examinee response and to find the performance level that best corresponds to the observed characteristics. The method’s advantages are that it does not require panelists to conceptualize a hypothetical target examinee, nor to assume or estimate a specific response probability. This judgment

task is also more intuitive for panelists, especially teachers who are accustomed to evaluating student work (Kingston, Kahl, Sweeney, & Bay, 2001; Hambleton & Pitoniak, 2006).

The Body of Work method is an iterative process whereby panelists first complete a range-finding step to identify approximate cut score regions on the score scale on the basis of examining a subset of examinee responses. The subset is chosen to represent examinee work from the entire score scale at wide score point intervals. Panelists then engage in a more in-depth process referred to as pinpointing, which involves the review of additional examinee responses within more narrow ranges of the score scale that had previously been identified during range-finding. The two-step process makes the review of examinee responses more manageable, since response sets from noncritical score regions can be removed, making room for additional work samples from critical score regions. Obtaining more judgments near the cut score locations then ensures greater stability of the final cut scores (Hambleton & Pitoniak, 2006).

Final cut scores in the Body of Work method are typically determined through analytic procedures. Kingston et al. (2001) describe the use of logistic regression which determines the cut score as the point on the score scale where panelists' classification of examinee work into one of two adjacent performance levels is of equal likelihood (50%). Related methods, for example, the analytic judgment method by Plake and Hambleton (2001), compute averages of scores near the performance level boundary to determine the final cut scores.

In comparison to other standard-setting methods, cut scores obtained from the Body of Work method tend to be higher (Hambleton & Pitoniak, 2006). Kingston et al. (2001) also reported that when Body of Work cut scores were compared to classroom teacher judgments of their own students, the cut scores tended to be higher, especially for the top performance levels.

Although the Body of Work method has been implemented with several state assessment programs (Hambleton & Pitoniak, 2006) as well as with NAEP (e.g., the 2011 NAEP Writing assessment [National Assessment Governing Board, 2011]), the method remains relatively unexplored in the research literature. Some challenges deserving further exploration concern how materials are selected and prepared for review. For example, few guidelines exist concerning the selection of examinee work. Although Kingston et al. (2001) recommended that examinee responses with particularly discrepant item scores should not be included in a review, the issue of how to treat responses with different item score profiles has not been sufficiently addressed in the research literature. Other issues concern the maximum number of examinee responses that panelists can reliably and validly judge, the inclusion and presentation of examinee work on selected response items, and the choice of analytic method used to derive cut scores.

Other Approaches

While the Angoff, Bookmark, and Body of Work approaches represent some of the most common choices in standard setting, they are certainly not representative of the whole spectrum of available methods. Two frequently employed approaches that have not been discussed here include the *Borderline Group* and *Contrasting*

Group methods which focus on the evaluation of actual examinees known to standard-setting participants. Several methods have been developed specifically to accommodate complex, multidimensional assessments where conjunctive decision models for examinee classifications are needed. These methods may be particularly of relevance to the language-testing context where such assessments are prevalent. Examples are the *Judgmental Policy Capturing* method (Jaeger, 1995a, 1995b) and the *Dominant Profile* method (Plake, Hambleton, & Jaeger, 1997). Both require panelists to review profiles of examinee performance that are then assigned to performance categories.

There are a number of excellent sources in the literature that provide overviews and in-depth discussions of many existing standard-setting methods. In particular, the reader is referred to Hambleton and Pitoniak (2006) and Cizek and Bunch (2007). For a discussion of standard-setting methods proposed specifically for performance-based assessments, the article by Hambleton, Jaeger, et al. (2000) is recommended.

Current Research

Standard Setting in the Assessment Use Argument

Messick's (1989) seminal definition of validity solidified the developing notion in educational measurement that the validity of a test ultimately lies in theoretically and empirically justifying the actions and inferences about test takers that are made based on their performances on tests. In language testing, Bachman (2005) and Bachman and Palmer (2010) have provided an assessment use argument model for presenting evidence supporting the valid use of test scores. The model links test takers' *performance* (i.e., the behaviors elicited through the test's assessment tasks) to *assessment records* (i.e., the test takers' scores on the assessment) to the *interpretation(s)* of those scores (i.e., what the scores reveal about the test takers' language ability) to *decision(s)* (i.e., actions made about test takers based on the score interpretations) to *consequences* (i.e., what happens as a result of the decisions made). The usefulness of models such as the assessment use argument is their ability to make explicit what is often only implicit—to explicate important aspects of the whole picture that can easily be overlooked.

Standard-setting procedures play an important role in at least two levels in the assessment use argument. The first level is in establishing and justifying the link between assessment records and the interpretations of those scores. In language testing, for example, several major descriptors of general language proficiency have acquired a great deal of currency; in particular, the Interagency Language Roundtable (ILR) Skill Level Descriptions for the US government (ILR, 2012); the Proficiency Guidelines of the American Council on the Teaching of Foreign Languages (ACTFL) (ACTFL, 2012), and the levels of the Common European Framework of Reference (CEFR) (Council of Europe, 2001). Other descriptions of levels of language proficiency may have a more local currency, such as for a placement test within a language-teaching institution. Where a proficiency level description is used, a decision needs to be made, and justified, that links performances

on the test to the proficiency levels. Justifying that link includes fundamental considerations, such as the match between the model of language underlying the test and the model underlying the proficiency level descriptions; the match between the aspects of language covered by the assessment and the aspects of language contained in the proficiency level descriptions; and the match between the types of language behavior elicited by the test tasks and those described in the proficiency level descriptions. Even if all other claims for the link between performances on the assessment and interpretation of performances in terms of proficiency level descriptors can be supported by evidence, the question still arises as to *how much* of a performance is necessary to be labeled by the proficiency level(s). Is a score of 89 or 90 required to be interpreted as “1” or “Intermediate Mid” or “B1” or as the proficiency level required for entrance into the Intermediate-level class? Standard setting provides a defensible way of making that determination.

The second level in the assessment use argument in which standard setting plays a role is in the link between interpretations and decisions. Which test takers’ language ability, as demonstrated on an assessment, qualifies them for certain actions, such as entrance into a university program, qualifications for a job, receipt of additional incentive pay, or for professional certification? Sometimes, decisions are accomplished in two steps: a determination is made that a performance at the “superior” level is required for the job (the link between interpretations and decisions), and a separate determination is made that indicates the link between assessment scores and an interpretation of what constitutes “superior” level performance. Other times the link is made in one step, where decisions are made directly on the basis of performances on the assessment. It is most defensible for those making decisions to have access to a thorough knowledge of what actual test performances look like, such as can be gained in the application of a standard-setting process. Although the local context and the stakes involved for decisions and subsequent consequences based on those decisions may determine how formal or informal the process to set standards may be, it is useful for all language testers to consider and document how these decisions, that directly relate to actions taken that involve test takers, are reached.

Examples of Applications in Language Testing

Standard-setting methods based in the tradition of educational measurement are beginning to be more widely applied, and researched, in the context of language testing. One impetus has been, in the European context, the appearance of the Common European Framework of Reference (CEFR) (Council of Europe, 2001) with its six corresponding levels of proficiency: A1, A2, B1, B2, C1, and C2. The widespread adoption of these language proficiency levels, in particular by policy makers (for example, as minimum proficiency levels required for citizenship in certain European countries), has necessitated the need for test developers and publishers to link performances on their assessments to the CEFR levels. To aid in this endeavor, the Council of Europe produced a handbook, the *Manual for Relating Language Examinations to the Common European Framework of Reference for Languages (CEFR) and Reference Supplement* (Council of Europe, 2009). Section 6 of the manual provides an overview of several methods and their variations,

including the “Tucker–Angoff” method, Body of Work method, and Bookmark method.

As evidence of the increasing work in standard setting in the CEFR context, the Council of Europe, together with the Cito Institute for Educational Measurement and the European Association for Language Testing and Assessment (EALTA), published in 2009 proceedings from a colloquium entitled “Standard Setting Research and Its Relevance to the CEFR” (Figueras & Noijons, 2009). Another collection of papers from an invited colloquium held in Cambridge, organized by the Association of Language Testers in Europe (ALTE) on behalf of the Council of Europe, is found in *Aligning Tests With the CEFR: Reflections on Using the Council of Europe’s Draft Manual* (Martyniuk, 2010). These colloquia allowed researchers to explicate some important issues in standard setting and practitioners to present on their experiences in linking exams to the CEFR and represent a start in the professionalizing and dissemination of standard-setting methodologies based in educational measurement in the European context. The publication of both collections of papers indicates the Council of Europe’s support to promulgating good practices. Surprisingly, few references in any of the papers appear from research and studies on standard setting in the context of US education, which has had a much longer history, though not specifically in language testing. (Interestingly, two examples conducted in the USA using standard-setting methodology to link the TOEFL to the CEFR levels are available as ETS Research Reports: Tannenbaum and Wylie’s *Mapping English Language Proficiency Test Scores Onto the Common European Framework*, 2005, and *Linking English-Language Test Scores Onto the Common European Framework of Reference: An Application of Standard-Setting Methodology*, 2008.)

A second impetus to the application of psychometrically based standard-setting methodology to language testing stems from the requirement of the 2002 “No Child Left Behind” legislation in the USA, that, among other accountability testing, required that all English language learners be assessed annually against English language standards to demonstrate their acquisition of English. At the time, the US Department of Education funded the development of several “new generation” English language proficiency tests for use by consortia of states. Although at present each state can determine at what proficiency level English language learners may be exited from federally required language support services, all states in a consortium use the same standards and the proficiency levels defined in them. Kenyon (2006) provides an example of how standard-setting methodology was applied to the ACCESS for ELLs® test used by the (currently) 27 member states of the World-Class Instructional Design and Assessment (WIDA) Consortium to link performances on the assessment to the proficiency levels described by the WIDA Consortium’s English language proficiency standards.

Challenges

One challenge facing language testers in approaching standard setting is the psychometric sophistication required to conduct rigorous standard-setting studies. For example, the Yes/No Angoff method, while touted as being cognitively user-friendly for panelists, has been shown to have systematic bias—recommendations

being lower for lower performance standards and higher for higher performance standards (Reckase & Bay, 1999). Additionally, the pace of research on standard-setting methodologies (and the proliferation of new methodologies) rapidly increases and is difficult to keep up with. For example, while the Angoff method or one of its modifications is considered to be the most widely used, the National Assessment of Educational Progress, which funded and continues to fund much research on standard setting, discontinued using a modified Angoff methodology in 2005, when a modified Bookmark approach was used for 12th grade mathematics (National Center for Educational Statistics, 2012). Keeping abreast of current research and practice in standard setting, which has arisen as its own subarea in educational measurement, is a challenging task. Language testers needing to implement standard setting in any type of high stakes environment may need to draw on expertise from outside their own field.

A second challenge is resources. Although standard setting in many contexts is an integral part of the assessment use argument for a language test, many language test development projects are under-resourced. Conducting such studies requires resources of time (for preparation of materials, conducting the studies, doing the analyses), of staff (for leading sessions), and for panelists, who may need to be paid for their time and expenses. Because in many contexts standard setting is a part of establishing the validity of the use of the test, language testing projects will need to begin to plan on this step prior to the tests becoming operational.

A third challenge in some contexts, particularly for relating tests to the CEFR, is the question of what authority or policy-making body stands behind the standard-setting results. For example, the Council of Europe's *Manual for Relating Language Examinations to the Common European Framework of Reference for Languages (CEFR)* opens with the following words:

The Manual is not the sole guide to linking a test to the CEFR and there is no compulsion on any institutions to undertake such linking. However, institutions wishing to make claims about the relationship of their examinations to the levels of the CEFR may find the procedures helpful to demonstrate the validity of those claims. (Council of Europe, 2009, p. 1)

This quote from the Council's manual stands in sharp contrast to the paper "Standard Setting Theory and Practice: Issues and Difficulties" by Reckase, presented in the colloquium supported by the Council of Europe: "Someone calls for a standard. For the purpose of proposing a general theory of standard setting the general term 'agency' will be used for those who call for the existence of a standard" (Reckase, 2009, p. 13). Reckase, examining the CEFR, continues: "In this case, the agency is clearly the Council of Europe. That organization has called for the standards for language proficiency and has provided a policy definition for a standard [elucidated in the CEFR]" (p. 17). The challenge, however, is that the political situation means that the Council of Europe cannot stand behind or authorize the results of any linking study of a language proficiency test to the CEFR. In the US context of educational accountability, it is the responsibility of the agency calling for the standards to ensure that they are appropriately set. For

example, the results of the WIDA standard-setting study (Kenyon, 2006) were ultimately approved by the Executive Committee of States in the WIDA Consortium, the policy-setting agency separate from the test developer (the Center for Applied Linguistics). From the US perspective, the situation in which individual test developers conduct, approve, and endorse the standard-setting studies seems not to recognize the policy-making aspect (and enforcement) of the entire socially moderated process and may reflect a conflict of interest. The upshot of the European situation appears to be caveat emptor; that is, test users will need to be informed enough to determine the sufficiency and adequacy of the linking procedures standing behind the claims of any testing company that asserts that performances on their tests may be interpreted in terms of CEFR levels.

A fourth challenge is the research that remains to be conducted to improve the theoretical and empirical knowledge base about all aspects of the standard-setting process. Because conducting a single standard-setting study is so resource intensive, controlled comparative studies on the strengths and weaknesses of different approaches and their various modifications are very rare. Language testers, with their appreciation of the social uses of language and practice in more qualitative approaches to research, can make a substantial contribution to the psychometric literature. For example, data from panelists are routinely collected in standard-setting studies as part of the evidence for the procedural validity of the study, yet this data tends to be superficially analyzed and little research is actually done on the cognitive and social processes at work in the standard-setting process. Qualitative approaches need to be added to the psychometric literature to give a full-orbed understanding of what takes place in a standard-setting study. An example of a qualitative study is Papageorgiou (2010), who investigated decision-making processes used by standard-setting panelists in the CEFR context. Further research by language testers, who for example have so well investigated the decision-making processes of test scorers, needs to appear.

A final challenge particular to language testing will be the standard setting of multiple languages to one common frame of reference, whether the ILR Scale, the ACTFL scale, or the CEFR. It is one thing to create links to proficiency level descriptions within a single language, but another to show that these linkings are consistent across languages. Does it then become necessary to develop new methodologies to simultaneously conduct both types of linkings? At present this situation does not seem to have any analogy in the educational measurement literature.

Future Directions

Because standard setting is quite new in language testing, future directions revolve around addressing the challenges above. As language testers approach test validity in a more holistic and principled way through the model provided by Bachman and Palmer's assessment use argument, potential applications of standard-setting methodologies, applied formally or informally depending on the stakes of the assessments, will become clearer as a means to provide evidence for the link between assessment scores and interpretations or decisions, or both, made on the

basis of test performances. Language test development projects will need to plan on the resources, in time and money, to implement required studies. In situations that are more local, language testers may acquire sufficient skills in standard-setting methodologies to meet the purposes required. However, for language tests in high stakes situations, an interdisciplinary approach combining the expertise of language testers and psychometricians will probably be called for. Language testers will do well to become as acquainted as possible with current approaches, evaluating them for appropriateness in each situation.

On the other hand, language testers should not shy away from asking difficult questions about methodologies coming out of educational measurement traditions and then work to conduct research from their expertise to build a knowledge base to improve practice. For example, studies that clarify what most influences panelists in making their judgments may improve practice by removing, to the extent possible, those influences that are most irrelevant to the process. The analysis of the discourse produced during group discussions may also provide insight on how to avoid groups from being overly swayed in their judgments by any one individual. Indeed, as a socially moderated process, standard-setting procedure is an area in which language testers may be able to provide particular insight that educational measurement professionals may miss. Nevertheless, to move the field forward will require language testers to be acquainted with the essentials coming from the educational measurement tradition and to present their research in this area in a way that is accessible to educational measurement professionals.

Administration, Scoring, and Reporting Scores

Ari Huhta

University of Jyväskylä, Finland

Introduction

Administration, scoring, and reporting scores are essential elements of the testing process because they can significantly impact the quality of the inferences that can be drawn from test results, that is, the validity of the tests (Bachman & Palmer, 1996; McCallin, 2006; Ryan, 2006). Not surprisingly, therefore, professional language-testing organizations and educational bodies more generally cover these elements in some detail in their guidelines of good practice.

The Standards for Educational and Psychological Testing devote several pages to describing standards that relate specifically to test administration, scoring, and reporting scores (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education [AERA, APA, & NCME], 1999, pp. 61–6). Also the three major international language-testing organizations, namely the International Language Testing Association (ILTA), the European Association for Language Testing and Assessment (EALTA), and the Association of Language Testers in Europe (ALTE), make specific recommendations about administration, scoring, and reporting scores for different contexts and purposes (e.g., classroom tests and large-scale examinations) and for different stakeholders (e.g., test designers, institutions, and test takers).

Although the detailed recommendations vary depending on the context, stakeholder, and professional association, the above guidelines endorse very similar practices. Guidelines on the administration of assessments typically aim at creating standardized conditions that would allow test takers to have a fair and equal opportunity to demonstrate their language proficiency. These include, for example, clear and uniform directions to test takers, an environment that is free of noise and disruptions, and adequate accommodations for disadvantaged test takers, such as extra time for people with dyslexia or a different version of the test for

blind learners. A slightly different consideration is test security: Individual test takers should not have an unfair advantage over others by accessing test material prior to the test or by copying answers from others during the test because of inadequate invigilation, for example. Administration thus concerns everything that is involved in presenting the test to the test takers: time, place, equipment, and instructions, as well as support and invigilation procedures (see Mousavi, 1999, for a detailed definition).

Scoring—giving numerical values to test items and tasks (Mousavi, 1999)—is a major concern for all types of testing, and professional associations therefore give several recommendations. From the point of view of test design, these associations emphasize the creation of clear and detailed scoring guidelines for all kinds of tests but especially for those that contain constructed response items and speaking and writing tasks. Accurate and exhaustive answer keys should be developed for open-ended items, raters should be given adequate training, and the quality of their work should be regularly monitored. Test scores and ratings should also be analyzed to examine their quality, and appropriate action should be taken to address any issues to ensure adequate reliability and validity.

The main theme in reporting, namely communicating test results to stakeholders (Cohen & Wollack, 2006, p. 380), is ensuring the intelligibility and interpretability of the scores. Reporting just the raw test scores is not generally recommended, so usually test providers convert test scores onto some reporting scale that has a limited number of score levels or bands, which are often defined verbally. An increasingly popular trend in reporting scores is to use the Common European Framework of Reference (CEFR) to provide extra meaning to scores. Other recommendations on reporting scores include that test providers give information about the quality (validity, reliability) of their tests, and about the accuracy of the scores, that is, how much the score is likely to vary around the reported score.

Test Administration, Scoring, and Reporting Scores

In the following, test administration, scoring, and reporting scores are described in terms of what is involved in each, and of how differences in the language skills tested and the purposes and contexts of assessment can affect the way tests are administered, scored, and reported. An account is also given of how these might have changed over time and whether any current trends can be discerned.

Administration of Tests

The administration of language tests and other types of language assessments is highly dependent on the skill tested and task types used, and also on the purpose and stakes involved. Different administration conditions can significantly affect test takers' performance and, thus, the inferences drawn from test scores. As was described above, certain themes emerge in the professional guidelines that are fairly common across all kinds of test administrations. The key point is to create standardized conditions that allow test takers a fair opportunity to demonstrate what they can do in the language assessed, and so to get valid, comparable

information about their language skills. Clear instructions, a chance for the test taker to ask for clarifications, and appropriate physical environment in terms of, for example, noise, temperature, ventilation, and space all contribute in their own ways to creating a fair setting (see Cohen & Wollack, 2006, pp. 356–60, for a detailed discussion of test administration and special accommodations).

A general administration condition that is certain to affect administration conditions and also performance is the time limit set for the test. Some tests can be speeded on purpose, especially if they attempt to tap time-critical aspects of performance, such as in a scanning task where test takers have to locate specific information in the text fast. Setting up a speeded task in an otherwise nonspeeded paper-based test is challenging administratively; on computer, task-specific time limits are obviously easy to implement. In most tests, time is not a key component of the construct measured, so enough time is given for almost everybody to finish the test. However, speededness can occur in nonspeeded tests when some learners cannot fully complete the test or have to change their response strategy to be able to reply to all questions. Omitted items at the end of a test are easy to spot but other effects of unintended speededness are more difficult to discover (see Cohen & Wollack, 2006, pp. 357–8 on research into the latter issue).

A major factor in test administration is the aspect of language assessed; in practice, this boils down to testing speaking versus testing the other skills (reading, writing, and listening). Most aspects of language can be tested in groups, sometimes in very large groups indeed. The prototypical test administration context is a classroom or a lecture hall full of learners sitting at their own tables writing in their test booklets. Testing reading and writing or vocabulary and structures can be quite efficiently done in big groups, which is obviously an important practical consideration in large-scale testing, as the per learner administration time and costs are low (for more on test practicality as an aspect of overall test usefulness, see Bachman & Palmer, 1996). Listening, too, can be administered to big groups, if equal acoustic reception can be ensured for everybody.

Certain tests are more likely to be administered to somewhat smaller groups. Listening tests and, more recently, computerized tests of any skill are typically administered to groups of 10–30 learners in dedicated language studios or computer laboratories that create more standardized conditions for listening tests, as all test takers can wear headphones.

Testing speaking often differs most from testing the other skills when it comes to administration. If the preferred approach to testing speaking is face to face with an interviewer or with another test taker, group administrations become almost impossible. The vast majority of face-to-face speaking tests involve one or two test takers at a time (for different oral test types, see Luoma, 2004; Fulcher, 2003; Taylor, 2011). International language tests are no exception: Tests such as the International English Language Testing System (IELTS), the Cambridge examinations, the Goethe Institut's examinations, and the French Diplôme d'études en langue française (DELF) and Diplôme approfondi de langue française (DALF) examinations all test one or two candidates at a time.

Interestingly, the practical issues in testing speaking have led to innovations in test administration such as the creation of semidirect tests. These are administered in a language or computer laboratory: Test takers, wearing headphones and micro-

phones, perform speaking tasks following instructions they hear from a tape or computer, and possibly also read in a test booklet. Their responses are recorded and rated afterwards. There has been considerable debate about the validity of this semidirect approach to testing speaking. The advocates argue that these tests cover a wider range of contexts, their administration is more standardized, and they result in very similar speaking grades compared with face-to-face tests (for a summary of research, see Malone, 2000). The approach has been criticized on the grounds that it solicits somewhat different language from face-to-face tests (Shohamy, 1994). Of the international examinations, the Test of English as a Foreign Language Internet-based test (TOEFL iBT) and the Test Deutsch als Fremdsprache (TestDaF), for example, use computerized semidirect speaking tests that are scored afterwards by human raters. The new Pearson Test of English (PTE) Academic also employs a computerized speaking test but goes a step further as the scoring is also done by the computer.

The testing context, purpose, and stakes involved can have a marked effect on test administration. The higher the stakes, the more need there is for standardization of test administration, security, confidentiality, checking of identity, and measures against all kinds of test fraud (see Cohen & Wollack, 2006, for a detailed discussion on how these affect test administration). Such is typically the case in tests that aim at making important selections or certifying language proficiency or achievement. All international language examinations are prime examples of such tests. However, in lower stakes formative or diagnostic assessments, administration conditions can be more relaxed, as learners should have fewer reasons to cheat, for example (though of course, if an originally low stakes test becomes more important over time, its administration conditions should be reviewed). Obviously, avoidance of noise and other disturbances makes sense in all kinds of testing, unless the specific aim is to measure performance under such conditions. Low stakes tests are also not tied to a specific place and time in the same way as high stakes tests are. Computerization, in particular, offers considerable freedom in this respect. A good example is DIALANG, an online diagnostic assessment system which is freely downloadable from the Internet (Alderson, 2005) and which can thus be taken anywhere, any time. Administration conditions of some forms of continuous assessment can also differ from the prototypical invigilated setting: Learners can be given tasks and tests that they do at home in their own time. These tasks can be included in a portfolio, for example, which is a collection of different types of evidence of learners' abilities and progress for either formative or summative purposes, or both (on the popular European Language Portfolio, see Little, 2005).

Scoring and Rating Procedures

The scoring of test takers' responses and performances should be as directly related as possible to the constructs that the tests aim at measuring (Bachman & Palmer, 1996). If the test has test specifications, they typically contain information about the principles of scoring items, as well as the scales and procedures for the rating of speaking and writing. Traditionally, a major concern about scoring has been reliability: To what extent are the scoring and rating consistent over time and

Figure 58.1 Steps in scoring item-based tests

across raters? The rating of speaking and writing performances, in particular, continues to be a major worry and considerable attention is paid to ensuring a fair and consistent assessment, especially in high stakes contexts. A whole new trend in scoring is computerization, which is quite straightforward in selected response items but much more challenging the more open-ended the tasks are. Despite the challenges, computerized scoring of all skills is slowly becoming a viable option, and some international language examinations have begun employing it.

As was the case with test administration, scoring, too, is highly dependent on the aspects of language tested and the task types used. The purpose and stakes of the test do not appear to have such a significant effect on how scoring is done, although attention to, for instance, rater consistency is obviously closer in high stakes contexts. The approach to scoring is largely determined by the nature of the tasks and responses to be scored (see Millman & Greene, 1993; Bachman & Palmer, 1996). Scoring selected response items dichotomously as correct versus incorrect is a rather different process from rating learners' performances on speaking and writing tasks with the help of a rating scale or scoring constructed response items polytomously (that is, awarding points on a simple scale depending on the content and quality of the response).

Let us first consider the scoring of item-based tests. Figure 58.1 shows the main steps in a typical scoring process: It starts with the test takers' responses, which can be choices made in selected response items (e.g., A, B, C, D) or free responses to gap-fill or short answer items (parts of words, words, sentences). Prototypical responses are test takers' markings on the test booklets that also contain the task materials. Large-scale tests often use separate optically readable answer sheets for multiple choice items. Paper is not, obviously, the only medium used to deliver tests and collect responses. Tape-mediated speaking tests often contain items that are scored rather than rated, and test takers' responses to such items are normally recorded on tape. In computer-based tests, responses are captured in electronic format, too, to be scored either by the computer applying some scoring algorithm or by a human rater.

In small-scale classroom testing the route to step 2, scoring, is quite straightforward. The teacher simply collects the booklets from the students and marks the papers. In large-scale testing this phase is considerably more complex, unless we have a computer-based test that automatically scores the responses. If the scoring is centralized, booklets and answer sheets first need to be mailed from local test

centers to the main regional, national, or even international center(s). There the optically readable answer sheets, if any, are scanned into electronic files for further processing and analyses (see Cohen & Wollack, 2006, pp. 372–7 for an extended discussion of the steps in processing answer documents in large-scale examinations).

Scoring key: An essential element of scoring is the scoring key, which for the selected response items simply tells how many points each option will be awarded. Typically, one option is given one point and the others zero points. However, sometimes different options receive different numbers of points depending on their degree of correctness or appropriateness. For productive items, the scoring can be considerably more complex. Some items have only one acceptable answer; this is typical of items focusing on grammar or vocabulary. For short answer items on reading and listening, the scoring key can include a number of different but acceptable answers but the scoring may still be simply right versus wrong, or it can be partial-credit and polytomous (that is, some answers receive more points than others).

The scoring key is usually designed when the test items are constructed. The key can, however, be modified during the scoring process, especially for open-ended items. Some examinations employ a two-stage process in which a proportion of the responses is first scored by a core group of markers who then complement the key for the marking of the majority of papers by adding to the list of acceptable answers based on their work with the first real responses.

Markers and their training: Another key element of the scoring plan is the selection of scorers or markers and their training. In school-based testing, the teacher is usually the scorer, although sometimes she may give the task to the students themselves or, more often, do it in cooperation with colleagues. In high stakes contexts, the markers and raters usually have to meet specified criteria to qualify. For example, they may have to be native speakers or non-native speakers with adequate proficiency and they probably need to have formally studied the language in question.

Item analyses: An important part of the scoring process in the professionally designed language tests is item analyses. The so-called “classical” item analyses are probably still the most common approach; they aim to find out how demanding the items are (item difficulty or facility) and how well they discriminate between good and poor test takers. These analyses can also identify problematic items or items tapping different constructs. Item analyses can result in the acceptance of additional responses or answer options for certain items—a change in the scoring key—or the removal of entire items from the test, which can change the overall test score.

Test score scale: When the scores of all items are ready, the next logical step is to combine them in some way into one or more overall scores. The simplest way to arrive at an overall test score is to sum up the item scores; here the maximum score equals the number of items in the test, if each item is worth one point. The scoring of a test comprising a mixture of dichotomously (0 or 1 point per item) scored multiple choice items and partial-credit/polytomous short answer items is obviously more complex. A straightforward sum of such items results in the short answer questions being given more weight because test takers get more

points from them; for example, three points for a completely acceptable answer compared with only point from a multiple choice item. This may be what we want, if the short answer items have been designed to tap more important aspects of proficiency than the other items. However, if we want all items to be equally important, each item score should be weighted by an appropriate number.

Language test providers increasingly complement classical item analyses with analyses based on what is known as modern test theory or item response theory (IRT; one often-used IRT approach is Rasch analysis). What makes them particularly useful is that they are far less dependent than the classical approaches on the characteristics of the learners who happened to take the test and the items in the test. With the help of IRT analyses, it is possible to construct test score scales that go beyond the simple summing up of item scores, since they are adjusted for item difficulty and test takers' ability, and sometimes also for item discrimination or guessing. Most large-scale international language tests rely on IRT analyses as part of their test analyses, and also to ensure that their tests are comparable across administrations.

An example of a language test that combines IRT analysis and item weighting in the computation of its score scale is DIALANG, the low stakes, multilingual diagnostic language assessment system mentioned above (Alderson, 2005). In the fully developed test languages of the system, the items are weighted differentially, ranging from 1 to 5 points, depending on their ability to discriminate.

Setting cutoff points for the reporting scale: Instead of reporting raw or weighted test scores many language tests convert the score to a simpler scale for reporting purposes, to make the test results easier to interpret. The majority of educational systems probably use simple scales comprising a few numbers (e.g., 1–5 or 1–10) or letters (e.g., A–F). Sometimes it is enough to report whether the test taker passes or fails a particular test, and thus a simple two-level scale (pass or fail) is sufficient for the purpose. Alternatively, test results can be turned into developmental scores such as age- or grade-equivalent scores, if the group tested are children and if such age- or grade-related interpretations can be made from the particular test scores. Furthermore, if the reporting focuses on rank ordering test takers or comparing them for some normative group, percentiles or standard scores (z or T scores) can be used, for example (see Cohen & Wollack, 2006, p. 380).

The conversion of the total test score to a reporting scale requires some mechanism for deciding how the scores correspond to the levels on the reporting scale. The process through which such cutoff points (cut scores) for each level are decided is called standard setting (step 6 in Figure 58.1).

Intuition and tradition are likely to play at least as big a role as any empirical evidence in setting the cutoffs; few language tests have the means to conduct systematic and sufficient standard-setting exercises. Possibly the only empirical evidence available to teachers, in particular, is to compare their students with each other (ranking), with the students' performances on previous tests, or with other students' performance on the same test (norm referencing). The teacher may focus on the best and weakest students and decide to use cutoffs that result in the regular top students getting top scores in the current test, too, and so on. If the results of the current test are unexpectedly low or high, the teacher may raise or lower the cutoffs accordingly.

Many large-scale tests are obviously in a better position to make more empirically based decisions about cutoff points than individual teachers and schools. A considerable range of standard-setting methods has been developed to inform decisions about cutoffs on test score scales (for reviews, see Kaftandjieva, 2004; Cizek & Bunch, 2006). The most common standard-setting methods focus on the test tasks; typically, experts evaluate how individual test items match the levels of the reporting scale. Empirical data on test takers' performance on the items or the whole test can also be considered when making judgments. In addition to these test-centered standard-setting methods, there are examinee-centered methods in which persons who know the test takers well (typically teachers) make judgments about their level. Learners' performances on the items and the test are then compared with the teachers' estimates of the learners to arrive at the most appropriate cutoffs.

Interestingly, the examinee-centered approaches resemble what most teachers are likely to do when deciding on the cutoffs for their own tests. Given the difficulty and inherent subjectivity of any formal standard-setting procedure, one wonders whether experienced teachers who know their students can in fact make at least equally good decisions about cutoffs as experts relying on test-centered methods, provided that the teachers also know the reporting scale well.

Sometimes the scale score conversion is based on a type of norm referencing where the proportion of test takers at the different reporting scale levels is kept constant across different tests and administrations. For example, the Finnish school-leaving matriculation examination for 18-year-olds reports test results on a scale where the highest mark is always given to the top 5% in the score distribution, the next 15% get the second highest grade, the next 20% the third grade, and so on (Finnish Matriculation Examination Board, *n.d.*).

A recent trend in score conversion concerns the CEFR. Many language tests have examined how their test scores relate to the CEFR levels in order to give added meaning to their results and to help compare them with the results of other language tests (for a review, see Martyniuk, 2011). This is in fact score conversion (or setting cutoffs) at a higher or secondary level: The first one involves converting the test scores to the reporting scale the test uses, and the second is about converting the reporting scale to the CEFR scale.

Scoring Tests Based on Performance Samples

The scoring of speaking and writing tasks usually takes place with the help of one or more rating scales that describe test-taker performance at each scale level. The rater observes the test taker's performance and decides which scale level best matches the observed performance. Such rating is inherently criterion referenced in nature as the scale serves as the criteria against which test takers' performances are judged (Bachman & Palmer, 1996, p. 212). This is in fact where the rating of speaking and writing differs the most from the scoring of tests consisting of items (e.g., reading or listening): In many tests the point or level on the rating scale assigned to the test taker is what will be reported to him or her. There is thus no need to count a total speaking score and then convert it to a different reporting scale, which is the standard practice in item-based tests. The above simplifies

matters somewhat because in reality some examinations use more complex procedures and may do some scale conversion and setting of cutoffs also for speaking and writing. However, in its most straightforward form, the rating scale for speaking and writing is the same as the reporting scale, although the wording of the two probably differs because they target different users (raters vs. test score users).

It should be noted that instead of rating, it is possible to count, for example, features of language in speaking and writing samples. Such attention to detail at the expense of the bigger picture may be appropriate in diagnostic or formative assessment that provides learners with detailed feedback.

Rating scales are a specific type of proficiency scale and differ from the more general descriptive scales designed to guide selection test content and teaching materials or to inform test users about the test results (Alderson, 1991). Rating scales should focus on what is observable in test takers' performance, and they should be relatively concise in order to be practical. Most rating scales refer to both what the learners can and what they cannot do at each level; other types of scales may often avoid references to deficiencies in learners' proficiency (e.g., the CEFR scales focus on what learners can do with the language, even at the lowest proficiency levels).

Details of the design of rating scales are beyond the scope of this chapter; the reader is advised to consult, for example, McNamara (1996) and Bachman and Palmer (1996). Suffice it to say that test purpose significantly influences scale design, as do the designers' views about the constructs measured. A major decision concerns whether to use only one overall (holistic) scale or several scales. For obtaining broad information about a skill for summative, selection, and placement purposes, one holistic scale is often preferred as a quick and practical option. To provide more detailed information for diagnostic or formative purposes, analytic rating makes more sense. Certain issues concerning the validity of holistic rating, such as difficulties in balancing the different aspects lumped together in the level descriptions, have led to recommendations to use analytic rating, and if one overall score is required, to combine the component ratings (Bachman & Palmer, 1996, p. 211). Another major design feature relates to whether only language is to be rated or also content (Bachman & Palmer, 1996, p. 217). A further important question concerns the number of levels in a rating scale. Although a very fine-grained scale could yield more precise information than a scale consisting of just three or four levels, if the raters are unable to distinguish the levels it would cancel out these benefits. The aspect of language captured in the scale can also affect the number of points in the scale; it is quite possible that some aspects lend themselves to be split into quite a few distinct levels whereas others do not (see, e.g., the examples in Bachman & Palmer, 1996, pp. 214–18).

Since rating performances is usually more complex than scoring objective items, a lot of attention is normally devoted, in high stakes tests in particular, to ensuring the dependability of ratings. Figure 58.2 describes the steps in typical high stakes tests of speaking and writing. While most classroom assessment is based on only one rater, namely the teacher, the standard practice in most high stakes tests is for at least a proportion of performances to be double rated (step 3 in Figure 58.2). Sometimes the first rating is done during the (speaking) test (e.g., the rater is present in the Cambridge examinations but leaves the conduct of the test to an

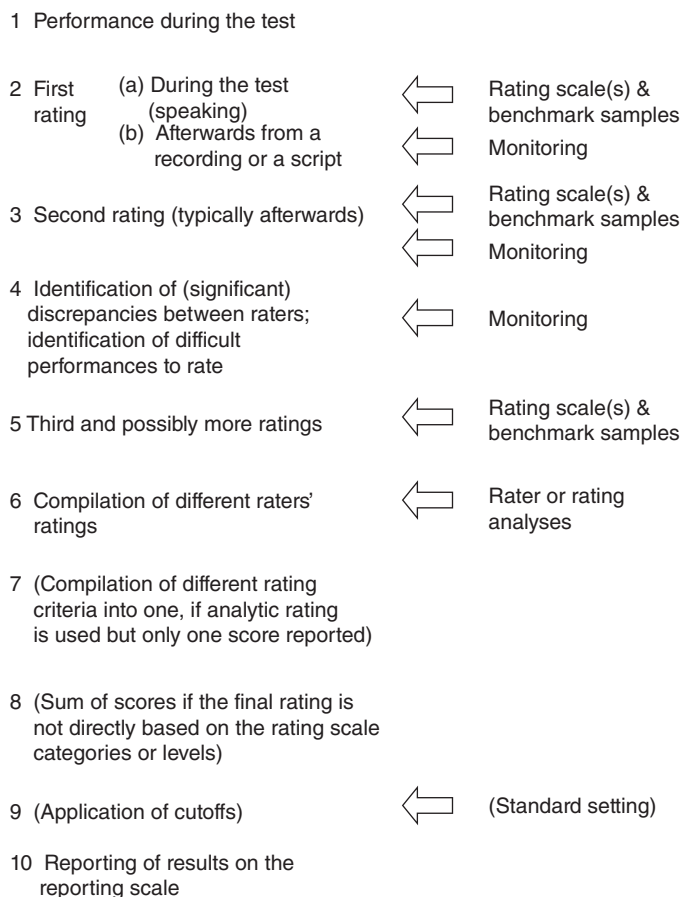

Figure 58.2 Steps in rating speaking and writing performances

interlocutor), but often the first and second ratings are done afterwards from an audio- or videorecording, or from the scripts in the writing tests. Typically, all raters involved are employed and trained by the testing organization, but sometimes the first rater, even in high stakes tests, is the teacher (as in the Finnish matriculation examination) even if the second and decisive rating is done by the examination board.

Large-scale language tests employ various monitoring procedures to try to ensure that their raters work consistently enough. Double rating is in fact one such monitoring device, as it will reveal significant rater disagreement in their ratings; if this can be spotted while rating is still in progress, one or both of the raters can be given feedback and possibly retrained before being allowed to continue. Some tests use a small number of experienced master raters who continuously sample and check the ratings of a group of raters assigned to them. The TOEFL iBT has an online system that forces the raters to start each new rating session by assessing a number of calibration samples, and only if the rater passes them is he or she allowed to proceed to the actual ratings.

A slightly different approach to monitoring raters involves adjusting their ratings up or down depending on their severity or lenience, which can be estimated with the help of multifaceted Rasch analysis. For example, the TestDaF, which measures German needed in academic studies, regularly adjusts reported scores for rater severity or lenience (Eckes et al., 2005, p. 373).

Analytic rating scales appear to be the most common approach to rating speaking and writing in large-scale international language examinations, irrespective of language. Several English (IELTS, TOEFL, Cambridge, Pearson), German (Goethe Institut, TestDaF), and French (DELF, DALF) language examinations implement analytic rating scales, although they typically report speaking and writing as a single score or band.

It is usually also the case that international tests relying on analytic rating weigh all criteria equally and take the arithmetic or conceptual mean rating as the overall score for speaking or writing (step 7, Figure 58.2). Exceptions to this occur, however. The International Civil Aviation Organization (ICAO) specifies that all aviation English tests adhering to their guidelines must implement the five dimensions of oral proficiency in a noncompensatory fashion (Bachman & Palmer, 1996, p. 224). That is, the lowest rating across the five criteria determines the overall level reached by the test taker (ICAO, 2004).

Reporting Scores

Score reports inform different stakeholders, such as test takers, parents, admission officers, and educational authorities, about individuals' or groups' test results for possible action. Thus, these reports can be considered more formal feedback to the stakeholders. Score reports are usually pieces of paper that list the scores or grades obtained by the learner, possibly with some description of the test and the meaning of the grades. Some, typically more informal reports may be electronic in format, if they are based on computerized tests and intended only for the learners and their teachers (e.g., the report and feedback from DIALANG). Score reports use the reporting scale onto which raw scores were converted, as described in the previous section.

Score reports are forms of communication and thus have a sender, receiver, content, and medium; furthermore, they serve particular purposes (Ryan, 2006, p. 677). Score reports can be divided into two broad types: reports on individuals and reports on groups. Reporting scores is greatly affected by the purpose and type of testing.

The typical sender of score reports on individual learners and based on classroom tests is the teacher, who acts on behalf of the school and municipality and ultimately also as a representative of some larger public or private educational system. The sender of more formal end-of-term school reports or final school-leaving certificates is most often the school, again acting on behalf of a larger entity. The main audiences of both score reports and formal certificates are the students and their parents, who may want to take some action based on the results (feedback) given to them. School-leaving certificates have also other users such as higher-level educational institutions or employers making decisions about admitting and hiring individual applicants.

School-external tests and examinations are another major originator of score reports for individuals. The sender here is typically an examination board, a regional or national educational authority, or a commercial test provider. Often such score reports are related to examinations that take place only at important points in the learners' careers, such as the end of compulsory education, end of pre-university education, or when students apply for a place in a university. The main users of such reports are basically the same as for school-based reports except that in many contexts external reports are considered more prestigious and trustworthy, and may thus be the only ones accepted as proof of language proficiency, for instance for studying in a university abroad.

In addition to score reports on individuals' performance, group-level reports are also quite common. They may be simply summaries of individual score reports at the class, school, regional, or national level. Sometimes tests are administered from which no reports are issued to individual learners; only group-level results are reported. The latter are typically tests given by educational authorities to evaluate students' achievement across the regions of a country or across different curricula. International comparative studies on educational achievement exist, in language subjects among others. The best known is the Programme for International Student Assessment (PISA) by the Organisation for Economic Co-operation and Development (OECD), which regularly tests and reports country-level reports of 15-year-olds' reading skills in their language of education.

The content of score reports clearly depends on the purpose of assessment. The prototypical language score report provides information about the test takers' proficiency on the reporting scale used in the educational system or the test in question. Scales consisting of numbers or letters are used in most if not all educational systems across the world. With the increase in criterion-referenced testing, such simple scales are nowadays often accompanied by descriptions of what different scale points mean in terms of language proficiency. Entirely non-numeric reports also exist; in some countries the reporting of achievement in the first years of schooling consists of only verbal descriptions.

Score reports from language proficiency examinations and achievement tests often report on overall proficiency only as a single number or letter (e.g., the Finnish matriculation examination). Some proficiency tests, such as the TOEFL iBT and the IELTS, issue subtest scores in addition to a total score. In many placement contexts, too, it may not be necessary to report more than an overall estimate of candidates' proficiency. However, the more the test aims at supporting learning, as diagnostic and formative tests do, the more useful it is to report profiles based on subtests or even individual tasks and items. For example, the diagnostic DIALANG test reports on test-, subskill-, and item-level performance.

Current Research

Research on the three aspects of the testing process covered here is very uneven. Test administration appears to be the least studied (McCallin, 2006, pp. 639–40),

except for the types of testing where it is intertwined with the test format, such as in computerized testing, which is often compared with paper-based testing, and in oral testing, where factors related to the setting and participants have been studied. Major concerns with computerized tests include the effect of computer familiarity on the test results and to what extent such tests are, or should be, comparable with paper-based tests (e.g., adaptivity is really possible only with computerized tests) (Chapelle & Douglas, 2006).

As far as oral tests are concerned, their characteristics and administration have been studied for decades. In particular, the nature of the communication and the effect of the tester (interviewer) have been hotly debated. For example, can the prototypical test format, the oral interview, represent “normal” face-to-face communication? The imbalance of power, in particular, has been criticized (Luoma, 2004, p. 35), which has contributed to the use of paired tasks in which two candidates interact with each other, in a supposedly more equal setting. Whether the pairs are in fact equal has also been a point of contention (Luoma, 2004, p. 37). Research seems to have led to more mixed use of different types of speaking tasks in the same test, such as both interviews and paired tasks. Another issue with the administration conditions and equal treatment of test takers concerns the consistency of interviewers’ behavior: Do they treat different candidates in the same way? Findings indicating that they do not (Brown, 2003) have led the IELTS, for example, to impose stricter guidelines on their interviewers to standardize their behavior.

An exception to the paucity of research into the more general aspects of test administration concerns testing time. According to studies reviewed by McCallin (2006, pp. 631–2), allowing examinees more time on tests often benefits everybody, not just examinees with disabilities. One likely reason for this is that many tests that are intended to test learners’ knowledge (“power” tests) may in fact be at least partly speeded.

Compared with test administration, research on scoring and rating of performances has a long tradition. Space does not allow a comprehensive treatment but a list of some of the important topics gives an idea of the research foci:

- analysis of factors involved in rating speaking and writing, such as the rater, rating scales, and participants (e.g., Cumming, Kantor, & Powers, 2002; Brown, 2003; Lumley, 2005);
- linking test scores (and reporting scales) with the CEFR (e.g., Martyniuk, 2011);
- validity of automated scoring of writing and speaking (e.g., Bernstein, Van Moere, & Cheng, 2010; Xi, 2010); and
- scoring short answer questions (e.g., Carr & Xi, 2010).

Research into reporting scores is not as common as studies on scoring and rating. Goodman and Hambleton (2004) and Ryan (2006) provide reviews of practices, issues, and research into reporting scores. Given that the main purpose of reports is to provide different users with information, Ryan’s statement that whatever research exists “presents a fairly consistent picture of the ineffectiveness of score reports to communicate meaningful information to various stakeholder groups” (2006, p. 684) is rather discouraging. The comprehensibility of large-scale

assessment reports, in particular, seems to be poor due to, for example, the use of technical terms, too much information too densely packed, and lack of descriptive information (Ryan, 2006, p. 685). Such reports could be made more readable, for example, by making them more concise, by providing a glossary of the terms used, by displaying more information visually, and by supporting figures and tables with adequate descriptive text.

Ryan's own study on educators' expectations of the score reports from the state-wide assessments in South Carolina, USA, showed that his informants wanted more specific information about the students' performance and better descriptions of what different scores and achievement levels meant in terms of knowledge and ability (2006, p. 691). The educators also reviewed different types of individual and group score reports for mathematics and English. The most meaningful report was the "achievement performance level narrative," a four-level description of content and content demands that systematically covered what learners at a particular level could and could not do (Ryan, 2006, pp. 692–705).

Challenges

Reviews of test administration (e.g., McCallin, 2006, p. 640) suggest that nonstandard administration practices can be a major source of construct-irrelevant variation in test results. The scarcity of research on test administration is therefore all the more surprising. McCallin calls for a more systematic gathering of information from test takers about administration practices and conditions, and for a more widespread use of, for example, test administration training courseware as effective ways of increasing the validity of test scores (2006, p. 642).

Scoring and rating continue to pose a host of challenges, despite considerable research. The multiple factors that can affect ratings of speaking and writing, in particular, deserve further attention across all contexts where these are tested. One challenge such research faces is that applying such powerful approaches as multifaceted Rasch analysis in the study of rating data requires considerable expertise.

Automated scoring will increase in the future, and will face at least two major challenges. The first is the validity of such scoring: to what extent it can capture everything that is relevant in speaking and writing, in particular, and whether it works equally well with all kinds of tasks. The second is the acceptability of automated scoring, if used as the sole means of rating. Recent surveys of users indicate that the majority of test takers feel uneasy about fully automated rating of speaking (Xi, Wang, & Schmidgall, 2011).

As concerns reporting scores, little is known about how different reports are actually used by different stakeholders (Ryan, 2006, p. 709), although something is already known about what makes a score report easy or difficult to understand. Another challenge is how to report reliable profile scores for several aspects of proficiency when each aspect is measured by only a few items (see, e.g., Ryan, 2006, p. 699). This is particularly worrying from the point of view of diagnostic and formative testing, where rich and detailed profiling of abilities would be useful.

Future Directions

The major change in the administration and scoring of language tests and in the reporting of test results in the past decades has been the gradual introduction of different technologies. Computer-based administration, automated scoring of fairly simple items, and the immediate reporting of scores have been technically possible for decades, even if not widely implemented across educational systems. With the advent of new forms of information and communication technologies (ICT) such as the Internet and the World Wide Web, all kinds of online and computer-based examinations, tests, and quizzes have proliferated.

High stakes international language tests have implemented ICT since the time optical scanners were invented. Some of the more modern applications are less obvious, such as the distribution of writing and speaking samples for online rating. The introduction of a computerized version of such high stakes examinations as the TOEFL in the early 2000s marked the beginning of a new era. The new computerized TOEFL iBT and the PTE are likely to show the way most large-scale language tests are headed.

The most important recent technological innovation concerns automated assessment of speaking and writing performances. The TOEFL iBT combines human and computer scoring in the writing test, and implements automated rating in its online practice speaking tasks. The PTE implements automated scoring in both speaking and writing, with a certain amount of human quality control involved (see also the Versant suite of automated speaking tests [Pearson, *n.d.*]). It can be predicted that many other high stakes national and international language tests will become computerized and will also implement fully or partially automated scoring procedures.

What will happen at the classroom level? Changes in major examinations will obviously impact schools, especially if the country has high stakes national examinations. Thus, the inevitable computerization of national examinations will have some effect on schools over time, irrespective of their current use of ICT. The effect may simply be a computerization of test preparation activities, but changes may be more profound, because there is another possible trend in computerized testing that may impact classrooms: more widespread use of computerized formative and diagnostic tests. Computers have potential for highly individualized feedback and exercises based on diagnosis of learners' current proficiency and previous learning paths. The design of truly useful diagnostic tools and meaningful interventions for foreign and second language learning are still in their infancy and much more basic research is needed to understand language development (Alderson, 2005). However, different approaches to designing more useful diagnosis and feedback are being taken currently, including studies that make use of insights into dyslexia in the first language (Alderson & Huhta, 2011), analyses of proficiency tests for their diagnostic potential (Jang, 2009), and dynamic assessment based on dialogical views on learning (Lantolf & Poehner, 2004), all of which could potentially lead to tools that are capable of diagnostic scoring and reporting, and could thus have a major impact on language education.

Detecting Plagiarism and Cheating

Ardeshir Geranpayeh

University of Cambridge, ESOL Examinations, England

Introduction

Plagiarism and cheating have become very serious problems in schools and colleges alike. The 2011 cheating scandal in Atlanta, the biggest in US history, which involved 178 teachers and principals showed how Atlanta public school officials cheated to raise student scores on high stakes standardized tests. The 413-page investigative report published by the Georgia governor showed that more than three quarters of the 56 schools investigated cheated on a 2009 standardized state test. Many teachers, according to the report, confessed that they erased students' answers and corrected tests. The report traces the extensive cheating exercise back to 2001. This widespread scandal testifies that cheating is no longer seen as an old-fashioned battle between teachers and students. When the stakes are high, teachers are also willing to cheat.

One aspect of data quality control is a professional vigilance about threats to the accuracy and dependability of test information. Against this background, cheating may directly put into question the validity of a test. Any single examination score obtained by fraudulent means is not valid; it cannot be interpreted as a fair reflection of the candidate's abilities. Results obtained through cheating have a negative impact on the validity of scores obtained by other candidates. When access to university places or employment opportunities is limited, the candidate who succeeds through fraud denies these opportunities to others. Where cheating is seen to be widespread, even honestly obtained test results may lose credibility and certificates become devalued.

In this chapter, the concept of cheating and plagiarism is reviewed in the context of educational measurement and its implication in language assessment. Plagiarism is treated here as a special act of cheating that only relates to coursework assessments and that may not be directly related to standardized language assessment. Because it only relates to writing assessment in coursework, plagiarism is not explored in much detail here. The chapter examines the context in which

cheating happens and what is at stake, and explores the reasons underlying this increasingly widespread phenomenon. The discussion first briefly reviews the concept of plagiarism, its definition, manifestation, and techniques associated with the detection of plagiarism for essay-type coursework. The chapter then reviews the cheating concept, its manifestations, and consequences more broadly, and focuses extensively on various psychometric techniques for the detection of various forms of cheating in high stakes standardized language assessments. The practical and political dimensions of cheating are discussed and recommendations are made to help test developers prevent cheating.

Prevention of Cheating in Large-Scale Assessment

There are at least five explicit statements in the *Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999) for the prevention of cheating. Standard 11.7 requires that test publishers “protect the security of their tests.” Standard 13.10 expects the test publishers to “ensure that individuals who administer the tests are proficient in administration procedures and understand the importance of adhering to directions provided by the test developer.” Standard 8.7 focuses on the responsibility of the testing organization to “inform examinees that it is inappropriate for them to have someone else take the test, for them to disclose secure test materials, or engage in any other form of cheating.” Under standard 13.11 we are asked to look at assurances “that test preparation activities and materials provided to students will not adversely affect the validity of test score inferences” and finally standard 15.9 requires examination boards to “maintain the integrity of test results by eliminating practices designed to raise test scores without improving students’ real knowledge, skills, or abilities in the area tested.”

The statements above clearly show the importance of the prevention of cheating in educational measurement. This raises the question of what counts as cheating. According to Cizek (1999), any action that violates the rules for administering a test is considered cheating. Cheating can take a wide variety of forms and may involve any of the stakeholders in the testing process, including candidates, their teachers, and those responsible for administering the test. Cheats may be motivated by material rewards such as access to life chances, by personal needs such as competitiveness or a lack of self-confidence, or, in the case of school examinations, by the publication of league tables, as was the case in the Atlanta scandal. Whatever the cause, teachers, examination boards, and their agents clearly have a responsibility to discourage cheating on their tests and to minimize it wherever possible.

Plagiarism

Plagiarism is a special act of cheating associated with essay writing. According to Webster’s *Third New International Dictionary*, “to plagiarize” means “to steal and pass off as one’s own [the ideas or words of another] or use without crediting the

source.” It goes on to say that it is “to commit literary theft.” The problem with plagiarism is twofold. It involves stealing someone else’s work, and then lying about it. Although plagiarism is a serious offence in academic contexts, its nebulous boundary with copying (legitimate) is not always clear-cut. There are guidelines about what counts as plagiarism. According to www.plagiarism.org, the following are considered acts of plagiarism:

- turning in someone else’s work as your own;
- copying words or ideas from someone else without giving credit;
- failing to put a quotation in quotation marks;
- giving incorrect information about the source of a quotation;
- changing words but copying the sentence structure of a source without giving credit;
- copying so many words or ideas from a source that it makes up the majority of your work, whether you give credit or not.

Educational researchers have repeatedly found academic dishonesty to be disturbingly common, and more common than is generally believed by educators. It is not uncommon to hear from students that they frequently plagiarize papers or defy honesty codes in other ways. Cizek (1999, p. 3), reviewing a large body of survey and experimental research, states that “nearly every research report on cheating . . . has concluded that cheating is rampant.” Cizek reports that about 40% of sixth graders copy and that about 60% of undergraduates do so at some point during their college careers. Cheating can significantly compromise the assessment process (Frary, 1993; Cizek, 1999). These percentages have significantly increased with easier accessibility of online resources, which has led to even higher widespread electronic cheating within higher and further education institutions. Online plagiarism has turned into a profitable industry offering students a wide range of downloaded papers on a variety of topics. Since there are potentially millions of online essays available to students, the detection of plagiarism becomes an impossible task for individual faculty members.

The increase in online cheating brings about the need for the availability of online detection solutions. Many colleges and higher education institutions now use commercial online-detecting software tools to check the originality of an essay. There are numerous online detection software tools available, which check essays submitted by students against a huge quantity of electronic media. Turnitin (turnitin.com), Dupli Checker (duplichecker.com), iThenticate (ithenticate.com), WriteCheck (writecheck.com), and AntiPlagiarism.net (antiplagiarism.net) are but a few examples of such online cheating detection solutions. There is little information on technical details of such software detection tools due to confidential commercial sensitivity, but the principal algorithms of online detection solutions are similar: Each paper submitted to the detection tool is compared to massive databases of content, including billions of Web pages, millions of student papers previously submitted to online engines, and research databases of subscription-based journal articles and periodicals. Some of the tools even provide user-friendly fully formatted color-coded “originality reports” to help faculty members and their students identify issues of originality. Online verbatim copied manuscripts can

easily be identified by these tools, but most students know better than to copy an essay verbatim from the Internet; they often make changes to the original manuscript by using minor word substitution (synonyms) and sentence addition, and by altering the order of paragraphs or inserting content from a second source. Some online tools claim that they can deal with these complex cheating behaviors adequately by means of their sophisticated searching engines, which look for multiple sources of copying within the same text and present their accuracy in terms of a plagiarism index. Although the plagiarism index drops when texts are added to the original copied material, the tool can pinpoint where the verbatim copying took place in the manuscript.

Most online detection systems have tools to help students avoid copying from other published sources while providing faculties with plagiarism detection services. This is on the assumption that the best way to avoid plagiarism is to change the cheating culture which drives it in the first place. Academic institutions are now interested in the use of such dual antiplagiarism tools and their impact on students' coursework. Some institutions have taken further steps to investigate not only the reliability of such detection techniques but also their user-friendliness for staff and students alike. For example, Humes, Stiffler, and Malsed (2003) conducted a survey of antiplagiarism software at the Claremont McKenna College. One of the interesting findings from their research was that, after one semester's deployment of antiplagiarism software, it appeared that faculty could detect student plagiarism with higher accuracy, and that students felt comfortable with both the detection program and learning the rules of academic honesty.

Cheating in High Stakes Language Assessment

All high stakes language tests are expected to provide a snapshot of candidates' language proficiency at the time of testing. The results from language tests are often used to make decisions about a candidate's preparedness to cope with the target language of communication. The candidate's performance on a language test could be reported as simply passing or failing, or scored against a system of ordered descriptors of performance such as the Common European Framework of Reference for Languages (CEFR). With the increasing importance of candidate test performance in contexts such as immigration, access to higher education, or job opportunities, the stakes associated with the use of test results will increase. This is particularly true of international standardized language proficiency tests such as IELTS and TOEFL. The consequences of results of such tests become quite weighty; such tests are called high stakes. Once a test is used for high stakes decision making, candidates will try harder to succeed in the test, even if it means cheating. One can argue that cheating is an inevitable consequence and a by-product of high stakes testing.

Definition

Cheating, of course, can take various shapes and forms. As mentioned earlier, Cizek (1999) defines cheating as any action that violates the rules for administering a test. Cizek (2001, p. 5) furthermore, defines cheating as

any behavior that gives an examinee an unfair advantage over other examinees, or any action on the part of an examinee or test administrator that decreases the accuracy of the intended inferences arising from the examinee's test score or performance.

This definition is quite broad and includes a range of test administration violations by either candidates or the people involved in the testing process. Caveon, a test security company, has categorized cheaters in 10 different classes: the impersonator, the smuggler, the storyteller, the chain gang, the time traveler, the collaborators, Robin Hood, the hacker, the ticket scalper, and the insider and the fence.

The *impersonator*, also known as proxy test taker, is the person who takes the test on behalf of someone else. The *smuggler* is someone who brings into the test setting materials or devices intended to provide an advantage over honest examinees. The *storyteller* is the individual who memorizes test items only to "retell" them later to others. The *chain gang* is the group that memorizes and sells items, typically through the Internet. The *time traveler* is the person who shares test materials that are used in multiple time zones. The *collaborators* are candidates who work together as a team to share responses to the test or steal the test material. The *Robin Hood* category refers to test takers who are not involved, but whose teachers or other authorities are involved in changing student responses with or without the students' knowledge. The Atlanta scandal falls under this category. The *hacker* is the person who infiltrates computer systems to change candidate results. The *ticket scalper* sits an exam's beta test for the sole purpose of obtaining a free voucher which they will then sell to others for a profit, interrupting the pretesting development of a test. The *insider* steals the question and the *fence* sells the results. People in the latter category are most difficult to identify, as they work for the testing organization and know how to avoid being recognized.

Cheating Detection Indices

There are many ways, statistical and otherwise, to detect any number of cheating behaviors that may occur in a language test, but this chapter focuses only on cheating detection techniques that are based on candidates' item response analysis. This is mainly due to the confidentiality of techniques used by test developers to identify potential breaches of security in their tests.

Most instances of cheating take place through copying responses or collusion of some kind. The collusion phenomenon has been known for many decades, and numerous statistical indices have been developed to detect collusion or cheating in examinations since 1927. The very first collusion detection methods were Bird (1927, 1929), Crawford (1930), Dickenson (1945), Anikeef (1954), and Saupe (1960). Due to the complexity of computing and the unavailability of statistical software at that time, the detection power of such indices could not be thoroughly investigated. Angoff (1974) developed eight statistical indices by a variety of variables to detect cheaters using the same method as Saupe (1960). He found that the variables involving counts of right and wrong answers were more successful in detecting copying cases. Since then, many other indices have been developed (Frary,

Tideman, & Watts, 1977; Schumacher, 1980; Cody, 1985; Hanson, Harris, & Brennan, 1987; Roberts, 1987; Belleza & Belleza, 1989; Harpp, Hogan, & Jennings, 1996; Holland, 1996; Wollack, 1997; Kadane, 1999; Ercole, Whittlestone, Melvin, & Rashbass, 2002; Sotaridona & Meijer, 2002; van der Linden & Sotaridona, 2004; Sotaridona, van der Linden, & Meijer, 2006; van der Linden & Sotaridona, 2006; Below & Armstrong, 2010; and van der Linden & Jeon, 2012).

Statistical methods for collusion detection can be divided into two groups based on their theoretical foundation: classical test theory (CTT) or item response theory (IRT). Many existing techniques are modeled using CTT. They are designed to compare the response-pattern similarity between examinees with an expected amount of similarity. CTT item statistics are dependent on the trait levels of all examinees. The response pattern of each examinee is usually compared with the response patterns of everyone in the group who took the test including those who were not within physical copying distance. Thus, biased estimates of the expected number of matches between pairs of examinees are obtained.

The alternative method for detecting collusion is the use of IRT. There are different IRT models that can be used to detect cheating, depending on the test format/method. For example, for a multiple choice option test, a nominal response model is used. Under IRT, the probability of an examinee answering an item correctly given an estimate of his or her ability is independent of the other examinees taking the test. IRT detection models take into account the item parameter of the test: difficulty level of the items and discrimination indices of the alternatives or choices of the test. They are also designed to compare patterns of responses for an examinee with those of other examinees of a similar ability level. Despite various advantages of IRT detection approaches to CTT, the cheating literature only mentions two IRT-based indices: the ω index of Wollack (1997) and the index proposed by van der Linden and Sotaridona (2006).

The CTT detection techniques are discussed first. The following indices are just a few examples of numerous available detection methods in the CTT literature.

The Bird Index The earliest method documented in the literature was proposed by Bird (1927, 1929). For pairs of examinees, Bird suggested three approaches based on the inspection of observed distributions of the number of identical wrong responses.

The Dickenson Index Dickenson (1945) derived a theoretical ratio of identical errors which he called probable percentage of errors. The expression for this ratio is

$$IE = \frac{C-1}{C^2}$$

where IE denotes identical errors and C is the number of item choices. Dickenson only considered the number of options per item, and did not consider the distribution characteristics for the observed percentages of identical errors.

The Regression Index Saupe (1960) proposed a technique based on linear regression analysis to identify the suspected examinees. Saupe incorporated both correct

and incorrect identical responses and derived two detection indices applicable to the number of right and wrong similarities in the responses.

The Angoff Index Angoff found three of the methods (A, B, and H) he had developed to be promising. The procedure is expressed as follows. Let candidate I answer R_i questions correctly in an exam, candidate J answer R_j questions correctly, and R_{ij} be the number of correct answers shared by the two candidates. R_{ij} is not a good measure of similarity because the number of similar answers increases with examinee knowledge. To examine R_{ij} in relation to R_i and R_j , one needs to assess the unusualness of R_{ij} by calculating the residual of R_{ij} after regression on $\sqrt{(R_i \cdot R_j)}$ and $R_i \cdot R_j$. Residuals are distributed normally and expressed as probabilities. Alternatively, Index B can be computed in a similar way as defined above for Index A by calculating the residual of Q_{ij} after regression on $\sqrt{(W_i \cdot W_j)}$ and $W_i \cdot W_j$. Index H is based on identical incorrect responses in the longest string of items and number of items answered incorrectly. Pairs with positive standardized residuals beyond a certain critical value can be treated as suspicious. The regression expressions for indices A, B, and H are:

$$R_{ij} = \sqrt{(R_i \cdot R_j)} + R_i \cdot R_j + \epsilon$$

$$Q_{ij} = \sqrt{(W_i \cdot W_j)} + W_i \cdot W_j + \epsilon$$

$$K_{ij} = \sqrt{S_i} + S_i + \epsilon$$

where

- Q_{ij} = the number of items answered incorrectly in the same way by both i and j
- $W_i \cdot W_j$ = the number of items answered incorrectly by i times the number of items answered incorrectly by j
- S_i = the number of items answered incorrectly by either i or j + the number of items omitted by the examinee whose number of items answered incorrectly is smaller
- K_{ij} = identically marked incorrect and omitted responses in the longest string of items

The Score Difference Index Roberts (1987) applies a score difference method where alternate test forms, with different answer keys, are administered in the same room without the direct knowledge of the examinees. The procedure involves (a) scoring each answer document using the key appropriate to the examinee's form, (b) scoring the answer document using the alternative, inappropriate keys, and (c) finding the difference between the scores obtained from the appropriate and inappropriate keys. A large difference, especially upward, is taken as evidence of cheating.

The NBME Index In NBME, two statistical methods are used to flag suspected pairs of examinees. The method suggested by Schumacher (1980) is a detection method based on the chi-square and requires knowledge of seating locations of

suspected examinees to evaluate the likelihood of independence of identical and nonidentical responses. Another requirement is that examinees be seated close to each other for one part of an examination and apart for another.

The Error Similarity Analysis Index Bellezza and Bellezza (1989) suggested an error similarity analysis based on binomial probabilities. This computes the probability that a pair of examinees should have a certain number of identically incorrect responses to test items. If the probability is low enough for any pair of examinees, that pair is flagged as potentially engaging in collusion.

The K-Index The K-index is a statistic that can be used to assess the degree of unusual agreement between incorrect answers on the multiple choice test of two examinees: one referred to as the source (*s*) and the other as the copier (*c*). The copier is suspected of copying answers from the source. The K-index only takes the incorrect answers of the examinees into account.

Scrutiny! Scrutiny! has received very little attention in the measurement literature. Scrutiny! is similar to the K-index in that it uses information from only the incorrect answers. Scrutiny! detects answer copying by implementing a modification of the error similarity analysis (ESA) first proposed by Bellezza and Bellezza (1989). Scrutiny! uses a normal approximation to the binomial (corrected for continuity), which compares the number of answer matches on incorrectly answered items with the number expected by chance, given the number of items answered incorrectly (though not necessarily identically) by both *c* and *s*.

The S-Index Sotaridona and Meijer (2002) proposed two new indices called S_1 and S_2 to describe the probability of the suspect having at least the same incorrect answers as other examinees in the same subgroup, based on an assumed Poisson probability distribution. Examinees are also divided into *R* subgroups based on the number of incorrect answers, in such a way that examinees in each subgroup have the same number of wrong answers.

The Shifted Binomial Index Van der Linden and Sotaridona (2004) proposed a similar index related to the S-index, based on shifted binomial distribution. The test is based on the idea that examinees' answers to test items may be the result of three possible processes: (a) knowing, (b) guessing, and (c) copying, but that examinees who do not have access to the answers of other examinees can arrive at their answers only through the first two processes. This assumption leads to a distribution for the number of matched incorrect alternatives between the examinee suspected of copying and the examinee believed to be the source that belongs to a family of "shifted binomials."

The Kappa Index A statistical test for answer copying on multiple choice tests based on Cohen's kappa was developed by Sotaridona, van der Linden, and Meijer (2006). The test is free of any assumptions on the response processes of the examinees suspected of copying and having served as the source, except for the usual assumption that these processes are probabilistic.

The most common CTT cheating detection index is the Angoff index. The index logic is very simple, although the significance of the outcome is statistically very strong. It is also very easy to implement in any testing program without the need to write complex syntax codes or use a specialized statistical package.

Despite the popularity and simplicity of CTT cheating detection, it is limited in what it can detect. All CTT indices are based on the number of correct/incorrect responses and ignore any other information available in a test. Hence, they suffer from test power and are subject to type I and type II errors. In recent years, there has been a shift toward using IRT cheating detection indices that control type I and type II errors while adding power to the detection methods. There are two well-developed IRT cheating detection methods: the ω statistics and the Wim index.

The ω Statistics Wollack (1997) proposed the ω copying index that is formulated in the context of the nominal response model (NRM) as developed by Bock (1972). To determine ω , the NRM is used to estimate the probability of an examinee's response to one of the item response categories $v = [1, \dots, h, \dots, V]$. Under the NRM, the probability of examinee j with ability level θ_j responding to option h of item i with intercept and slope parameters ζ_{ih} and λ_{ih} is given as

$$P_{ih}(\theta_j) = \frac{\exp(\zeta_{ih} + \lambda_{ih}\theta_j)}{\sum_{v=1}^V \exp(\zeta_{iv} + \lambda_{iv}\theta_j)}$$

Let h_{cs} be the number of identically answered items of s and c , and let $E(h_{cs} | \theta_c, U_s, \zeta)$ be the expected value of h_{cs} conditional on the ability level of the copier (θ_c), the item response vector of the source (U_s), and the item parameters (ζ). Furthermore, let σ_{hcs} be the standard deviation of h_{cs} .

Then ω is given by

$$\omega = \frac{h_{cs} - E(h_{cs} | \theta_c, U_s, \zeta)}{\sigma_{hcs}}$$

where

$$E(h_{cs} | \theta_c, U_s, \zeta) = \sum_{i=1}^I P_{ih}(\theta_j) \text{ and}$$

$$\sigma_{hcs} = \sqrt{\sum_{i=1}^I P_{ih}(\theta_j) \left(1 - \sum_{i=1}^I P_{ih}(\theta_j)\right)}$$

The Wim Index There is officially no name for this index. The author took the liberty of naming it "Wim" because he received a version of the final index from Wim van der Linden before the article presenting the index was published in 2006. Van der Linden and Sotaridona (2006) have provided a comprehensive IRT-based framework for modeling collusion between examinees. The assumption of the

procedure is that the probabilities with which a test taker who has not copied any answers chooses a response alternative follow a known response model.

Application of Cheating Indices in Language Testing

Testing organizations rarely discuss what method they use for detection of cheating in their examinations. It is assumed that some of the indices listed above are used in the detection of cheating in language tests. Geranpayeh and Khalid (2012) report on a comprehensive study where they applied the K-index, Scrutiny!, ω , and the Wim index to investigate the type I error rate and power of the cheating indices using real test data over a number of sessions of an English language proficiency test. Using simulations, they studied different impacts of varying test length, sample sizes, and proportion of answer copying in the study. They demonstrated that all the aforementioned indices were powerful enough to detect collusion in the test with relative consistency. However, the Wim index (IRT-based) was found to be the most powerful index which could identify copying even in small sample sizes and mixed format item types.

Geranpayeh (2009, 2011) also reports several cheating detection methods for high stakes language assessments. These methods look for:

- unusually high scores on one measure in relation to others;
- identical/similar pattern of responses: copying or collusion;
- grouping candidates' responses on some meaningful external criterion, such as seating plan, class membership, school, and so on.

Using various statistical significance testing techniques, the probability of the occurrence of each response pattern is estimated and is compared against pure chance. The probability of patterns that are two to three standard deviations above the norm will be flagged and such responses will be further investigated for possible collusion.

It is important to emphasize that statistical tests can only flag improbable candidate responses for further investigation; they cannot be the only source of cheating detection. They have to be complemented by other objective and subjective methods, such as forensic handwriting analysis, test invigilator reports, and so forth.

Practical Consequences

The testing programs have a duty to protect the abuse of their test results by fraudulent means. This is achieved by various cheating detection techniques employed in their examinations, which allow them to detect any abnormality of test results that may occur in test administration. Once cheating is detected, action has to be taken to not only stop the fraudulent use of the specific test results but also act as a deterrent to future cheaters. This is usually done by allocating the blame and punishing the test taker or the other people involved in the fraudulent use of test results. The question is what punishment would be suitable for the

fraudulent use. The level of punishment is related to the level of cheating that is detected. This chapter has already classified cheaters in several different categories, each requiring a different treatment. Examination boards draw their policy with respect to the seriousness of the fraudulent activity that they detect. The seriousness of cheating and the impact on the validity of test results often depends on five levels of cheating detection: individual candidates, groups of candidates, school collusion, center collusion, and widespread cheating.

When the cheating detection identifies individual candidates as having suspect results, the punishment would normally be the withdrawal of test results for the individuals concerned. This is the minimum punishment by the examination boards. In some very high stakes contexts, candidates may be barred from sitting the exam again. It is understood that the fraudulent action of individuals would not put into question the validity of the overall test results. If, however, the detection shows the collaboration of a group of candidates in trying to obtain fraudulent test results, the punishment may be different. Depending on the level of their cheating (i.e., whether they collaborated on a few items or on the entire test), the punishment may be more severe.

School collusion is an entirely different issue. In such cases the students implicated may not have been directly involved in the cheating. While candidate results may be cancelled if the school is at fault, no further action will normally be taken against individual candidates. In the case of collusion by an insider, legal action may be taken against the employee who might have been involved in the collusion. In short, once cheating is detected, examination boards may punish test takers by withdrawing their results, asking them to retake the test, ban them for life from taking their test, inform stakeholders if the results are already issued, or take legal action.

Policies on Prevention

The Association of Test Publishers (ATP) security committee has recommended a messaging campaign to ensure that all the stakeholders involved in the testing process are aware of the consequences of cheating. Their campaign is basically focused on three areas: test development and administration (before the exam), general communications and marketing (during the exam process), and messaging related to enforcement (after the exam). They emphasize communication of security policies to stakeholders as the best measure to prevent cheating. At test development stage all communication needs to ensure that staff and volunteers working on the exam are aware of security considerations and will adhere to rules designed to protect the integrity of the exam. The key messages to incorporate into employee security agreements should cover what behaviors are prohibited, the time period that the agreement covers, and the requirements around conflicts of interest. During the exam process, communication about the importance of security should include candidates as well as other stakeholders. The key messages to incorporate into general communications and marketing materials should cover what behaviors are prohibited, the impact of cheating on the value of credentials, how to report misbehavior, and consequences of misbehavior. Com-

munication relating to enforcement (after the exam) should include information about how the program may choose to communicate its enforcement actions. This is a delicate area and depends on how much information a testing organization is willing to reveal about the techniques they use to monitor test fraud. On the one hand, exam boards need to let stakeholders know that they monitor, enforce, and prosecute illegal behavior; this shows that the integrity of the test is paramount. It also sends the signal to cheats and criminals that their behavior will not be tolerated. On the other hand, giving too much information about cheating detection could be detrimental to the program, as it may give the impression that cheating is widespread. The balance between the two is not always easy to find.

The ATP concludes that security messaging is a “best practice” that is critical to a program’s exam security efforts. The average stakeholder must be exposed to security messages several times before the information “sticks,” so a layered approach is recommended. Security messaging is most effective when it is woven through every aspect of the program and repeated at multiple points in the exam cycle.

Final Remarks

It has already been argued that cheating is an inevitable consequence and a by-product of high stakes testing; as the stakes of a test increase, so does the level of cheating. The first decade of the 21st century has seen a significant increase in innovative approaches to cheating. The new fraudulent activities tend to happen mostly by means of technology, using imposters and engaging local schools. New gadgets such as cell phones, pen scanners, calculators, memory devices, tiny button cameras, advanced micro earphones, to name but a few, have facilitated cheating and have introduced serious challenges to combating this widespread phenomenon. Numerous advertisements can be found from imposters who promise to take the test on behalf of candidates. Government league table comparisons have led to a new category of teacher involvement in cheating, as was seen in Atlanta. To combat these, examination boards have responded by banning gadgets in test centers, installing CCTV, and introducing identification measures such as passport checks and biometrics before candidates are allowed to enter examination halls. There are also new psychometric techniques to address new cheating methods. For example, van der Linden and Jeon (2012) have developed a new technique to address answer erasure cheating that happens at school level.

The battle between cheaters—who try to gain advantage of security loopholes in tests—and examination boards—who try to protect the integrity of their tests—is never ending. The cheating phenomenon has attracted a lot of attention in the media, political circles, and academia. The issue has become so serious that the National Council on Measurement in Education has devoted invited presidential sessions on test security for the 75th anniversary gathering of the organization in San Francisco in 2013.

New Media in Language Assessments

Paul Gruba

University of Melbourne, Australia

New media, such as digital video clips, wikis, and podcasts, are integrated throughout an increasing number of second and foreign language programs, yet their use in language assessments continues to lag. In this chapter, I explore the role of new media in language assessments. After setting out key concepts, I begin with a brief review of computer-assisted language learning and computer-based testing. I then turn to issues in the use of new media in assessment for learning with regard to institutional resources, professional development, and educational policies. In a third section, I shift the focus to discuss the challenges of new media language assessments. I conclude with a proposed agenda to spur the integration of new media into language assessments.

Introduction

Increasingly, educators across the disciplines are urged to use new media in assessments to better prepare students to meet the demands of the 21st century (Wyatt-Smith & Cumming, 2009). Indeed, in the early 2000s, Bennett (2002) argued that the use of technologies in assessments would be “inexorable and inevitable”; accordingly, Bennett argued, debate about their inclusion in testing would cease and efforts would come to focus on “how to do it responsibly, not only to preserve the validity, fairness, utility, and credibility of the measurement enterprise but, even more so, to enhance it” (p. 15).

Before further discussion, an overview of key concepts may be helpful. In this chapter, I follow Lievrouw (2011, p. 7) to view new media as a blend of information and communication technologies and their social contexts that includes:

- 1) the material *artifacts* or devices that enable and extend people's abilities to communicate and share meaning;
- 2) the communication activities or *practices* that people engage in as they develop and use those devices; and
- 3) the larger social *arrangements* and organizational forms that people create and build around the artifacts and practices. (italics in the original)

In this view, "new media" is a term that attempts to bring together technologies, activities, and structures. As devices, new media are perhaps best symbolized by smartphones and multitouch tablet computers. The use of powerful new media devices influences the way people communicate across local and global networks. In their use of these devices, people are able to choose how to communicate, for example, through texting, talking, or sending images, and whether to communicate synchronously or asynchronously. Such usage fosters social participation, and each day hundreds of millions of people use new media to interact through forms such as chat lines, digital video clips, wikis, blogs, and podcasts. Collectively, the global use of new media has prompted large organizations to provide online services and interactions in areas that include "e-government," "e-commerce," and "e-learning." New media are now used to such an extent that core elements of language and discourse have changed (Herring, in press), and they increasingly shape the expectations and identities of language students (Higgins, 2011).

Perhaps subtly, any discussion of new media in language assessment must maintain a distinction between using new media to test language proficiency (e.g., as a device, technology, or platform for development and delivery) and seeing new media use as a required part of language skills (e.g., in writing a blog, speaking in a live streaming video, or creating a podcast). With regard to the former, Chapelle (2008) identifies three reasons to use technologies in assessment. First, practitioners may want to create assessments that are more efficient than paper and pencil formats. A second reason is to create equivalents of established paper and pencil formats that are not only reliable and valid, but also more efficient. A third reason is to innovate in ways that are fit for purpose, meet specific needs of a program, or best align with pedagogical approaches and intended outcomes. In this chapter, I focus on the third of these reasons to argue for a greater alignment of new media language teaching and assessment practices.

Discussions concerning the proficient use of new media by students can often be located alongside work to do with "media literacy" or "new literacies" skills that are seen to be an imperative in education to promote engaged citizenry and strong economies in an era of digital globalization (Coiro, Knobel, Lankshear, & Leu, 2008). Scholars, however, have yet to establish a basis for the assessment of media literacy skills (Christ, 2004) as they continue to establish a range of concepts and issues (Potter, 2011). Throughout this chapter, I focus on "assessment for learning" defined as "a process of seeking and interpreting evidence for use by learners and their teachers to decide where the learners are in their learning, where they need to go and how best to get there" (Assessment Reform Group, 2002, p. 2). Because research concerning new media in language assessments is still in its infancy, an emphasis on immediate pedagogical goals is warranted.

Computer-Assisted Language Learning and Testing

One way to gain a background in the use of new media in assessment is to review developments in *computer-assisted language learning* (CALL) over the last few decades (Levy, 1997; Chapelle, 2001; Levy & Stockwell, 2006). In general, work in CALL has run alongside that in applied linguistics, most notably in its move from a behaviorist perspective of language learning to a cognitive view, and now to a social approach to language learning, teaching, and assessment (Delcloque, 2000). Nowadays, CALL is widely defined as “the full integration of technology in language learning” consisting of a “dynamic complex in which technology, theory, and pedagogy are inseparably interwoven” (Garrett, 2009, pp. 719–20).

To foster the integration of new media, large educational organizations have established standards for the pedagogical use of digital technologies (e.g., International Society for Technology in Education, 2012). With specific regard to language learning, the Teachers of English to Speakers of Other Languages (TESOL) established a technology standards framework (Healey et al., 2009) to set out baseline expectations for both learners and instructors. The aim of these technology standards is to promote “pedagogically solid ways of integrating and using technologies in all language classrooms” (p. 1). Briefly, a summary of intended goals of the TESOL technology standards includes:

1. to acquire and maintain foundational skills and knowledge in technology for professional purposes;
2. to integrate pedagogical knowledge and skills with technology to enhance language teaching and learning;
3. to apply technology in record keeping, feedback, and assessment; and
4. to use technology to improve communication, collaboration, and efficiency.

Perhaps somewhat counterintuitively, the use of new media is both increasing and disappearing in language education as they become more and more mainstream and are simply blended into the routine practices of everyday teaching (Gruba & Hinkelman, 2012).

Another way to gain insights into new media use is to understand developments in computer-based language testing. Chapelle and Douglas (2006) provide a comprehensive overview of the area. Following a historical overview (Burstein, Frase, Ginther, & Grant, 1996), they identify the presence of technology throughout many aspects of language teaching and assessment, and note that a persistent concern for researchers has been “whether or not test takers’ apprehension about computer use might affect their language performance” (p. 17). Such worries are fading, Chapelle and Douglas point out, as current students report that the *lack* of computer use may inhibit their performance; indeed, as Douglas and Hegelheimer (2007) argue, simple paper and pencil tests may now appear to be antiquated and irrelevant to an increasing number of language students.

In their work, Chapelle and Douglas (2006, p. 23) set out the advantages and limitations of workstation computers with regard to test method characteristics. Efficiency and convenience are seen to be two key advantages; practical

limitations of use may include the cost, location, and availability of appropriate workstations for test administration, and issues related to test security and the verification of candidate identification.

Importantly, discussion of the potential of technologies to influence construct definitions is prominent throughout language assessment research (Chapelle, 2008). Constructs, or the target concept that defines what is to be measured, have long been framed in terms of “traditional media” that include black-and-white print for reading, face-to-face interactions for speaking, audiotapes for listening, and handwritten products for writing (Gruba, 2006). With the growing use of new media in language programs, Royce (2007) argues for a greater recognition of “multimodal communicative competence” as a way to better acknowledge an understanding of the role of intersemiotic elements in textual comprehension and lead students to “becoming competent in interpreting and constructing appropriate meanings multimodally” (p. 374).

When new media are used as modes of presentation as well as in the production and demonstration of student learning, theorists argue for a fundamental shift in the view of assessments (Wyatt-Smith & Cumming, 2009). Studies involving the role of digital video in second language listening assessment may help to illustrate some of the issues that arise through the use of new media. Based on the analysis of verbal report protocols of Australian learners attending to Japanese news videotexts, Gruba (2006) found that understanding of the foreign medium was best seen as variations of “play”; that is, rather than rely on traditional audiocentric definitions of listening, it was more helpful to conceptualize learner interactions with digital media as variations of curiosity, puzzlement, and engagement. Across a series of studies that compared “audio-only” versions with videotext formats in listening assessments, Wagner (2008) questioned ways to define listening when a multimodal medium was used as a mode of presentation. More recently, Cross (2011) showed how multimodal elements of a news broadcast in English were attended to by pairs of Japanese learners. Cross found that the multimodal elements facilitated comprehension in a variety of ways, but notably such elements could also inhibit the processing of audio content as they triggered differing expectations and inferences. Collectively, such studies point to the need to disentangle the complex interplay among learner abilities, technical affordances, and multimodal texts as a way to refine, or even to redefine, language constructs with sufficient clarity that they can be used in assessment designs (Ockey, 2009).

Assessment specialists have created both *computer-based* and *computer-adaptive* test designs. In the former, the workstation computer is seen as a platform equivalent to, but more efficient than, paper and pencil formats; in the latter, computer software responds to candidate input to continually adjust the selection and presentation of tasks to a calibrated level of language proficiency. López-Cuadrado, Armendariz, Latapy, and Lopistéguy (2008) explain the fundamentals of computer-adaptive tests. In brief, task designs are grounded on the probability that candidate responses will align with the particular values associated with given psychometric characteristics, or parameters, that have been established in a model of the language construct. The complexity of the model, then, can vary depending on the range of traits under examination. Variations in the design complexity can be expressed in terms such as *assisted self-adapted tests*, *testlet-based models*, and *tests with content*

balancing. At its core, computer-adaptive test development research seeks to arrive at a measurement of language ability through a calibration of the candidates' dynamic interpretations of material in light of their reported language-learning achievements, age, gender, learning styles, and attitudes (López-Cuadrado et al., 2008).

In summary, knowledge of both CALL and computer-based testing provides a background for understanding the complexities for creating new media assessments. At present, language assessment specialists employ networked workstations to deliver computer-based, or in some cases computer-adaptive, tests that meet the requirements of reliable, valid, and efficient examinations. The successful development of large-scale, high stakes examinations such as the Test of English as a Foreign Language Internet-based test (TOEFL iBT) (www.ets.org/toefl) demonstrates the ability to use computers in the assessment of listening, reading, speaking, and writing skills in testing centers throughout the world.

The use of new media in language assessments adds to the complexities of instrument design, particularly with regard to construct definition and the separation of candidate abilities from device capability. Within the current literature, computer-based instruments remain the focus of attention. Development of valid and reliable instruments demands significant resources and teams of disciplinary experts. For these reasons, it is prudent to first examine new media use in low stakes settings in which assessment for learning is a primary goal.

Assessment 2.0, Multiliteracies, and Mobility

According to Elliott (2008), the role of technology in assessment can be characterized in ways that correspond to the use of the Internet. Briefly, in Web 1.0 site designs, users are allowed to access and download material that cannot be altered, as is often the case for government policy Web sites; in Web 2.0 designs, users are encouraged to interact with tools on the site that enable them to post their own productions, write and exchange comments, or merge elements from other online sites. Web 2.0 designs include social network sites such as Facebook, Twitter, and YouTube, and are increasingly used for "telecollaboration" for a wide range of language-learning contexts and purposes (Guth & Helm, 2010).

Akin to the static nature of Web 1.0 sites, *Assessment 1.0* designs are formally administered, are paper- or workstation-based, are given at specific times and locations, and focus on individual performance. At the next incremental stage, *Assessment 1.5* designs are based on a range of *e-assessments* that are workstation-based and enable candidates to demonstrate their abilities in online simulations, as is found in virtual chemistry labs. Additionally, *e-assessment* design allows students to contribute work to online portfolios, conduct reviews of peer work, or interact in established virtual communities (e.g., Crisp, 2007). Efforts to develop *Assessment 1.5* designs can be found at sites that include, for example, Assessment Futures (<http://www.iml.uts.edu.au/assessment-futures/index.html>), Transforming Assessment (www.transformingassessment.com), or the Central Michigan University Assessment Toolkit (<https://academicaffairs.cmich.edu/caa/assessment/resources/toolkit.shtml>).

Elliot (2008) foresees *Assessment 2.0* designs, not yet realized, as those that would involve measures of performances through extensive interactions with social network sites, provide opportunities to both access and post original productions, and allow for unrestrained navigation across global networks; that is, in such assessments, uses would mimic ways in which the Web is currently used. Importantly, Assessment 2.0 designs would place a strong emphasis on independent learning, collaboration, and the demonstration of higher order cognitive skills such as those that involve deep and complex problem solving. The challenges of Assessment 2.0, as Elliot (2008) writes, are both large and familiar: limited digital literacies among students and instructors, a lack of criteria for evaluating new communicative practices, difficulties in pinpointing individual contribution to group assessments, and the demands of equipping efforts to meet a rapidly changing plethora of new technologies.

Research concerning the comprehension of multimodal texts, learning in digital environments, and the intersections of literacy and technology can be found in topic areas such as *media literacy*, *new literacies*, and *multiliteracies* (for an overview see, e.g., Coiro et al., 2008). Briefly, new literacies scholars in education discuss the pedagogical implications inherent in the use of new media and foresee the need for a wholesale change in many established ways of teaching, learning, and assessment. As theorists argue, the growing use of new media must spur the design of innovative assessments that can better account for the complex interactions that are woven into the everyday communicative practices of the current generation of students (Brown, Lockyer, & Caputi, 2010).

Grounded in work to do with literacy in the age of new media, Kress (2009) discusses the implications of a growing awareness of multimodality in studies of interactions and meaning. Two urgent questions for educators, according to Kress, arise from this point: "How do we assess learning expressed in multimodal texts, objects and processes?" and "What theories are needed to deal with *assessment* in this environment?" (p. 19; italics in the original). For Kress, assessment attempts to reconcile the relationship between what is expected to be learned and what is actually learned. To be assessed, learning must first be "recognized" by an assessor; when learners utilize modes and processes that lie outside the normal boundaries of recognition, their work may not be well understood or legitimized and thus they may seem to fail to produce any evidence of achievement. Ideally, Kress writes, any theory of assessment would take it into account that valuation happens with regard to all actions within all environments. For assessors, Kress argues, the implications of coming to recognize the signs of learning in new media environments lead to a choice: On the one hand, assessors can attend to the "metrics of conformity" or, on the other hand, assessors can strive to evaluate the "principles of semiotic engagement" (p. 37).

Adding to the challenges of Assessment 2.0 designs and the recognition of multimodal learning, the mobility of new media devices disrupts the security and control of workstation environments. Presently, language assessors direct candidates to sit for examinations at specified times and locations, and to make use of computers with particular configurations of hardware and software. Theoretically, the reasons candidates sit at secure sites and computers is to meet the demands of test designers, not to take the test itself. As mobile devices, including smart-

phones, laptop computers, and multitouch tablet computers, become near ubiquitous and more powerful, their use is “converging” to shift the locus of power from the producer to the consumer (Jenkins, 2006). In the near future, perhaps, test candidates will ask: “Why do we need to travel to a particular location to use a particular device at a particular time of day?”

To see how assessment specialists and others are investigating such tensions, we now turn to current research.

Challenges

Extensive searches of the literature found few investigations concerning the use of new media in language assessments. To date, I would argue that research has focused on the potentialities and affordances of new media in language assessments through the conduct of small-scale, descriptive studies that have been situated in single-site classrooms or related educational settings. For example, Blake, Wilson, Cetto, and Pardo-Ballester (2008) found that variations in their measures of oral proficiency were caused by the use of different technologies. On a similar note, Miyazoe and Anderson (2010) found that student attitudes and learning outcomes varied when students wrote online in a forum, blog, or wiki as writing styles varied in line with the differing media. Further, O’Dowd (2010) explores the assessments of telecollaborative activities, arguing that they need to better align with social Web 2.0 practices to result in a determination of varying levels of intercultural awareness, new literacies, and multimodal language competence. As O’Dowd argues, language educators have to consider ethical, practical, and pedagogical dimensions of assessing telecollaboration. For the moment, O’Dowd suggests, language educators can make greater use of principled and appropriate rubrics to assess a range of student work that can be embodied in online portfolios.

Douglas (2010) imagines a time in the near future when candidates are directed to interact with sophisticated avatars within immersive virtual worlds in ways that probe aspects of language proficiency. Language-learning initiatives in virtual worlds have flourished since the early 2000s; again, I would argue, much of the empirical research concerning interaction in virtual worlds has focused largely on discourse features (e.g., Herring, *in press*), pedagogical approaches (e.g., Collentine, 2011), or both rather than on assessment concerns. Intended for use in higher education, sites such as Transforming Assessment provide regular online discussions and Webinars about the development of assessments for virtual worlds across a range of disciplines. To my knowledge, no framework yet exists that can underpin the development of new media language assessments.

It would be fair to suggest, I would argue, that assessment professionals have directed their attention to the development of computer-based instruments that are designed to meet the demands of test efficiency, reliability, and validity. For their part, scholars concerned with CALL and new literacies practices have generally set aside matters to do with assessment of language proficiencies. Because of the growing integration of new media throughout society and education, as well as an increased awareness of the new literacies agenda, research on and

development of new media language assessments will no doubt draw much greater attention in the near future. From this point, I set out a series of challenges that I think will arise in the development of new media language assessments.

Being Social

New media are often associated with *social media*, in which frequent interactions are fostered across a range of social network sites, micro-blogging facilities, and smartphone applications. McNamara and Roever (2006) have set out a broad agenda for the role of social concepts in language assessment, and ask, for example, whether social dimensions of language proficiency are testable. Issues to do with the assessment of discourse and pragmatics come to the fore in social settings. Practical concerns include timely completion and an ability to score performances with little expense. One way to address such issues would be to produce five-minute videoconferences between assessors and candidates. The clips of the recorded sessions could then be hosted on a server for distribution and scoring by experienced raters, and later archived on backup systems to meet legal concerns. The way forward, McNamara and Roever suggest, is to move beyond assessing aspects of pragmatics in isolation while remaining clear about what elements are to be specifically examined.

Defining Constructs

One recurring theme is that language assessments that make use of new media and technologies may require both a reworking of established constructs and an identification of emerging ones to better acknowledge candidate performances of new literacies. The traditional language construct definitions of reading, writing, listening, and speaking require fundamental reconsideration and may best be seen as complex variations of “multimodal communicative competence” (Royce, 2007).

Consider the assessment of online writing in sites that involve a wiki, mash-up, or micro-blogging. Factors such as willingness to collaborate, fluency, grammatical accuracy, and key social discourse markers may be taken into account. In addition to such factors, it may be challenging to distinguish candidate computer literacy skills from contribution to the collaboration as well as from an ability to produce coherent writing. When the use of new media results in large variations in the production and reception of language, such as in the case of speaking into a smartphone to create a written message, the traditional understanding of what is to be measured shifts; thus, to separate what is truly “language” and what are the technical capabilities of users and their devices will challenge language assessors.

Evaluating New Media Language Assessments

Chapelle and Douglas (2006) pointed out that because computer-based versions of language assessments differed from paper and pencil instruments, they required a different set of evaluation standards. Accordingly, new media assessments will differ from those designed to be used on computer workstations, and thus a third set of evaluation criteria will be needed. All language assessments

should be evaluated on sound theoretical and practical principles, and guidelines identified by Chapelle and Douglas (2006) offer a strong basis.

Access and Equity

Dooley (2008) discusses a range of challenges that may accompany the transition to a new era of language assessments. Importantly, Dooley reminds assessment professionals of access and equity issues for candidates who may come from low-technology educational settings such as those in developing countries. As a solution, Dooley recommends that paper and pencil versions be maintained and be made available for high stakes tests. Legal or ethical requirements, such as those outlined in the Web Access Initiative (www.w3.org/WAI), encourage the creation of designs for inclusion that may be challenging for technology-mediated instruments to meet. Institutional operability to share resources and reduce costs can also be included in designs (see, for example, IMS Global Learning Consortium, www.imsglobal.org).

Security and Verification

The mobile and configurable nature of new media devices will heighten concerns surrounding candidate verification and test security. Such issues have arisen in other areas of network-based interactions, including those for legal and medical records (e.g., Klosek, 2011), and assessment professionals will also be pressed to deliver solutions that are secure as well as cost-effective, user-friendly, and fit for purpose.

Devices with biometric capabilities are becoming more prevalent, and the verification of a candidate identity may eventually lead to biometric scans that have, to date, been the stuff of science fiction movies. Unique individual physical attributes related to a series of physical characteristics, of the face in particular, will be the focus of many security measures for identity (Gates, 2011). During actual use, security for mobile devices raises such a wide range of risks that new architectures may be needed to handle the challenges (see, e.g., Rouse, 2012). Such challenges include, for example, a need to maintain the persistence of communication between the computers serving assessments and the receiving devices, and the need to detect interruptions or out-of-boundary variations in individual performance (e.g., differing rhythms in typing) as possible alerts for security breaches.

Training Assessment Professionals

Currently situated within applied linguistics, and often trained in language teaching, quantitative research, and aspects of project management, language assessment professionals will increasingly need to understand fields as diverse as human-computer interaction, artificial intelligence, and computational linguistics. Clearly, the combination of economic pressures (loss of clientele, loss of markets, and increased competition) and the shifting nature of language use and performance will force language assessment design to become increasingly complex and multidisciplinary. Future teams of professionals, perhaps configured virtually for

short-term projects, will need to involve software engineers, systems engineers, lawyers, e-security experts, and human–computer interaction specialists to work with assessment specialists. Chappelle (2008) sees a need to enhance graduate-level training with a focus on an understanding of software tools, particularly in the areas of natural language processing and automatic speech recognition (Chappelle & Chung, 2010).

In the short term, assessments for learning intended for use within formal language programs will be designed and delivered through institutional learning management systems, and perhaps served to devices such as multitouch tablet computers, laptops, and smartphones. In the establishment of hardware specifications for the institution, language educators will need to insist that the typing of non-roman characters be enabled through the provision of a piece of software known as an input method editor. Under the auspices of the institute perhaps, legal requirements for accessibility within new media assessment designs may be more easily met.

Future Directions

If assessment is seen to lead the language curriculum, the lack of development in new media assessments could well prevent educators from encouraging students to produce work in digital forms that are likely to dominate in coming generations. Looking to future directions, language assessment specialists will eventually have to contend with the rise in new literacies. For Kress (2009), a choice must be made between the “metrics of conformity” and the “principles of social engagement.” In short, how are second language proficiencies to be demonstrated, and recognized, in 21st-century learners?

Ironically, as a push for standardized testing grows, so too does the push in educational systems to adopt innovative assessment solutions that meet the needs of the 21st century (Wyatt-Smith & Cumming, 2009).

Workstation-based instruments, now established, will continue to be the platform for large-scale language testing research; in the near future, it is likely that innovative and well-resourced institutes will foster the development of new media assessments. Assessment *for* learning, rather than an assessment *of* learning (Gardner, Harlen, Hayward, & Stobart, 2008; Gipps & Stobart, 2003), could help to expand emerging frameworks on classroom-based assessment (Hill & McNamara, 2012). As a preliminary research agenda, I would suggest that this needs to deliver four key outcomes: (1) an understanding of the appropriate conditions that may foster the uptake of new media assessments within institutional language programs, (2) principled designs of new media in language assessments, (3) empirical investigation of student uses of new media assessments, and (4) an evaluation and diffusion of new media assessments in institutional practices. Delivery of these outcomes would make a significant contribution to the current body of research.

The purpose of the initial stage of the research agenda would be to investigate the influences of new media use and adoption in the wider institutional context. Instructor decisions concerning assessment, and learner perceptions of assess-

Table 60.1 Summary of research on the institutional context

<i>Area of inquiry</i>	<i>Research techniques</i>	<i>Focal questions</i>
Survey of institutional policies regarding language assessment	Online quantitative survey	What are the general perceptions of the role of new media and technologies in language assessment practices?
Institutional supports for innovation	Semistructured interviews with information technology (IT) support staff; document analysis	In what ways does the institute actively promote educational innovation, especially with regard to the use of new media in assessment?
Institutional expectations of academic staff	Semistructured interviews with heads of school and subject coordinators; document analysis	How do the criteria for promotion, workload expectations, and opportunities for professional development influence innovation in assessment?

Table 60.2 Summary of research on principled designs

<i>Area of inquiry</i>	<i>Research techniques</i>	<i>Focal questions</i>
Construct definitions for language assessment	Semistructured interviews	What are the general perceptions of the role of new media and technologies in language assessment practices?
Participatory designs	Use models	How do various experts, from teachers to assessment specialists, contribute to co-designed new media assessments?

ments, do not take place in a vacuum. What institutional factors are there, if any, that both enable and constrain the integration of new media into existing language assessments? See Table 60.1.

In a second phase, an agenda would seek to establish a clear *assessment use argument* as the basis of new media assessment, and involve stakeholders in making a series of informed choices to build strong designs that could differentiate among candidate proficiencies (Bachman & Palmer, 2010). In this stage, we first interview assessment specialists and language instructors concerning assessment goals, construct definitions, and fit-for-purpose factors. In the second phase, participatory design techniques (Cardenas-Claros & Gruba, 2010) could help to bring together complementary teams of experts to co-create preliminary new assessments (see Table 60.2).

Although it is clear that a move to be innovative is a driving force in the ascendancy of technology use in language programs, little work has been done on the view of second language learners concerning new media assessment practices. One key aspect of an agenda, then, is to examine how learners respond to new media assessment tasks. Responses are important to build theory that accounts for the influence of one media effect over another (see Table 60.3).

Table 60.3 Summary of research of learner perception and use of new media assessments

<i>Area of inquiry</i>	<i>Research techniques</i>	<i>Focal questions</i>
Computer literacy skills	Quantitative surveys; semistructured interviews	What computer literacy skills are required of learners such that Web 2.0 technologies pose no barriers to the use of new media in language assessment?
Perception of innovative assessment tasks	Quantitative surveys; semistructured interviews	What skills do you think are being assessed with the use of these new media? How do you rate the tasks?
Work with new media assessment tasks	Immediately retrospective and delayed verbal report protocols	What test-taking strategies do candidates employ under test conditions?

Table 60.4 Summary of the integration and evaluation of new media assessments

<i>Area of inquiry</i>	<i>Research techniques</i>	<i>Focal questions</i>
Change management	Focus group sessions; semistructured interviews	In your opinion, has the innovation using new media assessment been successful? Why or why not?
Diffusion of innovation	Focus group sessions; semistructured interviews	Why, and how, have stakeholders made use of recommendations for the integration of new media into assessment practices?
Social shaping of technologies	Focus group sessions; semistructured interviews	How have stakeholders adapted and modified innovations to fit local needs and the context of use?
Program evaluation	Document analysis; semistructured interviews	In what ways have innovations been integrated into the language curriculum, and to what effect on stakeholders?

As Chapelle (2007, p. 30) asks: “How can those who are investing significant resources into learning and teaching be shown that innovation might be for the best?” At this stage of the agenda, program evaluation framework would motivate work with a range of stakeholders, with attention directed not only to new media assessments but also to change management, the diffusion of innovation, and the social shaping of technologies (see Table 60.4).

Given the complexity of the area, investigations in the near future need to remain small-scale, descriptive, and situated in “assessment for learning” contexts as a way to establish the groundwork for later, large-scale instrument designs and administrations. The core challenge is to identify and isolate the measurement of language proficiency in a digital environment where wide ranges of choices and options conflate the inter-related effects of multimodal texts, mobile technologies, and individual abilities.

Eventually, I would argue, work on computer-based testing must dovetail with work on new media language assessments, for a number of reasons. First and

foremost, test developers must create instruments that meet the lifestyle demands of a global generation accustomed to near-ubiquitous digital access and interaction; that is, test candidates will come to expect to take assessments on their own mobile devices at a time and location of their own choosing. Second, as mainstream education adopts digital assessments, language educators will need to maintain a similar rate of adoption to remain relevant and current. Finally, the constructs of language use and performance are shifting under the influence of new media use, and language instrument design will need to align with such shifts to remain valid.

Using Corpora to Design Assessment

Fiona Barker

University of Cambridge, ESOL Examinations, England

Introduction

Language corpora are electronic databases of written, spoken, or other types of texts that are amenable to annotation and detailed linguistic analysis. Corpora have been applied to various fields related to assessment since the 1960s and have been increasingly visible within the language testing and assessment (LTA) field since the 1990s. This chapter describes the development and use of corpora within LTA, exploring their theoretical insights and practical applications for language assessment. Here we focus on formal language assessment, that is, the high stakes testing of language proficiency for academic, professional, or immigration purposes. I will first describe how corpora can inform various aspects of language testing and the main types of corpora in existence, before considering some case studies of corpus usage.

At the beginning of the lengthy process of designing a new test, the language tester needs to identify the test *construct* (which entails having a clear concept of what is to be tested) and can then work out how to assess this construct. Corpora can aid this conceptualization stage as they can support or refute commonly held beliefs about language structure, functions, and use, and may even reveal previously unknown facts from the written or spoken output of learner, novice, and expert users. This approach works equally well in general or specific language domains, which include professional fields such as international finance or law.

Once a test's construct has been identified, corpora can aid test design in terms of the range, level, and genre of tasks required and the individual items to be targeted in a test. This can be achieved through studying learner or native speaker output, or learning materials, all of which can be stored electronically in a corpus, marked up for various features, and searched using corpus linguistics (CL) techniques.

There are many design criteria to take into account when developing or selecting a corpus to be used to inform language assessment. A major consideration is whether the texts are from competent native users of a language or whether a *learner* corpus containing non-native language is required; there is also the expert/nonexpert aspect of competency within a specific field to take into account. Two further points to note are the domain specificity and spread of text types within a corpus, and whether it is a snapshot of a specific time period (a *synchronic* corpus) or whether it is updated (a *monitor* corpus). National language corpora tend to contain a broad and balanced language sample, for example the 100 million word British National Corpus of late 20th-century speech and writing (www.natcorp.ox.ac.uk). This is often used as a *reference* corpus, that is, as a benchmark against which another, smaller corpus can be compared. While native corpora tend to be used for reference, there are both native and learner monitor corpora which provide records of changing language use or proficiency levels over time. Reference corpora are clearly relevant to *content validity*, that is, whether test tasks or items are representative of the knowledge or ability to be tested. Particularly relevant to language for specific purposes (LSP) assessment are corpora containing domain-specific texts, for example the British Academic Written English (BAWE) corpus (<http://www2.warwick.ac.uk/fac/soc/al/research/collect/bawe>), which contains academic written assignments from 35 disciplines from the Universities of Warwick, Reading, and Oxford Brookes in England. The earlier British Academic Spoken English (BASE) corpus contains recordings of lectures and seminars from the Universities of Warwick and Reading (<http://www2.warwick.ac.uk/fac/soc/al/research/collect/base>).

The largest relevant corpora for language assessment contain hundreds of millions of words, such as the Corpus of Contemporary American English (COCA) (425 million words; <http://corpus.byu.edu/coca>) and the Russian National Corpus (150 million words; www.ruscorpora.ru/en). Such corpora are typically used for computational applications or lexicographic research, whereas smaller corpora are better suited to the mix of quantitative and qualitative approaches found in LTA. Learner corpora vary in size from the Cambridge Learner Corpus (50 million words of second language [L2] English; described in the following section) to the 0.6 million word Corpus Escrito del Español L2 (www.uam.es/woslac/cedel2.htm). There are also domain-specific learner corpora such as the 1 million word Business Letter Corpus of British and American English (swww.someya-net.com/concordancer). For language assessment research, any statistical procedure requires a suitable number of examples from a spread of source texts or learner responses. Within corpus studies, normalization (that is, reporting the calculated frequency of a feature in a specified number of words, such as 1 million) provides a comparison of a feature across subcorpora (groups of texts) of different sizes within a corpus.

Once a corpus is correctly formatted, possibly using a common standard such as the Corpus Encoding Standard (www.tei-c.org), specially designed software programs, such as Key Word in Context (KWIC) concordancers, can analyze linguistic features and display them in meaningful ways for the end user. This is even more useful when corpora are annotated with additional linguistic information, such as part-of-speech (POS) tagging (that is, indicating each word's part of

speech) or parsing a text to reveal its syntactic structure. Both of these processes can be achieved using software, so reducing the need for manual intervention. Learner corpora can also be marked up with learners' errors manually or using editing software (Díaz-Negrillo & Fernández-Domínguez, 2006).

Each language-testing context requires a careful needs analysis of whether to use an existing corpus or to develop one's own, how to analyze the data, and how best to interpret the results, all within the overarching test development cycle (Saville, 2003) and following best practice guidelines in assessment such as Cambridge ESOL's *Principles of Good Practice* (2013).

The key point for language testers is that any corpus used to inform, develop, or validate assessment should itself be valid, reliable, and fit for purpose, an example of "essential measurement qualities" (Bachman & Palmer, 1996, p. 19). We should also note that corpora are not the only tool available to language testers to help them to design assessments, and that a corpus's fitness for purpose should always be established and balanced with theoretical and experimental findings and language testers' own expertise.

Having outlined the range of corpora available to language testers, I will now describe the earliest applications of language corpora to LTA.

Previous Views

The computerized collection of written texts started in 1964 with the 1 million word Brown Corpus of American English (<http://icame.uib.no/brown/bcm.html>) and has expanded rapidly since then, with corpora and analytical software being distributed since the 1970s through organizations such as the International Computer Archive of Modern and Medieval English (ICAME) in Norway (<http://icame.uib.no>). The Survey of English Usage at University College London aimed to describe the grammar of educated adult native speakers through written and spoken texts collected between 1955 and 1985 (www.ucl.ac.uk/english-usage). The native speaker norm implied by these corpora was shifting throughout this period and in 1990 the International Corpus of English was initiated, which contains regional and national varieties of English to enable comparative studies (<http://ice-corpora.net/ice>). Against this backdrop, the first learner corpus collections were being conceptualized.

At the start of the 1990s various teams from academic and collaborating organizations began to collect learner writing to complement the existing native corpora for English which had been informing dictionary publishing and related activities for several decades (see Taylor & Barker, 2008, for an overview). Two types of learner corpora were instigated: those designed for assessment purposes (so linked to proficiency levels), and those designed for pedagogical research, with a less empirical basis for level assignment. In England, the English as a Foreign Language (EFL) Division of the University of Cambridge Local Examinations Syndicate (UCLES) (now Cambridge ESOL) started building the Cambridge Learner Corpus (CLC) in 1993 with Cambridge University Press (www.cambridge.org/gb/elt/catalogue/subject/custom/item3646603). This corpus contains written exam scripts and associated questions from a wide range of general, academic,

and professional English tests, covering all six levels, A1–C2, of the Common European Framework of Reference for Languages (CEFR) (Council of Europe, 2001). Scripts are manually keyed with learners' errors intact, and half of the corpus has been error tagged, which, along with learners' demographic information and score data, can be used to filter searches (Nicholls, 2003). The CLC contained 50 million words (around 600,000 texts) in 2012 and it can be searched by error types or lexically, by concordancer, collocation search, or frequency word lists, making it a powerful resource for designing language assessment and informing lexicographic research. The CLC has a stronger claim to reflect proficiency levels linked to the CEFR than other learner corpora as all of the texts within it come from learners' responses to language tests that have informed, and been informed by, the CEFR itself (Milanovic, 2009).

The International Corpus of Learner English (Granger, Dagneaux, Meunier, & Paquot, 2009) was also initiated in the early 1990s, in Louvain-la-Neuve, Belgium. This 4 million word corpus consists of argumentative essays and literature papers from higher intermediate to advanced EFL learners from 16 language backgrounds. Alongside the essays, learner profiles provide details of the learners' age, languages spoken at home, and other background information. Other corpora have since been developed by the same team for their Contrastive Interlanguage Analysis between native and non-native users (www.uclouvain.be/en-169937.html).

The potential applications of corpora for designing tests, writing test items, and scoring and reporting tests were signaled in 1996 by Alderson, based on their impact in linguistic analysis and language pedagogy. Alderson (1996) also urged language testers to keep in mind fundamental theoretical considerations (e.g., construct definition and issues of validity and reliability) alongside the results of empirical study. Language testers had started to apply corpora to assessment before this, however, using both corpora containing native or expert texts which had been developed independently of language testers, and corpora developed by language testers containing learner performances and test materials.

While there are few published accounts of corpora being used to design assessment in the early 1990s, within examination boards attempts were made to apply corpus findings to assessment from the inception of learner corpora. By the middle of the decade, the increase in the availability of native corpora and lexical analysis software such as WordSmith Tools (Scott, 1996) were beginning to impact more widely on the LTA field. Corpora started to be routinely used for selected aspects of test development and validation from this point onwards. In England, Cambridge ESOL used native and learner corpora to devise new test formats to test collocational knowledge within an advanced general English test (Hargreaves, 2000). A sample new task type aimed to target real contexts for collocational knowledge, with a learner corpus providing the expressions to be tested and several native corpora providing the contexts for use. Subsequent uses of corpora were to check and inform test revision activities for the Cambridge English: Proficiency (CPE) exam (Weir & Milanovic, 2003) and for the revision of word lists used by materials writers and candidates (Taylor & Barker, 2008).

In the USA, the University of Michigan's English Language Institute (ELI) started recording and transcribing academic speech in 1997, forming the Michigan Corpus of Academic Spoken English (MICASE) (<http://micase.elicorpora.info>).

This corpus enables researchers to identify the characteristics within the spoken academic domain and their variation across speakers, across academic disciplines, and over time. The ELI subsequently built a written academic corpus, the Michigan Corpus of Upper-Level Student Papers (MICUSP) (<http://micusp.elicorpora.info>), which was intended, like MICASE, to develop accurate English as a second language (ESL) and English for academic purposes (EAP) teaching and assessment materials.

So how should we characterize the use of corpora to design assessment in the 1990s? While the development of learner corpora was gaining momentum, there were various forays into how native and learner corpora could inform test design in specific areas by those organizations that were building their own corpora. The benefits of general reference or domain-specific native corpora for language testing were well established by the end of this decade, laying the foundations for a steady building of interest and involvement with corpora in the wider LTA community in the following decade.

In the following section I will outline the current views on using corpora to design assessment, moving through the 2000s.

Current Views

Since 2000 there has been huge growth and interest in corpus techniques within applied linguistics generally and language testing specifically, against a backdrop of a proliferation of corpora, with corpora increasingly built semiautomatically from the Internet and an increase in the number and size of learner corpora, including those for languages other than English (<http://tiny.cc/corpora>). There has also been an increased awareness of the importance of marking the relative positioning of learners within a corpus according to a framework of proficiency levels (e.g., American Council on the Teaching of Foreign Languages [ACTFL], 1999/2001; Council of Europe, 2001), or their relative expertise in a field, in order to ascertain how these factors impact on their language production. This latter distinction is particularly pertinent for domain-specific corpora where mastery of field-specific lexis and discourse conventions is required as well as a certain level of general language proficiency. Examination boards have therefore undertaken corpus-based research and development activities to support existing tests, including the Test of English as a Foreign Language (TOEFL) (Biber et al., 2004; www.ets.org/toefl) and the International English Language Testing System (IELTS) (Taylor & Falvey, 2007; www.IELTS.org).

The influence of corpora began to be seen at LTA conferences, starting with the 2001 Language Testing Research Colloquium at St. Louis, USA. In 2003 a symposium on the impact of corpora on language testing covered the testing of writing and reading, how oral testing might benefit from spoken CL, and the application of learner corpora to LTA (Taylor, Thompson, McCarthy, & Barker, 2003).

Let us now look in more detail at using corpora to develop new test items and validate existing test items or scoring criteria. Native speaker and learner corpora both play a useful role in the creation and validation of test materials. Language testers can use learner corpora to identify typical errors by language background

or proficiency level, which can inform the focus of test items or tasks and also test preparation materials. A learner corpus can help to validate test writers' intuitions about language features and frequencies associated with different proficiency levels. Learner data can also reveal frequent collocational errors which test writers can turn into *distracter* items for multiple choice questions, using learners' actual errors rather than writing potentially poor distracters that are not evident in learner output.

The TOEFL 2000 Spoken and Written Academic Language Corpus (T2K-SWAL) was designed to research the university-level language skills required for this high stakes test (Biber et al., 2004). An earlier study indicated that TOEFL reading and listening texts differed from real-life academic registers, leading the research team to include nontraditional institutional registers such as classroom management talk and service encounters in this corpus (Biber et al., 2004, p. 2). The researchers aimed to design diagnostic tools to help writers produce more representative test items of real academic language use and to provide empirical findings to accompany the intuitions previously used to design tests and write items. These aims relate to a test's construct definition and representation (Alderson, 1996).

Test writers can draw on native data as a source of original input texts for reading and listening tests, or as a means of checking the authentic features of specially written reading and listening texts (Biber et al., 2004; Green, Ünalı, & Weir, 2010). In relation to word frequency, Alderson (2007) investigated native-speaker frequency judgments of languages without large corpora; the surprising lack of agreement between the expert raters suggests that corpora are actually the best way to obtain reliable word frequency measures.

Corpora therefore enable test writers to base their tasks more closely on authentic language and to target those aspects of language of direct relevance to the test-taking population. More specifically, test writers can explore native or learner corpora to reveal collocational patterns that are suitable for testing as they distinguish between adjacent proficiency levels.

Turning to the use of corpora to develop and validate scoring criteria for language tests, the usefulness of the traditional native speaker norm for assessing L2 performance continues to be debated (Taylor, 2006), leading some applied linguists to question the use of native reference corpora as fair and appropriate comparisons for test-taker performances. There are associated debates about English as a lingua franca (ELF) usage in academic or business contexts (Mauranen, 2010), with ELF corpora such as the Vienna-Oxford International Corpus of English (VOICE) (www.univie.ac.at/voice) challenging native-speaker norms and providing new assessment opportunities (McNamara, 2012).

Both native and learner corpora, and possibly ELF corpora, can be used to identify relevant performance features that inform decisions about assessment criteria and the development of rating scales. Using learner corpus data and experimental written performances, Hawkey and Barker (2004) combined manual and corpus analyses to identify distinguishing features of performance at different proficiency levels within the development of a common scale for assessing L2 writing. Hasselgreen (2005) investigated the fluency markers of Norwegian secondary school pupils learning English to validate assessment criteria and rating scales for a paired format speaking test based on a learner corpus. Using a similar

approach based on corpus data, the Testing Division of the University of Michigan revised the criterion-referenced rating scales for a B2-level general English test, the Examination for the Certificate of Competency in English (ECCE), to better reflect the linguistic features of learners' output (www.cambridgemichigan.org).

In all of these case studies, corpus evidence was carefully analyzed along with expert judgment and other resources, for example proficiency frameworks. Experienced test item writers seem to have internalized what it means for a learner to be operating "at a level" by combining their knowledge and experience of what a learner can be expected to know at a certain level; however, corpora can still aid this process.

Research teams have developed ways to automatically score or evaluate written production since the late 1970s (with more recent work on assessing speech), partly based on the automatic detection of learner errors in corpora and on the provision of mutually agreed "gold standard" responses and larger training sets of learner responses (Foster & Andersen, 2009; Briscoe, Medlock, & Andersen, 2010). This area of research has informed a number of online evaluation services where learners complete a practice task or test, or upload a sample of writing, and the system gives back general or formative feedback (e.g., the Online Practice Tests at www.oxfordenglishtesting.com).

It is clear that corpora of various types—native and learner, general and domain-specific, reference and monitor—have been applied to different stages of test and scale development and validation throughout the 2000s, and much of this work is ongoing. In the next section I consider contemporary applications of corpora to the LTA field before discussing the challenges that these hold for language testers.

Current Research

Within LTA, corpora are currently being used in long-term research endeavors, in smaller-scale projects, and in regular test development or validation activities. There are also new forms of corpus being developed.

Corpora are central to the study of the discourse, grammatical, lexical, semantic, and functional features of L2 English at A1–C2 CEFR levels within the English Profile Programme (www.EnglishProfile.org). This international, interdisciplinary program is producing a set of "profiles" that together form a comprehensive set of reference level descriptions (RLDs) for English, that is, a systematic specification of learning objectives that describes what a learner can be expected to know at each proficiency level. While other projects are specifying RLDs for various languages (www.coe.int/t/dg4/linguistic/dnr_EN.asp#P55_9216), English Profile is unique in its triangulation of empirical findings, theory, and practice. The English Profile approach is not to describe every aspect of language, but to focus on those that discriminate between pairs or groups of levels, known as *critical features* (see Hawkins & Filipović, 2012, for a full discussion).

English Profile is using the CLC (described above), and further written and spoken corpora from nontesting contexts are being developed to complement this resource. Instructors from various educational contexts worldwide are submitting their learners' written responses and spoken data, together with detailed

demographic information plus assessments of proficiency levels; the resulting corpora provide a snapshot of learners' actual competence (what they can do) that are informing English Profile research. English Profile outcomes have a sound empirical and theoretical basis as well as being based on novel computational analytical approaches. The English Vocabulary Profile for American and British varieties is available online, and the English Grammar Profile and English Functions Profile were being developed in 2013 (see www.EnglishProfile.org for details of completed and ongoing research).

There are other new corpora being collected that are opening up further avenues of research for LTA, which may, in turn, inform specific types of language assessment in the future. Multimodal corpora are starting to be collected, such as the HeadTalk gesture corpus (Knight et al., 2006), which is adding to our understanding of the range and role of gesture in communication. The ELF corpora already described are also beginning to impact on LTA.

Corpus data are also being routinely collected from virtual learning environments (VLEs). Researchers at the University of Bristol, England, have built the British Sign Language Learner Corpus from video recordings and are using it to examine the interlanguage of beginner learners of British Sign Language (BSL) (www.bris.ac.uk/deaf/english/research/active). Assessment is built into the study via a baseline online assessment of BSL skills using communicative tasks; a directed course of instruction and practice based on existing course materials; and interactive and productive sign language tuition and assessment. The resulting corpus is error tagged to enable comparison with second language acquisition (SLA) research, so could be linked to the work of the Second Language Acquisition and Testing in Europe (SLATE) network (www.slate.eu.org).

A key area of current research is the further exploration of methods for extending the automated evaluation of learner written and spoken production, to improve on the accuracy, reliability, and utility offered by current systems (see the automated scoring bibliography at http://www.ets.org/research/topics/as_nlp/bibliography). The automated scoring of speaking is not as widespread as automated essay scoring, although some computer-delivered speaking tests are already computer marked, for example the Pearson Test of English (PTE) Academic (www.pearsonpte.com). However, further research is needed to ascertain what spoken measures can be assessed, by humans or machines, and to furthermore indicate which of these measures can distinguish between proficiency levels. Post, Galaczi, Graham, and Li (2012) applied a set of rhythm metrics to benchmarked speaking test performances and found statistically significant differences between stress-timed and syllable-timed language groups and between four proficiency levels, opening up this new line of inquiry.

Developments in natural language processing (NLP) and speech technology mean that future assessment systems should be flexible enough to be deployed in various ways on different suites of tests, both in live testing and in practice contexts (Briscoe et al., 2010). Automated rating systems will continue to benefit from the availability of larger collections of learner data, fully tagged and parsed and annotated for learner error, as well as up-to-date collections of native data and advances in computational techniques. One such example is the use of eye-tracking technology to study the behaviors of candidates taking online reading or listening

tests, which can provide construct validity for test items, also enhancing testers' understanding of how learners interact with computer-based tests of these skills (Bax & Weir, 2012).

In this section I have outlined major current areas of research and practice using corpora to design specific aspects of assessment. Next, the main challenges faced by language testers when seeking to build or use corpus data will be described, including theoretical considerations and issues of corpus compilation, annotation, and analysis.

Challenges

Despite the empirical benefits of using corpora and related analysis tools and techniques for LTA, there are a number of challenges involved when using a CL approach for test or rating design, test validation, or more experimental research.

In relation to test design, corpora tend not to be the driving force in creating innovative task types, although there are exceptions (including Hargreaves, 2000). As such studies relate to tasks within advanced level examinations with high stakes for the test taker, it is probable that language testers designing assessments at lower proficiency levels or with lower stakes for the test taker will be less likely to make the investment required to use a corpus or to adopt related analytical techniques.

A major challenge in using corpora to design assessment lies in the generalizability of corpus findings. Language testers need to understand the sampling approach and design of a corpus, since the criteria by which texts were selected, and the organization of the data within a corpus, constrain how it can be used (e.g., a corpus of native child language would not be relevant to a test of readiness to study in an academic context). The age and size of a corpus further affect its representativeness, so need to be acknowledged when interpreting corpus-based findings and using these in decision making, as noted by Alderson (1996).

Turning to rating scale design, while there have been a number of studies that successfully identified relevant performance features from learner corpora that fed into rating scale development (including Hawkey & Barker, 2004; Hasselgreen, 2005), the corpus findings informed decisions about assessment criteria alongside pre-existing proficiency frameworks and expert judgment rather than on their own.

There are additional challenges involved in using sets of learner test performances to train automated scoring systems such as those outlined earlier in this chapter. These concern the representativeness of the training data set and the confidence that the researchers have in the original ratings applied to the training data set. Having learner responses multiply marked or re-marked can counter this potential threat to the validity of the data set, but this can be costly or difficult if the format of the test or its scoring rubric has changed since the training data set tasks were taken.

The test validation cycle (that is, reviewing or performing regular checks on an existing test) is perhaps the most challenging area to apply corpus data to in the absence of a corpus of test-taker output from that specific assessment. Such a

corpus could provide qualitative evidence of whether test takers are performing as expected alongside the routine quantitative statistical analyses of results. Where there is no test-taker corpus available, a general native reference corpus or a domain-specific native corpus may be applicable, although it is highly unlikely that test revisions would be driven by corpus analysis; rather, they tend to result from a scheduled revision, or internal or external pressures to change specific aspects of a test.

Beyond these three areas, there are other, general limitations of using corpora to design assessment. While language testers may use several corpora to provide multiple views of linguistic features, it is important to bear in mind each corpus's design and intended purpose. For example, the CLC is an archive of test materials and performances and was intended to be used for both general and specific test development and validation activities, while the T2K-SWAL corpus was designed to enable the revision of a specific academic English test. The majority of corpora are not designed for language assessment applications so may not always include the required level of information, most importantly an accurate representation of the proficiency level of learners within the corpus. This, however, is not insurmountable, as texts can be retrospectively rated or rerated by experts or an automated system (Briscoe et al., 2010).

In terms of corpus compilation, this has to be planned, rigorous, and replicable if a corpus or an assessment based on it is to have merit. Using general reference corpora for purposes that they were not designed for (which has a parallel with language tests being used for higher stakes purposes or applied to different domains than they were intended to cover) is inadvisable. A reference corpus is more likely to contain easily obtainable data (that is, online material), which may not always be appropriate for language assessment purposes. Similarly, a domain-specific corpus can only be expected to provide information about that domain, so corpus-informed findings should not be overgeneralized.

The amount and level of background information available in a learner corpus may constrain how it can be applied to assessment. It is important for a language tester to obtain details of a learner's mother tongue, for example, together with the context of their written or spoken performance. Similarly, the level of annotation is important as non-POS tagged corpora make disambiguation of word classes difficult when viewing corpus-derived frequency word lists. Error tagging of learner corpora provides valuable insights into the linguistic problems faced by language learners at different proficiency levels and across first languages (L1s), but it needs to be consistently applied, and comparing results from corpora annotated using different approaches can be difficult (Díaz-Negrillo & Fernández-Domínguez, 2006).

Although annotated corpora provide richer data sets for analysis, the technical challenges and the resource implications are great. While most error tagging is completed manually, or with the aid of software, its automation is preferable (Foster & Andersen, 2009). Furthermore, automatic tagging at the semantic and discourse level remains challenging, although this is being undertaken within NLP for educational applications, which should inform language assessment in the future (see Lu, 2010, for recent developments in automated learner text analysis).

Interpreting outcomes from CL analyses requires the same care as the interpretation of statistical analyses in assessment, which can be challenging where the corpus data are strongly influenced by a task effect (which applies to any corpus of test-taker performance). Several studies highlight the value of undertaking manual analyses with corpus analyses, including Hawkey and Barker (2004).

Most corpora require substantial investments of time, money, and expertise, hence the collaborations between universities, examination boards, and publishers to build large corpora for research, educational, and other purposes. In the design phase, data protection, intellectual property rights, and associated issues need to be worked out, particularly for learner corpora that store test-taker performances, test scores, and background information. This is often the reason behind corpora not being made available to researchers, although progress is being made in making data more widely accessible to those with a related research agenda, for example through the English Profile Network.

Experimental research projects within LTA are perhaps the best places to explore the opportunities to use new types of corpora (e.g., gesture corpora) or related techniques (e.g., eye-tracking technology) in nonlive testing situations. In the final section I suggest the future needs of language testers in relation to corpus-informed assessment and the likely impact of such new types of corpora and related technologies on LTA.

Future Directions

Corpora and related analytical approaches and software have gradually assumed significance to LTA since the early 1990s. There have been periods of intense activity when examination boards started to collect their own corpora of learner texts instead of relying solely on native reference corpora, coupled with a steady increase in awareness, use, and geographical spread of corpora, as well as a burgeoning of different types of corpora covering more domains and text types. But what is the future for using corpora to design assessment?

If we first consider existing corpora, those that are static will remain representative of a group of texts sampled from a specific group of people collected over a set period of time. Such corpora will remain valuable archives for linguistic research and may continue to inform language assessment where a general reference corpus is required or where the corpus in question is of a specific domain relevant to an assessment need. The corpora of most relevance to LTA in the future will be those which continue to sample language over time, and those focused on professional domains, such as accountancy, aviation, or medicine, to ensure that valid and reliable LSP tests are produced. More unusual domain-specific corpora may be developed to meet the need to certificate entrants to various professions.

Texts from certain groups of language learners will also need to be collected, especially from very young or older language learners, due to the increase in lifelong language learning and the needs of people requiring language certification for immigration purposes. Age-relevant reference corpora may be contrasted with non-native language so that language testers can improve their

understanding of the criterial differences between child, adolescent, and adult proficiency, whether in L1, L2, or beyond. New types of corpora involving gesture and video could provide further information for language testers on the nature of nonverbal communication and the possibilities of developing assessments for sign languages, for example.

As the number of L2 users of English continues to grow, there are new corpora of emerging language varieties, for example the VOICE and English as a Lingua Franca in Academic Settings (ELFA) corpora (<http://www.helsinki.fi/englanti/elfa/elfacorporus.html>), which are 1 million word collections of spoken ELF in professional, educational and leisure domains. A written academic ELF corpus (WrELFA) and a Global English Corpus are also under development (www.helsinki.fi/englanti/elfa/wrelfa.html). Such corpora may provide sufficient evidence to inform decisions about the level of linguistic variation to be included in language tests or to validate models for teaching purposes (Taylor, 2006). It remains to be seen whether this research area will have major implications for LTA, although its influence is growing and it continues to challenge the concept of native speaker norms (see McNamara, 2012).

The current growth in content and language integrated learning (CLIL), whereby a subject (e.g., history) is taught through the medium of another language, means that there will be a requirement for data to be collected from CLIL contexts to ensure that language testers can base their assessments on how teachers and learners use the language of instruction. There is also increasing demand for language assessment, perhaps more formative in nature, in less well researched tertiary areas. Within the English Profile Programme, for example, the Cambridge, Limerick and Shannon Corpus of hotel management speech includes interactions between native and non-native students in practical training sessions, lectures, and tutorials, providing complex and multilayered transcriptions which will inform research into many areas of spoken proficiency (www.englishprofile.org).

Technical innovations will result in faster corpus building from computer-based tests, online materials (“Web as corpus”) (<http://webascorpus.sourceforge.net>), or online evaluation services. Advances in automated speech recognition and transcription will improve the onerous task of capturing, storing, and annotating spoken data in future, meaning that automated data capture, tagging, and analysis should be possible. This will be supplemented by a better understanding of the elements of successful spoken language ability, thereby improving the assessment of speaking.

The development of corpora specifically for LTA is now firmly established and their applications to language testing seem likely to expand, as innovative approaches to the annotation and analysis of corpus data are being attempted within the field, rather than being imposed on testing from other fields. An example is the Pearson International Corpus of Academic English (PICA), a 37 million word corpus which aims to represent the language that students encounter within and beyond their college studies in five major varieties of English (www.pearsonpte.com/research/Documents/RS_PICAE_2010.pdf). This resource was created by an external company to answer the question: What English does a non-native speaker need in order to be successful in academic settings where English is the main language? An outcome from this project is the

Academic Collocation List (of the most frequent pedagogically relevant collocations in the corpus), which is being used for PTE Academic item development and validity research alongside other assessment and pedagogical activities. This could well be the model for future corpus collection and analysis by language testers.

Language testers are now asking the right questions of corpora, and of the people who design them, showing a growth in understanding of their power to change long-held beliefs about learners and their language ability and to improve the quality of language assessment worldwide. There is a clear future for automated means of assessing learner output, which should bring benefits to assessment providers, learners, and more widely, as long as the limitations of such systems are borne in mind.

Despite the resources required to build or purchase corpora, and the long-term commitment that may be required to see results, there is a steady increase in language testers' engagement with corpora in relation to the areas of assessment outlined here, namely designing, validating, and rating language tests. There are also wider benefits, including the ability to work with researchers from different fields such as computational linguists, psycholinguists, or other groups whom language testers may not have had any impetus to interact with before.

These are certainly exciting times for language testers and applied corpus linguists, as the quantity and quality of corpora and related software and derived materials increase each year. Examination boards are establishing links with the best corpus and computational linguists to enhance their testing provision and additional services such as online courses, evaluation services, or training (e.g., Pearson's and English Profile's collaborative corpus developments described here). So the question of how we use corpora to design assessment has been answered in general terms over a range of contexts and types of assessment to date, but the future uses remain as yet unspecified, as the number and applications of corpora for assessment are set to increase further in the next decade and beyond.

In the last decade especially, corpora have assumed significance for LTA, with language testers around the world either developing or commissioning corpora and exploring how such resources can inform or improve our current understanding of language constructs and ways to test these, thereby enhancing best practice in the field. Contemporary language testing is guided by professional standards, and related models of quality assurance encourage the use of empirical study—which should include the use of language corpora—as a companion to testers' expertise and theoretical views, thereby providing a true triangulation of theory, practice, and evidence.

Eye-Tracking Technology for Reading

Paula M. Winke

Michigan State University, USA

Introduction

Eye movement data provide quantitative evidence of a person's visual attentional processes when performing a task such as reading (Reichle, Pollatsek, Fisher, & Rayner, 1998; Duchowski, 2002; Frenck-Mestre, 2005; Rayner, 1998, 2009). Research employing eye movement data to investigate reading processes is diverse, complex, and informs a large variety of theories (see Radach & Kennedy, 2004, for an overview). For example, recordings of eye movements while readers process words placed in various parts of sentences (in various syntactic structures) lend insight into how syntactic structure imparts *mental processing importance*—that is, whether variations in syntactic structure affect aspects of language processing (e.g., Birch & Rayner, 2010). Eye trackers are also commonly used to compare child versus adult readers' reading processes (e.g. Joseph et al., 2008); the results of such research are often used to better inform child-reading instructional practices. Additionally, eye-tracking is used to investigate how individuals with developmental reading disorders read and process textual information (i.e. Hatzidaki, Gianneli, Petrakis, Makaronas, & Aslanides, 2011). Outcomes assist the understanding of the effects of these disorders on the brain and guide pedagogues in how to better teach reading to such populations.

In second language acquisition, eye-tracking methods have been used to investigate how individuals reading in a second language resolve ambiguous sentences (e.g., Molly said that she will go to New Jersey yesterday: Dussias, 2010, p. 157; see also Dussias & Sagarra, 2007; Roberts, Gullberg, & Indefrey, 2008) or violations of gender agreement (Keating, 2009). Such studies help researchers understand second language (L2) reading processes and how they differ from first language (L1) reading processes. Other L2 studies employing eye-tracking methodologies (Godfroid, Housen, & Boers, 2010; Godfroid & Uggem, in press) have investigated

Schmidt's *noticing hypothesis* (Robinson, 1995; Leow, 1997; Schmidt, 1990, 1993, 1995, 2001)—that is, whether increased attention (measured through eye movement data) to novel linguistic forms (grammar or vocabulary forms) increases one's chances of learning that form and, if so, how and why or, if not, why not. Likewise, recordings of bilinguals' eye movements while they read sentences in their less dominant, second language (L2)—sentences that have in them words that are cognates in their dominant, first language (L1)—inform theorists on whether bilinguals' mental lexicons are integrated or separated by language (e.g., Van Assche, Drieghe, Duyck, Welvaert, & Hartsuiker, 2011). In such research results are mixed, but cognates are viewed as *recognized* if they are skipped or fixated on for less time, which provides evidence of an integrated lexicon.

Other diverse examples of the use of eye-tracking data to investigate reading processes include (a) investigations into task instructions (e.g., proofread or read for comprehension) on reading (Kaakinen & Hyona, 2010), (b) research on how adolescents read while simultaneously writing essays (Beers, Quinlan, & Harbaugh, 2010), (c) studies on the effects of compound words and word length on reading (Inhoff, Starr, Solomon, & Placke, 2008; Juhasz, 2008), (d) eye movement studies that investigate the reading of onscreen captions during the presentation of a video in the L1 (d'Ydewalle & De Bruycker, 2007) or in the L2 (Winke, Gass, & Sydorenko, 2013). Of particular note is a study by Bax and Weir (2012), in which the authors investigated the cognitive processes that English language learners employ when taking a computer-based academic English reading test. Studies such as these demonstrate the diversity of current eye-tracking/reading research. The recent surge in studies also indicates that eye-tracking systems are becoming financially more accessible and are easier to use than they were a decade ago (Duchowski, 2007); both of these features are helping to expand the eye-tracking research paradigm.

The Connection Between Eye Movements and Cognitive Reading Processes

Many different types of technology can be used to track a subject's eyes while reading. But, before employing such technology to examine reading processes, researchers need to embed their studies' research questions within current and well-defined theories of reading processes and to contextualize their research so as to make it accord with current theories on the proposed links among cognition, attention, visual intake patterns, and eye movements while reading. This is important, because any discussion of eye movement data needs to be backed up by current theory. Hence I start by reviewing some terms that are needed to understand eye movements during reading and models of eye movement control during reading comprehension.

Comprehensive overviews of eye movements during reading have been published (Reichle et al., 1998; Castelhana & Rayner, 2008; Rayner, 1998, 2009). These papers position eye movement during reading within the E-Z Reader model (Reichle, Rayner, & Pollatsek, 2003; Pollatsek, Reichle, & Rayner, 2006) of visual attention that accounts for the link between eye movement control and cognition.

As explained by Rayner (2009), during the complex task of reading, “either (a) eye location (overt attention) and covert attention are overlapping and at the same location or (b) *attention disengagement*” occurs, which happens when “attention precedes the eyes to the next saccade target” (p. 1458; emphasis added). In other words, much of the work involved in reading-processing research is about determining *where* and *for how long* (when) the eyes remain fixed on words and phrases in the text. Models of visual attention during reading also try to account for the engines that drive the decisions on where and when to look during reading. At the heart of the E-Z Reader model of eye movement control in reading are two premises: readers attend to words during *eye fixations*, and movements (*saccades*) from one fixation to the next are triggered by a cognitive event.

Essential Terminology and Concepts

Some definitions are in order here. According to the E-Z Reader model of eye movement control in reading (Pollatsek et al., 2006; Reichle et al., 2003), the following terms and concepts are very important for understanding eye movements during reading: (a) saccades; (b) fixations; (c) visual acuity; (d) saccade latency; (e) information access during eye fixations; (f) perceptual span; (g) parafoveal preview effects; (h) regressions; (i) eye movement control and patterns; and (j) measures of processing time. These important terms and concepts are briefly defined below. (Read Reichle et al., 2003, for a full review of them and of their importance in any model of eye movement control.)

- 1 *Saccades* are the short and rapid eye movements that readers make across the printed page while reading.
- 2 *Eye fixations* are the brief periods of time during which the eyes are fixed on the page (the periods of fixation between saccades).
- 3 *Visual acuity* is the limit in how much information can be processed during a fixation. As explained by Reichle et al. (2003), “visual acuity is maximal in the center of the retina and rapidly decreased towards the periphery, and fine visual discrimination can only be made with the *fovea*, or central 2° of vision” (p. 446; emphasis added). Visual acuity may account for the difficulty in processing longer words, especially novel, longer words, or ones with unexpected phoneme combinations.
- 4 *Saccade latency* is the time between when one plans to move on to the next saccade and when that movement occurs. It is estimated by Reichle et al., 2003, to be around 180–250 milliseconds in duration. The question is whether the saccadic movement is made while the mind is still processing the word, or whether the decision to move is made after the word is processed. In other words, does word recognition drive saccadic movement, or are the process of saccades and the word recognition process more complex and intertwined?
- 5 *Information is acquired during eye fixations*. While the eyes move to the next fixation (during saccades), vision is blurred or suppressed. Thus it is important to note that information is only obtained through eye fixations. The

theory is that the information needed for reading normally occurs rather quickly—within 50 to 60 milliseconds after a fixation starts.

- 6 The *perceptual span* or *parafovea* is the region that extends around the fovea (about 5 degrees around the fovea). The theory is that words can be partially processed in this area of perceptual span (see Rayner & Bertera, 1979, who first explained this phenomenon). Research on the parafovea is intriguing: as summarized in Reichle et al. (2003), the parafovea does not extend above or below the line being read; the span is relatively constant for readers of similar alphabetic orthographies; whereas the density and complexity of the writing system influences the span asymmetry and size, and the perceptual span is *not* hardwired. As readers develop reading skills, their spans become bigger, and, when presented with more difficult readings, spans become smaller. Predictable upcoming words also contribute to bigger spans.
- 7 *Parafoveal preview effects* occur when the processing of a word takes place before the word is fixated on. Such effects can shorten the fixation on the word itself. Parafoveal previewing may also contribute to word skipping. Thus a skipped word (a word not directly fixated on) is not evidence of an unprocessed or unviewed word.
- 8 *Regressions* are saccades that move backwards, to earlier or previous parts of the text. These can happen for two reasons: either there was some type of difficulty in the linguistic processing, so the reader reverts back to an earlier part of the text to aid processing or comprehension; or the reader regresses as a result of some type of simple motor error or viewing process by which the eye regresses to an earlier part of the text. Both of these regression types have been documented in empirical research, as reviewed by Reichle et al., 2003.
- 9 *Eye movement control*. Moving on (changing fixations) in a text involves two dimensions: (a) where and (b) when. The question is whether these two decisions (one spatial and one temporal) are controlled by the same thing or by two different things. Many believe that the two decisions are made online and independently; others do not.
- 10 *Measures of processing time*. Eye trackers can obtain incredibly accurate and copious amounts of data. First, researchers need to note the importance of reporting on and analyzing several different processing measures because each contributes unique information—some are associated with initial reading processes, others with later ones, and some are appropriate for measuring the processing of a given target word, while others are or can be associated with larger regions (that is, a region larger than a single target word). For example, data can be reduced to the following types, as explained in Reichle et al. (2003): *Gaze duration*, *first fixation duration*, *single fixation duration*, and *total time*.
 - *Gaze duration* is the sum of all fixation times on a single word. Gaze duration normally only includes time spent on the word before the eye has (or eyes have) left the word (fixations within the word). This could also be labeled as gaze duration during the *first pass*, that is, during the initial encounter with the word (not during regressions to the word).
 - *First fixation duration* is the time spent on the first fixation of the word during the first pass. It is useful for measuring the processing of a target

word and not a larger region (for example, a phrase) because, with a larger (longer) region, it is more likely that there will be further fixations on it.

- *Single fixation duration* is the average duration of fixation on words that are fixated on exactly once during the first pass.
- *Total time* is the sum of all fixations on the word, including fixations stemming from regressions back to the word.

Due to space limitations, I cannot explain the many other concepts, such as *rereading time* and *regression path duration*, but eye movement researchers should become familiar with the full range and scope of such measures (see also Rayner, 1998, and Roberts & Siyanova-Chanturia, in press, for more explanations of eye movement measures). Researchers also need to be aware that some cognitive reading processes are not represented in eye movements until the next word or region comes into view (a *spill-over* effect); thus reading researchers may analyze eye movements in relation to post-target words. And finally, because pupil size (dilation of the pupil) is often viewed as a measure of cognitive load, researchers may want to further explore it as an indication of reading processes (see Hyönä, Tommola, & Alaja, 1995).

While competing models of the visual perception (*oculomotor*) system and of the effects of word recognition exist—for example, the (autonomous) saccade generation with inhibition by foveal targets, or SWIFT system (see Engbert, Longtin, & Kliegl, 2002; Engbert, Nuthmann, Richter, & Kliegl, 2005)—they all rely on research that uses the terms reviewed above, or very similar ones, for operationalizing eye movements while reading. The terms and concepts above provide a common framework for organizing discussions on reading processes because together they describe and account for the *where* and *when* of fixations in reading.

Eye-Tracking Technology

Good eye trackers can be expensive. While learning to use them and to apply data from them to investigate reading processes is becoming less time-consuming and complex (Duchowski, 2002, 2007), do not be deceived. The thought of being able to rapidly set up and run experiments and immediately analyze data to obtain study results is, to put it bluntly, naive. The two main types of eye-tracking technology commonly used for L1 and L2 reading-processing research were developed by two companies: SR Research in Canada (www.sr-research.com) and Tobii Technology in Sweden (www.tobii.com). In this section of the chapter I review the technology, outline what it can and can't do, and present reasons why these two systems are preferred by researchers.

Commonalities in Systems for Recording Eye Movements

Both SR Research and Tobii Technology produce video-based eye trackers that measure saccadic eye movements associated with viewing images (pictures, video, or words) on a computer screen. In their eye-tracking systems, a camera uses infrared light to create a corneal reflection that is used to track one or both eyes

(with Tobii's T120, both eyes are tracked; with SR Research's EyeLink 1000, the researcher decides to track either the right or the left eye or both eyes); algorithms from them map what one is looking at on the screen. The setups of these systems vary greatly. Both offer head-free eye-tracking in which the participant can freely move his or her head about during the experiment—the Tobii TX300 uses two cameras that automatically follow and track the eyes during motion, and the EyeLink 1000 uses a sticker placed on the participant's forehead to run calibrations that allow for even a monocular system to track a single eye during head motion (the EyeLink 1000 can also track two eyes head-free). The EyeLink also has head-stabilized configurations in which the participant's head is stabilized on a mount, via a head or a chin rest; these configurations provide much more accurate eye movement data recording, which is often necessary if data are needed at the word or phoneme level (see Figure 62.1). Pictures of the EyeLink 1000 and Tobii TX300, as set up at the Michigan State University, Second Language Studies Eye-Tracking Lab, are in Figures 62.2 and 62.3.

Figure 62.1 The EyeLink 1000 chin- and head-rest mount for head stabilization (and greater eye movement recording accuracy) while eye-tracking

Figure 62.2 The EyeLink 1000 system at Michigan State University

Figure 62.3 The Tobii TX300 system at Michigan State University

Before data collection begins, the researcher must work with the participant and the eye-tracking system to calibrate the participant's eyes (or eye, if he or she is using a monocular system) to the eye-tracking system. The camera setup and calibration session with the Tobii TX300 system are rather simple, while with the EyeLink 1000 system the camera set up and calibration session are a bit more involved. On both systems, during the pre-programmed camera setup and calibration session, the researcher (or the experimental program) instructs the

participant to look at images that appear on the screen one at a time (typically, 5, 9, or more dots or fixation crosses spread across the screen or, for children, little happy faces, quacking ducks, or the like). The eye-tracking system compares the true location of each image with where the camera (or cameras) detects the participant's gaze is on the screen and applies an algorithm to correct for future fixations. With the Tobii TX300, this is fairly automatized and there is actually no camera setup for the researcher to perform, since the cameras are built into the system (fixed within the display computer monitor); but with the EyeLink 1000 the researcher can manually adjust the camera's position and focus, can adjust the eye tracker's saccade detector sensitivity, can set pupil thresholds, and so on. In a nutshell, the Tobii is like an airplane that can fly on autopilot only, which is great for those not well versed in flying planes, but perhaps a bit scary for those used to flying on their own. And the EyeLink 1000 has no autopilot, meaning that researchers who run calibrations and eye-tracking experiments on an EyeLink 1000 system must learn a lot about corneal reflections, camera optimization, and what affects eye-camera calibrations such that they sometimes do not work well—which has its pros (researchers have better control over the data collection process; they can manually correct for some types of calibration errors) and its cons (there is a somewhat long, technical curve in learning to use the EyeLink 1000 system).

In both systems, software that comes with the eye tracker can be used to design robust research experiments. In those experiments, researchers can draw or create *interest areas*, that is, shapes (boxes, circles, or custom shapes) around visual areas of interest on the screen according to which eye movement data are to be segmented. For example, in Figure 62.4 below, interest areas are shown in two different reading texts. In the study that used the text in Figure 62.4, which was conducted on the EyeLink 1000 at Michigan State, two different groups of English language learners, matched in terms of their English language proficiency, read one of the two texts with verb forms either enhanced (in this case, in red font and underlined) or not enhanced (regular text). The purpose was to investigate the effects of enhancement on reading processes and subsequent learning of the forms. Because the forms themselves are what is of interest in this study, the researcher used the EyeLink 1000 Experiment Builder program to draw interest areas around

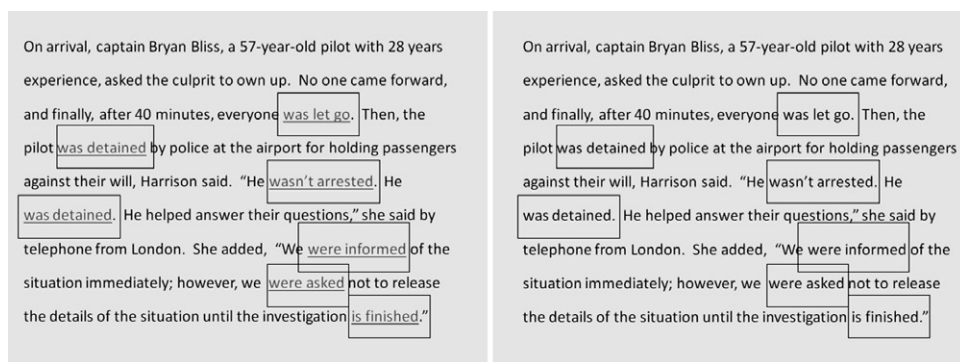

Figure 62.4 Interest areas drawn across data collection screens in an eye-tracking experiment at Michigan State University

the forms, so that eye movement data from within those particular regions would be segmented out from all the other data and could therefore be more easily used and compared in data analyses. Interest areas can be drawn before or after data collection, and they can be moved after data collection to zero in on, or capture, other data from other regions of interest. In reading studies, interest areas are often demarcated (automatically by the eye tracker experiment design program, or as established in the eye tracker data viewer program by the researcher) along word boundaries, or even between phonemes (in studies investigating gender assignment or phoneme effects on reading processes). When customized, the interest areas can partially accommodate for data drift, which is explained below.

Participants read either the screen on the right or the one on the left in Figure 62.4 (not both). Note that, while reading, the participant does not see the outline of the interest areas. (They are invisible during the experiment.) With the interest areas demarcated, eye movement data (gaze duration, total time) on the individual areas of interest (passive verb constructions) and across the two types of text presentation (enhanced and not enhanced) could be easily compared.

Additionally, in both systems, movies of the data collection sessions are captured, and these movies can be played back for additional analyses. Also, visual maps of the data tracking can be superimposed over the reading material, as in Figure 62.5. In Figure 62.5, fixations are represented as circles. The bigger the

fixation circle, the longer the gaze duration was. Correspondingly, the length of the fixation (the individual fixation’s gaze duration) is in milliseconds in the upper left, next to the fixation circle. Words the researchers were interested in are in boxes (hand-drawn interest areas). In Figure 62.6, the same type of data are shown, except that the interest areas were automatically generated at the word boundaries by the EyeLink 1000 Experiment Builder program. The Tobii TX300 produces similar maps, but records fewer fixations, and fixations in the Tobii TX300 system are or can be numbered to demonstrate visually the reader’s visual path as he or she worked through the text.

What the Systems Can and Can’t Do

While both systems are highly functional, provide accurate eye movement data, and are state of the art in their makeups, there are things the systems can and cannot do. In both systems, for example, over the course of an experiment, a participant’s gaze and the true fixation point may *drift* apart slightly, making data less accurate. Drift occurs when a participant changes head positions, or even blinks (after which the camera must relocate the pupil). In general, the longer the experiment, the more drift occurs, and thus the less precise the eye movement recordings become. This is why longer experiments are often divided into several subexperiments, with breaks and recalibration sessions between them. The EyeLink 1000 system allows for researchers to program within a single experiment *drift correct* sessions, but the Tobii TX300 eye tracker does not appear to allow for this. The systems differ fundamentally in other ways as well, as can be seen in Table 62.1.

Why These Systems Are Preferred by Reading Researchers

These two systems, and especially the EyeLink 1000, are preferred by reading researchers because they are extremely sophisticated pieces of equipment and are

accurate in recording eye movements as readers process text on screen. At Michigan State we own and maintain an SR Research EyeLink 1000 and a Tobii TX300 Eye Tracker. The two systems are very different, but we believe they complement each other as the strengths in one counterbalance the weaknesses in the other. But the two systems are diverse enough that data collection for a single experiment must consistently be collected on a single system—and at Michigan State we carefully guard that no spatially sensitive equipment (the camera, or the computer monitor that the participants see) is moved even a millimeter over the course of a study's data collection period, so that measurements within an experiment have as little technology-mediated variation as possible.

For very accurate word-level eye-tracking, we generally use the EyeLink 1000 system. For experiments that center on the gross reading processes of children (for example, where on the page they look during reading or listening tests) and that are not concerned so much with the possibility of analyzing regression data, we use the Tobii TX300. Anecdotally, we have found the EyeLink 1000 to be rather difficult to program, and we often rely on the very receptive and capable support staff at SR Research to help us fine-tune or finalize our experiments. The Tobii TX300, however, is much closer to being a real “plug and play” system, but one that collects less accurate data. In my opinion, the Tobii TX300 should *not* be used for measuring attention at the word level unless the text is presented in an extremely large font size.

Other types of commercial eye trackers exist. For example, both SR Research and Tobii offer various types of eye trackers that have different cameras, configurations, and processors, all offered at different prices. Other systems are also available, from Applied Science Laboratories (www.asleyetracking.com) and Mirametrix (<http://mirametrix.com/>). And other researchers, such as those at Iowa State University, are publicly printing information on how to build low cost eye trackers (see <http://thirtysixthspan.com/openEyes/>) that take advantage of commercial, off-the-shelf video cameras and computers in assembling systems that can record eye movements rather well. But a review of current studies published in cognitive science, psycholinguistics, and other fields will quickly reveal that the preferred systems are from SR Research and Tobii Technology.

The Ecological Validity of Eye-Tracking Research

Novice eye-tracking researchers very quickly come to understand that reading while having one's eyes tracked is not exactly the same as reading without having one's eyes tracked (Gibson, 1979). And the more accurate and finely tuned the data that the researcher wishes to obtain, the truer and more severe this issue becomes. From L1-processing studies we know that eye movements are heavily influenced by textual and typographical variations presented in the text (see Dussias, 2010, for a comprehensive review of this issue). Typographical variables that have been found to influence reading processing in this way include the quality of print, the length of the line of text, and the amount of space between the letters. Fixations are also longer when readers come across low frequency or contextually implausible words. When reading becomes more advanced or

Table 62.1 Comparisons of the EyeLink 1000 and Tobii TX300 eye-tracking systems

	<i>EyeLink 1000</i>	<i>Tobii TX300</i>
Company	SR Research, Canada	Tobii Systems, Sweden
Website	www.sr-research.com	www.tobii.com
Setup configuration	Comes with three or more configurations, for example: <ol style="list-style-type: none"> 1. Tower mount (camera above head) with head and chin rest (for most accurate eye-tracking) 2. Desktop mount (camera on table in front of monitor) with head and chin rest 3. No mount—head-free, sticker must be placed on forehead 	No mount—head-free only
Camera type	Binocular, can use one (left or right) only for monocular tracking	Binocular
Data sampling rate of camera	1000 Hz	300 Hz
Portability	Laboratory based, not portable	Portable (comes with a large suitcase-sized, padded carrying case)
Pros	<ul style="list-style-type: none"> • Extremely accurate data, especially when used with head/chin-rest mounts • Able to record data at the word and phoneme level • Interfaces with E-Prime • Videos of the eye movements can be played back (and slowed down to be seen in slow motion) • Options of drift corrections (fixation crosses) help with accuracy for longer experiments • Data can be easily accessed and transferred to Excel • Researchers can purchase multiple HSP keys, so additional programming and data viewing can be performed on computers that are separate from the main host computer • Researchers can obtain regression measures and pupil dilation measures 	<ul style="list-style-type: none"> • Eye-tracking cameras are very discreet; system particularly suited for eye movement studies conducted with children • Easier to program than most systems • Interfaces with E-Prime • Videos of the eye movements can be played back (and slowed down to be seen in slow motion) • Able to produce visual “heat maps” of what parts of the screen were looked at the most • Video and Web-based studies are easy • Some statistics can be calculated in Tobii studio (e.g., mean fixation time, fixation counts for a certain interest area) and can be viewed right after the experiment, without opening another program • Surveys can be easily integrated into the experiment design to collect participant information (age, gender, etc.)

Table 62.1 (Continued)

	<i>EyeLink 1000</i>	<i>Tobii TX300</i>
Cons	<ul style="list-style-type: none"> • It takes a while to learn how to program experiments and how to calibrate participants' eyes properly • The system is large, requiring a lot of dedicated lab space. It includes two computers, two monitors, etc. • Video-based studies are time-consuming to program. Web-based studies must be simple simulations or are impossible 	<ul style="list-style-type: none"> • Sample rate is lower than the EyeLink 1000; data are less accurate than in EyeLink 1000 • Does not record regressions automatically, as the EyeLink 1000 does; does not provide pupil size measures • Does not come with a computer to run the programs. Must supply a desktop or laptop to run the system

conceptually more complex, eye fixation duration increases and saccade length decreases (Duchowski, 2002).

Perhaps the number one difference between reading that is eye-tracked and regular reading is that most eye-tracking experiments require readers to read on a computer screen, which does not replicate all types of reading commonly undertaken by individuals—such as reading a book, reading on paper, or reading a partially crumpled newspaper while lounging on a couch or working at a table in a coffee shop. There are other differences. In our reading experiments using the EyeLink 1000, we have found that, for us to obtain extremely accurate word-level eye movement data, the text on screen needs to be at least double-spaced and the words and letters need to be in at least 18 to 24 point font. Eye-tracking data are more accurate at the center of the screen than at the peripheries, so interest areas (text or words we are most interested in tracking) normally should be placed toward the center of the screen, which may present text that is a bit different from what one would read in a normal, onscreen reading situation. Even though eye-tracking companies attest to the contrary, we find that contact lenses, makeup (especially mascara and eye-liner), and eye glasses can distort data recording, sometimes so much that participant data are rendered useless. And, as reported in Heuer and Hallowell (2007), young adults need to be recruited for eye-tracking research studies, because older individuals normally have some loss of visual acuity or have ocular motor deficits that distort the data. Participants are often required to pass a visual acuity test before data collection begins (for information on acuity tests, see Hyvärinen, Näsänen, & Laurinen, 1980; Woodhouse, Morjaria, & Adler, 2007).

For experiments in which we would like data from 30 to 40 participants, we find we normally need to collect data from 50 to 60 people, to allow for subject attrition due to problems in data collection or the nonability of the eye tracker to consistently and reliably track a person's eyes. Attrition and data loss are more acute with longer eye-tracking experiments on account of eye-tracking drift. And

having to collect data from participants one at a time (because we only have one of each type of eye tracker) constrains us to having studies with rather small sample sizes. Small sample sizes are problematic across eye-tracking studies because, as a consequence, such studies have little power—that is, they may lack the power to reject a null hypothesis when it is actually not true. For example, Birch and Rayner (2010, p. 201) stated that one of the problems in their eye-tracking study was the lack of power; thus, even though eye-tracking can produce copious and accurate eye movement data while individuals read, the type of reading and the amount of data (in terms of numbers of participants) are constrained, which limits in part the generalizability of results from eye-tracking studies.

Future Directions

Eye-tracking technology will continue to be used for understanding the mechanisms that underlie reading processes. And much of this work needs to be conducted in the context of second or foreign language acquisition and testing. Part of the problem is that cognitive reading-processing models that link visual attention with reading, such as the E-Z Reader model, do a very good job at modeling regular L1 reading behavior, but they may not model the full scope of the processes involved in the reading undertaken by second language learners. L2 reading is highly problematized, in that it is characterized by a very high number of processing difficulties (lexical, semantic, morphological, syntactical, even orthographical) that may be related to several factors, including the reader's L1 reading skills, his or her L2 proficiency, age, L2 reading skills and strategies, L2 vocabulary knowledge, and the L2 grammar itself. Thus, in L2 reading, the cognitive underpinnings that direct saccades and eye movements are extremely complex. If saccades are dependent on language processing during reading, as the E-Z Model proposes, and processing difficulties present aberrations to the model (when reading breaks down, the eyes do not move as planned to the next word, they may fixate longer where they are, or regress to problematic areas in the text), L2 reading may require a refined or modified model to account for all of the mental processes involved in L2 reading. E-Z Reader may be able to account for when processing difficulties during L2 reading occur, but not perhaps for why they do. This is why many L2 researchers are additionally collecting introspective data along with eye-tracking data (see Godfroid et al., 2010). Qualitative data from interviews, surveys, or even think-aloud protocols may triangulate eye-tracking data and reveal *why* L2 reading-processing difficulties occur.

Eye-tracking research in second language testing is in its infancy. But it is not without precedence. Heuer and Hallowell (2007) investigated the use of multiple choice tests that had images as options for testing comprehension in aphasia. They found that some visual characteristics of individual images influenced visual attention, which in turn influenced accuracy in the selection of a correct target image that corresponded to a verbal stimulus. And L1 and L2 reading research that uses eye-tracking technology has laid much of the groundwork that L2 testers can use. Within the testing field, Bax and Weir (2012) investigated the reading processes undertaken by English language learners when taking a test of academic English.

Using a Tobii T60, they found text and item reading patterns that were consistent across test takers. They explained that such patterns help validate the test itself as a measure of L2 reading comprehension. It is expected that research along this line will continue and expand. To conclude, further topics that may be addressed in the future by L2 testing, eye movement investigations include the following:

- 1 How do timed versus untimed L2 reading tests affect test takers' reading processes? Do differing levels of test anxiety affect the processes differentially?
- 2 How do various levels of *test-wiseness*—talent in being able to appropriately and effectively apply test-taking strategies that do not overlap with the skills the items on the test are intended to measure (Allan, 1992; Harmon, Morse, & Morse, 1996; Rogers & Yang, 1996; Kalechstein, Hocevar, & Kalechstein, 1998; Yang, 2000)—affect the reading of L2 test directions, test prompts, and item choices?
- 3 What are the differential effects of the number of options (in discrete-point or multiple choice items on L2 listening or reading tests) on test takers' processing of the test items?
- 4 Do child L2 learners read along with the directions when the directions are read out loud by the test administrator during an L2 proficiency test?
- 5 At what level of proficiency (and at what level of text) can L2 readers process multiple choice options written in the L2 without there being evidence of option-based, comprehension-limiting processing difficulties?
- 6 In the rating of L2 essay tests in which the raters use analytic rubrics, do novice versus advanced level raters pay attention differentially to the different categories on the rubric?
- 7 Why are some analytic rubric categories more difficult to use (as evidenced by low inter-rater reliability on scores from those categories) than others? Do the raters not read those sections of the rubric, or do they focus intently on, for example, grammatical errors in test essays, but not link what they read with what is on the rubric? Does this change with rating experience?
- 8 Following up on Wagner (2007, 2008, 2010), how are pictures and video in L2 listening tests utilized by language test takers?
- 9 How are pictures utilized in L2 reading texts?
- 10 How are visual cues interpreted in video-based tests of L2 listening or in integrated writing tests that include video watching as a precursor to writing?

Acoustic and Temporal Analysis for Assessing Speaking

Okim Kang

Northern Arizona University, USA

Lucy Pickering

Texas A&M University, Commerce, USA

Introduction

Oral assessment in language learning has received increasing attention among second language acquisition (SLA) researchers. This growing interest is likely a product of the increased interpretability of test scores and potential validity of the scores when linked to real-world criteria (Bonk & Ockey, 2003). However, assessing speaking skill can be more challenging than assessing other skills because of the possible subjective nature of listener comprehension, the complexity of rater reliability, and the validity of the performance itself. Of these challenges, the potential variability in rater judgments has been of particular concern for language assessment as a source of measurement error (e.g., Bachman, Lynch, & Mason, 1995).

A variety of human rater biases are attested to in the perceptions of speaking proficiency, and the speaking assessment may have a limited basis in the linguistic characteristics of the speaker's oral production. Although sophisticated statistical techniques derived from Rasch scaling or generalizability theory (G-theory) can in principle equate practiced ratings which may display different degrees of rigor or leniency among raters (Lumley & McNamara, 1995), a technology-based measurement strategy that compensates for the variation in rater judgments of oral proficiency is much to be desired (Kang, Rubin, & Pickering, 2010). In fact, certain acoustical and temporal features of non-native speakers' (NNSs') pronunciation, measurable by means of instrumentation rather than by listener impressions, can now provide supplementary parameters for "degree of accentedness."

Thanks to advances in speech science, we can readily identify acoustic and temporal features of pronunciation that affect listeners' comprehensibility. That is, computer-assisted instruments can conveniently examine some elements of the physical facts of human utterances. In this chapter, the primary focus lies in

a discussion of instrumental measures with regard to speaking assessment in general, and addresses both temporal (voice time and duration) and acoustic (e.g., fundamental frequency, amplitude, or spectral behavior for intonation in particular) parameters used for various operational constructs of NNS speech evaluation. For this purpose, the constructs of listeners' judgments such as intelligibility, comprehensibility, and accentedness are construed in one broad sense of listeners' evaluation of NNS speech, even though they are addressed separately in the literature (Derwing & Munro, 2005).¹ This broad approach includes listeners' ratings of NNSs' oral proficiency and fluency. This chapter will also address the difference between automated scoring systems and systems such as those discussed thus far that rely on both instrumental and auditory analyses.

One caveat to note initially is that the instrumental analysis can be indeed dependent upon perceptual subjectivity itself to some extent, although it is known to objectively describe and evaluate speech data. (See "Challenges for Objective Measures of the Speech Signal in Oral Assessment" below.) Thus, this chapter posits that the instrumental analysis alone should not be the sole basis for objective interpretation of candidates' scores in speaking assessment, but instead a useful methodology to identify information about a candidate's speech that would contribute to scoring decision making or to assessment rubric development.

Background to Acoustic and Temporal Measures

Perceptual ratings in oral assessment, such as measurement of the percentage of correctly identified words or rating scales using 5-, 7-, or 9-point scales, may suffer from measurement errors due to their dependency on raters' backgrounds, subjectivity, and other social issues (Kang & Rubin, 2009). In our social contexts, up to a quarter of the variance in listener judgment is attributed to factors such as listeners' expectations, attitudes, and stereotypes as opposed to the nature of the speech itself (Derwing, Frazer, Kang, & Thompson, in press). An alternative approach to supplement this human rater variability is the application of instrumental analysis which can objectively evaluate candidates' speech. Since computers began to become available to speech researchers in the 1960s, speech analysis research has evolved substantially (Mattingly, 2011). For example, computer-assisted speech analysis (e.g., use of a KayPentax Computerized Speech Laboratory [CSL], www.kayelemetrics.com, or freeware such as Praat, www.praat.org; see also www.fon.hum.uva.nl/praat and www.tc.umn.edu/~parke120/praat webfiles) is becoming more commonplace in the assessment of speech patterns (e.g., Pickering, 2004; Kang et al., 2010).

The instrumental analysis can examine the production of NNS speech at both segmental and suprasegmental levels. While the segmental analysis often focuses on the "accuracy" of NNSs' consonant and vowel formation, the suprasegmental analysis takes account of the role that differences in speaking rates, intonation patterns, and other prosodic features may play in listeners' comprehension. This methodology often incorporates discourse analysis to supplement the instrumental analysis, wherein an analyst identifies a pragmatic context in which a particular intonational contour would be expected (Pickering, 2001). Following the discourse

analysis, computer-based analysis is used to confirm (or disconfirm) that the expected contour does indeed appear at that site in the speech stream. This is especially one of the big methodological differences between computer-programmed automated scoring systems, which are described in the following paragraph, and auditory–instrumental combined analysis. Studies have suggested that features (e.g., pitch range) identified via the combined acoustic analysis explain variance in listeners' judgments of NNS speech (e.g., Kang et al., 2010).

Finally and most recently, instrumentally identified measures are used to help understand the process of automated scoring. This is the latest development in language assessment and testing due to advances in speech recognition and processing technologies (see, e.g., Xi, 2010b). Currently, tests are in some use in the English as a second language (ESL) field: for example, Versant, also known as PhonePass, produced by Ordinate Corporation; and Speech Rater, developed by Educational Testing Services alongside their Internet-based (iBT) Test of English as a Foreign Language (TOEFL) (http://www.ets.org/Media/Tests/TOEFL/pdf/Speaking_Rubrics.pdf). For instance, subscores of Versant tests for reading fluency and repeat fluency are measures of suprasegmental features (timing, pause, or rhythm). However, as Chapelle and Chung (2010) note, the mechanisms that underlie these tests remain largely opaque and unknown to most professionals in second language (L2) assessment, not least because these are commercial not academic ventures. In addition, adopting these automated speech scoring systems still faces various challenges in terms of establishing validity for test score use and decisions made on the basis of automated test scores, or accurately evaluating communicative functions. The lack of adequacy in testing the communicative competence of candidates is an ongoing concern for those who seek a valid means to automatically test and score learner speech.

Acoustic and Temporal Parameters Measured in Assessing Speaking

Various aspects of NNS pronunciation can be considered in listeners' assessments of speaker proficiency. Studies have investigated the impact of acoustic and temporal features on listeners' judgments of NNSs' oral performance (e.g., Kang et al., 2010) or the correlations between objective measures of speech rates and listeners' rating scores (e.g., Munro & Derwing, 2001; Cucchiarini, Strik, & Boves, 2002). In the early 1980s and 1990s, acoustic studies largely compared NNSs' speech production with the patterns of native speakers' (NSs') speech. Gradually, however, studies began to use acoustic and temporal parameters as indicators of listeners' perceptions.

Segmental acoustic parameters include features of accent such as consonants, Voice Onset Times (VOTs), or vowel formants. VOT refers to the duration of the period of time between the release of a stop consonant and the beginning of voicing. An easy way to visualize VOT is by reference to the waveform of a sound. Figure 63.1 shows a waveform of the word *tie* spoken by the first author, an advanced Korean speaker of English. The left vertical line indicates the moment of release of the stop consonant /t/ pronounced as [t^haɪ]. The VOT is about .08 milliseconds

Figure 63.1 The waveform of the word *tie* spoken by an advanced Korean speaker of English

from the spike indicating the release of the stop consonant to the start of the oscillating line indicating the vibration of the vocal folds in the vowel of [aɪ]. An example of the VOT study using NNSs' speech is Flege and Eefting's (1987) research, which compared VOT differences of English stop consonants (e.g., /p/, /t/, /k/) produced by NSs and Spanish L2 speakers. Spanish speakers of English produced shorter VOTs in English initial voiceless stops than did NSs.

In acoustic phonetics, vowels are classified according to particular values called formants, which are a concentration of acoustic energy, that is, "a group of overtones corresponding to a resonating frequency of the air in the vocal tract" (Ladefoged, 2001, p. 273). (Examples of the formants are shown as dark voice bars in Figure 63.2.) Accordingly, English vowels are characterized by three formants (F1, F2, and F3) which are used to describe vowel structures. For example, in Wilson, Fujinuma, Horiguchi, and Kazuaki's (2009) study analyzing the speech of low intermediate Japanese speakers, when a consonant /s/ occurs before a high front vowel /i/, it becomes palatalized as in /ʃ/. (i.e., *sea* and *sit* are pronounced as "she" and "shit"). As for the vowel formants, Japanese speakers' F1 value of the low back vowel as in /a/ is considerably lower than that of NSs. (In Figure 63.2, examples of the F1 formant are illustrated as the lowest voice bars.) Overall, using speech analysis programs we can identify the characteristics of individual phonemes, the location of formants, or the presence of voicing.

Numerous studies have investigated the relationships between temporal measures and listeners' judgments of NNS speech (e.g., Trofimovich & Baker, 2006; Isaacs, 2008; Kang, 2010). Following Munro and Derwing's (2001) finding, a common belief is that there is a curvilinear relationship between speaking rates and listeners' judgments of L2 comprehensibility and accent. That is, NNS utterances should be somewhat slower than the typical rate for an NS utterance but faster than what L2 learners often produce. Parameters of speaking rates are measured via syllables per second, articulation rate (mean number of syllables per second excluding pauses), phonation-time ratio (percentage of time producing audible speech), and mean length of run (an average number of syllables between pauses). Some or all of these temporal variables often strongly predict L2 performance judgments.

Pauses are an especially important element with regard to speaking rate, and relationships between pausing and speaking assessment have also been widely

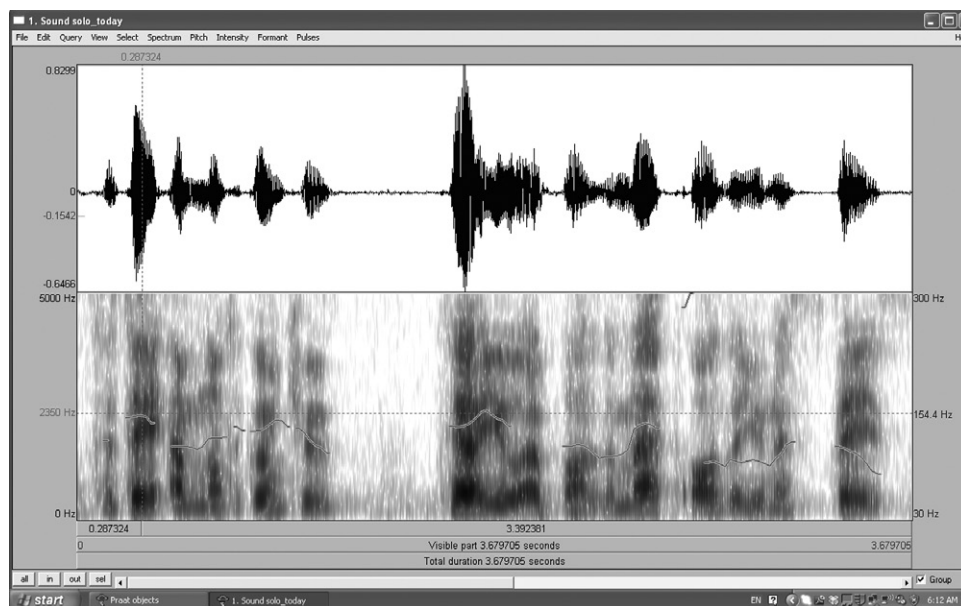

Figure 63.2 A spectrogram showing the waveform (top) and the fundamental frequency (bottom), using speech analysis software Praat, for *Today I'm not going to tell you about map of the United States* spoken by an advanced Chinese speaker of English

investigated. Pauses are measured by variables such as the number, the length, and the location of silent and filled (e.g., *eh* or *um*) pauses. Thus far, pause studies (e.g., Anderson-Hsieh & Venkatagiri, 1994; Kormos & Dénes, 2004) have demonstrated that low proficiency speakers tend to pause frequently and inappropriately, and their pause durations are longer, whereas higher proficiency learners speak faster, with less pausing and fewer unfilled pauses. Methodologically speaking, there continues to be an ongoing debate among researchers as to the appropriate cutoff point for silent pauses. That is, in previous studies cutoff points have varied between 0.1 second (Anderson-Hsieh & Venkatagiri, 1994), 0.2 (Zeches & Yorkston, 1995), or 0.25 (Towell, Hawkins, & Bazergui, 1996). Terminology-wise, the terms “pauses” and “silences” are often used synonymously in automated scoring systems (e.g., Zechner, Higgins, Xi, & Williamson, 2009). They use “disfluency” as a substitute for the term “filled pause.”

Speaking rate and pause measures are often preferred by automatic speech recognition (ASR) systems as objectively measurable parameters which show a high correlation with L2 fluency judgments (Zechner et al., 2009). De Jong and Wempe (2007) provide an example of the relationship between machine-based and human-based coding of temporal measures. In this study, Praat was used to automatically calculate the number of syllables in the utterance based on intensity (the amount of acoustic energy) and pitch peaks. The correlation between the human and automatic speech rate calculations was .71 (see more detail in De Jong & Wempe, 2007). Ginther, Dimova, and Yang (2010) also report robust correlations between temporal variables and other rated measures of oral proficiency; however,

these measures alone did not distinguish adjacent levels in the same way that human raters were able to. The authors add that automated rating systems are thus only able to measure a “narrow sense of fluency” (p. 394).

Prosodic features such as stress and intonation patterns also have a crucial role to play in L2 speaking assessment. First, stress features have been emphasized, as nonstandard word stress has been shown to undermine comprehensibility (Field, 2005). Misplacement of stress in disyllabic words has detrimental effects in speech processing (Cutler & Clifton, 1984). Stress patterns can be obscured in NNS speech production. Low proficiency NNSs often misuse primary stress, placing equal stress on every content word in the unit (Wennerstrom, 2000). In terms of fluency and oral proficiency judgments, advanced L2 learners used stressed words more appropriately than low–intermediate students (Kang, 2008). Acoustic parameters used for these analyses are numbers of stressed words per minute and proportion of stressed words, or the duration of stressed and unstressed syllables.

Non-native intonation patterns, particularly tone choices, have been studied in native listeners’ perception of L2 English learners’ speech (e.g., Kang et al., 2010). The intonation characteristics of many East Asian speakers may cause US listeners to lose concentration or to misunderstand the speaker’s intent (Pickering, 2001). In particular, the choice of a rising, falling, or level pitch on the focused word of a tone unit can affect both perceived information structure and social cues in L2 discourse. A tone unit is a basic unit of intonation known also as a tone group, which is a means of breaking up stretches of spoken discourse (Brazil, 1997). Another intonation feature that affects NSs’ comprehension of NNSs’ speech is pitch range variation. Low-proficiency NNSs tend to show a compressed pitch range and a lack of variety in pitch level choices (Wennerstrom, 2000). This contraction of pitch range particularly affects NNSs’ ability to indicate the beginning or the end of their discourse. Not surprisingly, this narrow pitch range factor exerts a significant negative effect on proficiency and comprehensibility ratings (Kang et al., 2010).

The intonation-related variables investigated as part of acoustic measures have included tone choices (high rising, high level, high falling, mid rising, mid level, mid falling, low rising, low level, and low falling), pitch-prominent syllables, pitch-nonprominent syllables, and other spoken discourse-related measures. (See “Applications of Acoustic Analysis and Sample Analyses” below for a fuller discussion of prominence.) In a study that distinguished these variables, Kang et al. (2010) reported that mid rising and high rising tone choices and pitch range variables were the strongest predictors for NNSs’ oral proficiency and comprehensibility ratings.

The physical features listed above along with suggestions from the literature (e.g., Cuccharini et al., 2002) are used as bases for automated scoring systems. Indeed, the knowledge of acoustic and temporal properties of sound can be helpful for understanding how speech recognition works. Acoustic models exclusively trained on NNS speech can extract these temporal and acoustic features, which are scaled and transformed into fluency and pronunciation scores in the system (Bernstein, Van Moere, & Cheng, 2010). For example, the TOEFL Practice Online (TPO) has a set of 11 features for use in the scoring model, whose focus is mainly on fluency, with pronunciation, vocabulary diversity, and grammatical

accuracy added to the mix (Zechner et al., 2009). Among the 11 selected features, 8 deal with fluency aspects (e.g., articulation rate or duration of silence per word) with 1 pronunciation and 2 other language-use features. One of the rationales for choosing these features is high correlations between these and human rating scores, as they are known to represent the overall quality of speech. Nevertheless, the intonation aspect and its interpretation in the pragmatic context are yet to be applied in these automated systems.

Applications of Acoustic Analysis and Sample Analyses

In this section some sample analyses of spoken discourse assessment are presented, using a combination of auditory and instrumental measures (Kang, 2010; Kang et al., 2010). In other words, the subjective auditory perceptions of a human analyst have been combined with the objective instrumental measurements of the speech signal. As noted above, although temporal measures can be fairly successfully scored automatically, crucial prosodic features such as intonation and stress are less easily scored. This is particularly the case when dealing with discourse as opposed to more constrained language samples. Combinations of auditory and instrumental analysis of acoustic features tend to use hardware and software programs such as CSL or Praat for pitch-related measures. As for temporal measures, sound-editing programs such as Audacity or Soundforge can be employed.

Speech samples are recorded in digital .wav format and transcribed orthographically and prosodically (see Excerpt 1 below). As acoustic parameters are gradient in nature, a range of baseline NS realizations of the features is also measured. As described in Ladefoged's (2001) *A Course in Phonetics*, sound consists of small variations in air pressure that occur rapidly one after another. Actions of the speakers' vocal organs cause these variations, which move through the air somewhat as ripples move on a pond. When these variations reach the ear of a listener, they cause the eardrum to vibrate, which creates sound waves. These waveforms of speech sounds can be readily observed on a computer program such as CSL or Praat.

For analysis, three acoustic indicators are generated: (1) spectrograms, (2) frequency or pitch of fundamental formant (F_0), and (3) intensity (volume of vocalization). A spectrogram is a "graphic representation of sounds in terms of their component frequencies, in which time is shown on the horizontal axis, frequency on the vertical axis, and the intensity of each frequency at each moment in time by the darkness of the mark" (Ladefoged, 2001, p. 276). "Frequency" is a technical term for an acoustic property of a sound. It refers to the number of complete cycles of variation in air pressure occurring in a second. The unit of this frequency measurement is the hertz (Hz). Figure 63.2 shows a spectrogram of an advanced Chinese speaker's speech, *Today I'm not going to tell you about map of the United States*, using Praat. The upper part of the figure shows the waveform. The fundamental frequency (pitch) is illustrated below. Time is shown on the horizontal axis, and frequency (from 0 to 5,000 Hz on the left and from 30 to 300 Hz on the right) on the vertical axis.

Figure 63.3 An example of the transcription shown for pitch ranges in Praat (Kang, 2010, p. 306). © 2010 with permission from Elsevier, <http://www.sciencedirect.com/science/journal/0346251X>

Due to the contraction of the spectrogram itself to fit the limited space, the pitch contour and phonological segments may not appear to be exactly parallel.

From the three indicators listed above, plotted against the transcripts of the speech samples, the variables of interest are derived. Figure 63.3 exemplifies a picture of the pitch analysis matched with a script via the Praat freeware program, using the Chinese speaker's speech in Figure 63.2. Note that the pitch of a sound depends on the rate of vibration of the vocal folds. A high pitch sound involves a higher frequency of vibration than a low pitch sound. Different sounds mean that there are differences in pitch, loudness, and quality. Especially, the higher pitch and louder volume (the darkness of the waveform) are represented as prominence (a peak of intonation) syllables.

In Figure 63.3, words such as "TODAY, GOING, TELL, MAP, UNITED, STATES" appear to have received prominence; therefore, they have been transcribed prosodically in capitalized letters. Note that in the final decision on these prominent syllables, the auditory judgments need to be combined with this instrumental analysis. For example, we can calculate the proportion of these prominent words relative to the total number of words. For the pitch range measure, we look at the midpoint of the vowel in the prominent syllable, read F_0 values, and calculate the range of the sample by subtracting the minimum F_0 from the maximum F_0 across the speech sample. In Figure 63.2, the dotted line points at the word "toDAY," of which the F_0 value is 154.4Hz, shown on the right-hand axis. More examples of variables measures for suprasegmental features are presented in Table 63.1.

Excerpt 1 below shows the prosodic transcription of the same speech sample. (Numbers in parentheses = the length of pauses produced; // = dividing run or tone unit; capital letters = prominent syllables; numbers below the stressed syllables = the F_0 reading of the vowel measured in Hz at the midpoint of the vowel.)

Table 63.1 Selected suprasegmental measures

<i>Measures</i>	<i>Submeasures</i>	<i>Descriptions</i>
Rate measures	Syllable per second	Mean number of syllables produced per second for the 60-second sample
	Articulation rate	Mean number of syllables produced per minute over total amount of time talking and excluding pause time
	Mean length of run	Average number of syllables produced in utterances between pauses of 0.1 second and above
	Phonation time ratio	Percentage of time spent speaking as a proportion of total time taken to produce the speech sample
Pause measures	Number of silent pauses	Number of silent pauses per 60-second task
	Mean length of silent pauses	Total length of pauses of 0.1 second or greater divided by total number of these pauses
	Number of filled pauses	Number of filled pauses (not including repetitions, restarts, or repairs) per 60-second task.
	Mean length of filled pauses	Average length of filled pauses occurring per 60-second task
Stress measures	Number of prominent syllables per run (pace)	Average number of prominent syllables per run
	Proportion of prominent words (space)	Proportion of prominent words to total number of words
	Prominence characteristics	Proportion of tone units (a run may have more than one unit) that do not contain a nuclear syllable (or final termination)
Pitch measures	Overall pitch range	Pitch range of the sample based on the point of F_0 minima and maxima appearing on prominent syllables per task
	Tone choice	The second measure of discourse-appropriate across-utterance pitch: Each complete unit is counted as comprising either a high, mid, or low termination accompanied by a rising (R), falling (P), or level (O) tone
	Average pitch difference between prominent and nonprominent syllables ^a	Calculated by measuring the F_0 of five prominent and five nonprominent syllables and calculating the average F_0 value for each category
	Average pitch difference between new and given items	Calculated by measuring the F_0 of the same lexical item presented initially as new information and thus appearing in following instances as given information (where possible, five lexical items were used to calculate the average F_0 for each category)

^aProminent syllables are divided into two categories based on where they appear in the tone unit. The first prominent syllable is called the *onset*, and the last is called the *tonic* syllable. It is the pitch level and pitch movement on these syllables that form the basis for the assessment of their communicative value within three systems (high, mid, and low). These systems realized on these two syllables (the onset and the tonic syllable) are *key*, realized on the onset syllable, and *termination*, realized on the tonic syllable (Brazil, 1997).

Combining measures used in a variety of recent studies, Kang et al. (2010) completed a detailed analysis of the speech signal comprising rate, pause, stress, and pitch measures, as shown in Table 63.1.

Challenges for Objective Measures of the Speech Signal in Oral Assessment

It is clear following decades of research that the nature of spoken language proficiency is complex. The studies reviewed here suggest that non-native temporal and intonation patterns account, at least in part, for native listeners' assessment of L2 English learners' speech. In fact, Kang et al. (2010) found that suprasegmental features alone accounted for approximately 50% of the variance in L2 speakers' proficiency ratings. Machine-based acoustic analysis suggests an additional resource to supplement human ratings in the field of language assessment. However, this objective technique still has challenges to overcome.

Acoustic analyses are indeed subject to perceptual limitations. As Crystal (2003) argues, it is important not to become too reliant on acoustic analyses because they rely on accurate calibration of measuring devices and are often open to multiple interpretations:

Sometimes, indeed, acoustic and auditory analyses of a sound conflict—for example, in intonation studies, one may hear a speech melody as rising, whereas the acoustic facts show the fundamental frequency of the sound to be steady. In such cases, it is for phoneticians to decide which evidence they will pay more attention to; there has been a longstanding debate concerning the respective merits of physical (i.e., acoustic) as opposed to psychological (i.e., auditory) solutions to such problems, and how apparent conflicts of this kind can be resolved. (Crystal, 2003, p. 7)

Possible ways to overcome such limitations include (1) using a combination of auditory and instrumental analysis and (2) checking inter-/intra-analyst reliability to ensure the consistency of the analysis. According to Kang (2010), in suprasegmental analyses, the internal consistency reliability between two phonetic analysts was lower in stress and pitch analyses (.86 or lower), but higher in temporal measures (.95 or higher). Discrepancies between the two analysts took place either in determining the start and end of each pause or in identifying prominent syllables. Therefore, a calibrating procedure having two analysts reach consensus may be required to ensure the reliability of the analysis. What people consider "objective" still relies on the "subjective" nature of listener perception.

Another caveat involves gender difference in acoustic analysis. Due to a gender confounding factor (i.e., male speakers having lower pitched voices than female

speakers in general) especially in intonation measures, some studies tend to use a single gender (e.g., Kang et al., 2010, investigates only male speakers). It is becoming increasingly common to make gender adjustments for pitch before starting any analysis with a different gender. That is, prior to any kind of pitch comparison between male and female voices, the pitch is transformed into semitones (Couper-Kuhlen, 1996).

Differences in spoken genre can result in additional variance to the accuracy of acoustic analyses. Scholars have used various speech stimuli for their analysis: NNSs' oral presentation speech for different proficiency levels (Hincks, 2005); international teaching assistants' in-class lectures (Pickering, 2001; Kang, 2010); iBT TOEFL responses to speaking tasks (Kang et al., 2010); and read versus spontaneous speech (Cucchiari et al., 2002). Depending on the types of speech samples used for analysis, speech patterns may appear differently, assuming that test-taker performance varies in response to various tasks (Fulcher, 2003).

When considering the practicality or applicability of an acoustic approach that combines auditory and instrumental analysis, one must take into account the labor intensiveness involved. For a one-minute NNS speech sample, it takes at least 30–45 minutes to identify runs and the location or length of pauses (silent and filled). It takes approximately another 45 minutes to perform the prosodic analysis (i.e., measure fundamental frequency [F_0] for prominent syllables and analyze tone choice).

Acknowledging this labor intensity, automatic speech assessment tools have received growing attention (Franco et al., 2010). However, ASR still faces numerous problems in terms of the accuracy of the measures and feedback (Levis, 2007). Speech recognition systems, at least up until now, seem to offer more accuracy for NS than for NNS speech (Ehsani & Knodt, 1998; see also www.speech.sri.com). With accented NNSs' speech, the accuracy of the speech program significantly dropped (95% with NS speech in Ehsani & Knodt, 1998, but 70% in Derwing, Munro, & Carbonaro, 2000). In addition, as the speech recognition systems tend to measure prosody of speech without reference to linguistic organization, the precision problem especially arises with suprasegmental errors (Levis, 2007). For instance, when it comes to tone choice analysis, there is great difficulty in identifying a tone unit especially with the speech of a low proficiency speaker. Following Brazil's (1997) protocol, a tone unit contains one or two prominent syllables, which may coincide with syntactic and pause boundaries. However, low proficient NNSs frequently use primary stress on every word in a message unit, regardless of its function or semantic importance (Wennerstrom, 2000). Their pauses often appear randomly and irregularly. As a result, recognizing tone unit boundaries is not a clear-cut procedure in much NNS speech.

Future Directions

To the degree that conformity to NS comprehensibility constitutes a criterion for oral proficiency, acoustic and temporal parameters measured via instrumentation can help interpret candidates' scores in assessing speaking skills. The knowledge of these instrumentally analyzed properties can be also used for rubric

development or rater training in oral proficiency testing. Currently, descriptors of rubrics used in high stakes testing are still relatively general in terms of describing the pronunciation features in particular. For example, the descriptor for the Delivery dimension in the TOEFL iBT speaking rubric for Score 4 (the highest score of the holistic rating) includes this: "It may include minor lapses, or minor difficulties with pronunciation or intonation patterns" (Educational Testing Service, 2004). Raters may be confused by the term "difficulties with intonation," as it can still be ambivalent when it comes to their decision making. Acoustically identified prosodic features such as pitch range or level (flat) tones can be used as the objects of sensitization in rater training and in developing the assessment criteria those raters will employ.

In addition, the physical properties of the acoustic and temporal measures can build bases for speech recognition and processing techniques, which have increasingly drawn the attention of language testers, as these can help develop automated scoring and feedback systems. Despite some existing drawbacks as listed in the previous section, this objective analysis approach or the combined method with a human rating may also be of use in the automatic assessment of speech production. As topics on ASR effectiveness for NNS speech continue to be of interest to L2 researchers (e.g., Oh, Yoon, & Kim, 2007), the improvement of this approach to speech assessment is certainly necessary.

Acoustic research has yet to be widely applied to the field of assessment of oral performance. In fact, human raters are considered to be more able to decipher meaning from utterances in response to test questions (Godwin-Jones, 2009). Xi (2010a) notes that automatic feedback systems may only "be acceptable in low-stakes practice environments with instructor support" (p. 298). For example, as seen from the set of features used for the TPO (Zechner et al., 2009), the focus of the automatic scoring model is mainly on fluency (temporal features) with some segmental acoustic aspects. Moreover, the ASR models still fall short in that they do not examine the aspects of communicative ability on the part of the candidates. This lack of adequacy in testing the communicative competence of test takers is of ongoing concern for those who seek a valid means to automatically test and score candidates' speech (Chapelle & Chung, 2010). Incorporating more of the acoustic suprasegmental features such as intonation (e.g., tone choices or pitch ranges) into the automated scoring models could help with the issue of communicative competence to some extent, as tones are associated with particular communicative values (e.g., proclaiming with falling tones and referring with rising tones) (Brazil, 1997). Thus, proactive collaborative projects among researchers in language assessment and linguistic analysis are much needed to better develop assessment criteria and to improve assessment training.

Whereas studies have traditionally tended to examine segmentals and suprasegmentals separately, future research may investigate a constellation of acoustic features conjointly for both. This will help to answer the question of the extent to which nonprosodic features of speech contribute to ratings of oral performance, compared to suprasegmentals. In addition, these pronunciation aspects of speech identified through acoustic analysis must be interpreted in conjunction with other linguistic features. That is, further research is necessary regarding whether grammatical and lexical performance variables contribute additional variance to oral

assessment ratings, and the degree to which those other linguistic elements can compensate for dysfunctional features of pronunciation.

The main discussion of this chapter has focused on issues in large-scale assessment. Yet advances made in instrumental analysis and ASR could be used in classroom-based assessment of speech in the future (although somewhat limited at the moment). De Jong and Wempe (2007) provide good evidence of practical application by describing a method to automatically measure speech rate without the need of a transcription, using Praat. The program can quickly identify silence in speech and ultimately provide information on speech rate for learners. The Higgins, Xi, Zechner, and Williamson (2011) study has advanced the technique and built into speech recognizers a component that is able to identify speech rate. A possible scenario is that free downloadable programs such as Praat can be used for formative assessments in which teachers can easily evaluate students' oral fluency development without labor-intensive scoring procedures. How this instrumental analysis can be used in classroom-based speaking assessment is an important topic for future research.

A qualitative approach to acoustic measures may be much needed for future language assessment. Speech evaluation often falls back on quantitative methods such as using data from a large speech corpus to explore the impact of certain acoustic features on listeners' judgments. On the other hand, in-depth interviews or discussions with NNSs (e.g., why they paused at certain locations or why they emphasized certain words) can provide insights into understanding the relationship between NNSs' speech production and listeners' evaluation. This approach will not only help clarify the acoustically identified features of accented speech, but also increase the validity and reliability of the measures.

Overall, the future direction of acoustic studies involves expanding the scope of interpretation of the parameters analyzed for assessing speaking. The features measured instrumentally (i.e., particularly acoustic properties such as tone choices) should be interpreted in a more contextualized way, recognizing the social nature of oral performance through discourse and interaction analysis. Moreover, a sociolinguistic approach may help us find out whether or not the test taker is disadvantaged by his or her interlocutors' particular speech patterns. For example, if an interlocutor does not use rising tones appropriately or frequently, the other interlocutor may feel offended or less supported (Pickering, 2001). Overuse of falling tones by NNSs can give NS listeners an impression of arrogance. Much research needs to be done in this area and to expand the capacity of acoustic research itself. Finally, this chapter has not touched on important socio-political issues regarding NNSs' accents, such as identity and motivation, as these are not the main concern of the argument here. Another area of future research should lie in the relationship between the speech properties and physiological traits.

Note

- 1 Unlike intelligibility, which refers to the extent to which a listener understands an utterance, comprehensibility pertains to the degree of difficulty the listener reports in attempting to understand an utterance, and accentedness represents the extent to which an L2 learner's speech is perceived to differ from native speaker norms (Derwing & Munro, 2005).

Computer-Automated Scoring of Written Responses

Nathan T. Carr

California State University, Fullerton, USA

Introduction

The study and use of computer-automated scoring (CAS) was entirely focused on written responses until relatively recently. CAS is now beginning to expand into spoken responses as well, but the scoring of written tasks has clearly been the subject of most CAS research thus far. It remains the subject of much ongoing research, and is the area in which most operational use of CAS takes place today. This chapter will discuss CAS of written responses in two main categories: extended response tasks such as essays, and limited production tasks such as short answer questions. Limited production responses will be further divided based on the approach to scoring that is being used.

Previous Views or Conceptualization

Before the inception of CAS, the tasks which could be scored automatically were highly restricted. Early on, multiple choice and other selected response formats could be scored rapidly using stencils placed over preformatted answer sheets. Later, as optical-scanning technology became available, a single answer sheet could be scored even faster, sometimes in less than one second. It was the ease of scoring offered by multiple choice tasks in particular—along with the greater ease of estimating reliability for item-based tests—that led them to become the dominant response format in standardized testing, at least in the USA, early in the 20th century (Spolsky, 1995; Williamson, 2009).

Constructed response tasks, in contrast, allowed no simple method of scoring that did not involve human evaluation of every single response. The greater expense required for evaluating constructed responses (particularly essays), along

with concern for reliability, helped lead to a greater focus in the USA on multiple choice testing of reading, listening, and grammar. This led, among other things, to writing not being commonly included in language assessments, particularly in the USA. For example, the Educational Testing Service did not include writing as a regular component of the TOEFL until the introduction of the computer-based TOEFL in 1998 (Educational Testing Service, 2007), although the optional Test of Written English (TWE) was available beginning in 1986 (Spolsky, 1995). In cases where extended production tasks *were* used in large-scale language testing, such as the Cambridge main suite exams, the TWE, or the Michigan English Language Aptitude Battery (MELAB), most scoring was done—and continues to be done today—using holistic rating scales (Hawkey & Shaw, 2005; Cambridge Michigan Language Assessments, 2012). Holistic scoring is presumably used in order to speed up the process and thereby reduce costs, in spite of the potential advantages analytic scoring can provide (see Carr, 2011a, for a discussion of this topic). Smaller-scale assessment carried out by language schools and programs, or by individual teachers, has naturally been more varied, and has more commonly included writing as an integral part.

As noted above, multiple choice tasks became firmly entrenched as the method of choice for assessing reading, listening, and grammar in large-scale US testing. As a result, limited production tasks such as short answer questions only saw high stakes use outside the USA. For example, the various Cambridge exams only began *including* multiple choice items in 1970, a practice which stemmed from a greater emphasis on expert judgment and less concern with rapidity and consistency of scoring (Spolsky, 1995). Generally speaking, though, teacher-made classroom tests have probably seen the greatest use of limited production items in recent decades. All of these writing tasks have, of course, been hand-scored until relatively recently.

Current Practices

This section discusses current practices in the use of automated scoring for written responses. It will begin by discussing the use of CAS for automated essay scoring, and then proceed to discuss two approaches to scoring limited production responses: approaches based on natural language processing (NLP), and approaches using keyword or regular expression matching. Automated essay scoring (AES) has received the most attention thus far in terms of research and operational use (Williamson, 2009). This most likely stems from the methods commonly used in large-scale language tests. Large-scale writing assessments typically include essays, as assessing writing without using extended response tasks would raise serious validity issues. Such tasks impose significant scoring costs when human ratings are used, however, so it is probably the increased practicality of AES that has made it the focus of most CAS research. In contrast, the use of selected response tasks to assess reading, listening, and grammar has produced at least somewhat satisfactory results, reducing pressure to move to limited production task formats. This non-use of limited production tasks has in turn meant that there has been limited progress in using CAS for them.

Automated Essay Scoring

The automated scoring of extended production responses is performed using various types of natural language processing (NLP) techniques, which are “the application of computational methods to analyze characteristics of electronic files of text or speech” (Burststein, 2003, p. 115). There are several AES systems in fairly widespread use at present, and a great many less widely used ones as well. At present, there are three systems that seem to be the most commonly used and best known: the Educational Testing Service’s e-rater; the Intelligent Essay Assessor, used to score the Pearson Test of English Academic; and Vantage Learning’s MY Access! (Herrington & Moran, 2006; Williamson, 2009).

Perhaps the best known and most widely researched of these is e-rater, for which an extensive amount of research has been conducted and made publicly available (see Educational Testing Service, 2012a, for a bibliography). The system was first used operationally for scoring the analytical section of the Graduate Management Admission Test (Burststein, 2003), which includes a mix of writing by both native and non-native English speakers. The Internet-based TOEFL (iBT) began using e-rater in combination with a single human rater to score the independent writing task in July 2009 (Tyson, 2010), and now uses that procedure to score the iBT integrated writing tasks as well (Educational Testing Service, 2012b). The e-rater engine is also used for the Criterion Online Writing Evaluation service, an automated essay scoring service which is marketed to colleges and universities, K-12 schools, and academic ESL/EFL programs as a tool for scoring and providing diagnostic feedback on essay drafts (Educational Testing Service, 2008, 2012c).

The Knowledge Analysis Technologies (KAT) scoring engine, previously known as the Intelligent Essay Assessor (IEA), is used to score the writing section of the Pearson Test of English Academic (PTE Academic), with no human scoring except for essays flagged by the system itself (Pearson Education, 2009). It is also used in Pearson’s WriteToLearn system, which is intended for students in grades 4–12, including non-native speakers of English (Pearson Education, 2011a). This scoring system is based on latent semantic analysis (Landauer, Laham, & Foltz, 2003), an approach discussed further below. Pearson’s site also includes a bibliography of research on automated scoring (Pearson Education, 2011b).

The third widely used AES system is Vantage Learning’s IntelliMetric, which is used by their MY Access! service to assess student writing in composition classes (Vantage Learning, *n.d.a*, *n.d.b*). In addition, it is used by the College Board to score WritePlacer and WritePlacer ESL essays (College Entrance Examination Board, 2004; Wang & Mikulis, 2005; Jones, 2006; James, 2008) and, in conjunction with a human rater, to score the analytical writing assessment portion of the Graduate Management Admission Test (GMAT) (Rudner, Garcia, & Welch, 2006).¹ Vantage Learning’s Web site includes a page on research on IntelliMetric (Vantage Learning, *n.d.c*) that refers to “more than 350 research studies” conducted on the system, and provides links to two studies as well as to a document summarizing the findings of a number of other studies (Vantage Learning, 2007). Of the three most widely used AES systems, only IntelliMetric can score writing in languages other than English, handling over 20 additional languages (Vantage Learning, *n.d.d*).

At present, AES systems work by analyzing a large sample of essays (several hundred, at least), all of which typically address the same prompt (but see the section on current research in AES below). These essays are scored by human raters, after which the AES system is “trained” on them; for this reason, this set of sample essays is referred to as the *training set* or *training sample*. The scoring engine then performs operational scoring by analyzing new essays and comparing each essay to those in the training set, or to essays in the training set that resemble the particular essay being scored. This comparison is made using some sort of statistical modeling, with approaches including regression-based techniques, Bayesian modeling, and dimensionality reduction methods² (Williamson, 2009). The essay features that are analyzed, and the statistical modeling approaches used, are what distinguish AES systems from each other.

In analyzing essays, the creators of AES systems are concerned to varying degrees with one or both of two areas: the linguistic features of the essay, and its semantic content. For example, the earliest effort at AES, Project Essay Grade (PEG), was based on an “objective” computerized analysis of linguistic features (Page, 2003). On the other hand, latent semantic analysis (LSA), the approach employed by Pearson’s KAT system, places much greater emphasis on an essay’s content than on grammar, style, or mechanics; in essence, it bases its statistical model of the test on the relationships—in terms of meaning—among words and passages (Landauer, Laham, & Foltz, 2003). That being said, the KAT implementation of LSA does not actually comprehend the text as such, but rather appears to look for appropriate content words in well-formed sentences. As a result, McGee (2006) reports that in some cases it can fail to detect whether content is correct or even logical—for example, when the steps of a process description are reversed.

As mentioned earlier, the features analyzed by different scoring engines will naturally vary. For example, e-rater includes modules that analyze the syntax, discourse, and topical content, with topical content identified by analyzing vocabulary (Burstein, 2003). These modules return estimates of several dozen variables, which fall into the categories of grammar, usage, mechanics, style, organization, development, lexical complexity, and topic-specific vocabulary usage (Quinlan, Higgins, & Wolff, 2009). Examples of other features that might be used in AES include gibberish detection, irrelevant statements detection, differentiating statements of fact from opinion, and checking the factual accuracy of statements in the essay (Kohli, Bhumkar, Bakshi, Ganapatibhotla, & Padhye, 2004).

As an illustration of how an AES system might analyze a given feature, we can consider the example of how thesis statements might be identified. NLP algorithms might identify them on the basis of several criteria, including their positions, words identified as commonly occurring in thesis statements, and the output of a rhetorical structure parsing system. Statistical modeling would then be applied to determine the likelihood that a given sentence is in fact a thesis statement (Burstein & Marcu, 2003).

One of the main criticisms of AES, of course, is that, because the system cannot actually understand the response (see, e.g., Condon, 2006), it is unable to catch some of the issues mentioned above (e.g., gibberish, irrelevance, illogic, or glaring errors of fact), or at least is less able to do so than any human rater would be.

Similarly, it cannot reward creative or interesting writing that might favorably impress human readers. This relates to another objection, one that is more philosophical, and which is best summarized by a position statement by the Conference on College Composition and Communication (2004, ¶ 36): “Because all writing is social, all writing should have human readers, regardless of the purpose of the writing.” This is something of a hard line on the subject, and should an NLP system ever be devised that could actually comprehend examinee writing, this position might become untenable, as the computer *would* be communicating. In the meantime, however, it is quite legitimate to wonder whether a system that *predicts* human scores without understanding poses a threat to the construct validity of a test, even if its predictions are highly accurate. There is probably no one-size-fits-all answer to this question, however, and test developers and users must balance a number of considerations and decide what course of action would best strengthen the assessment use argument (Bachman & Palmer, 2010) for using either AES or human scoring.

Another reason for which AES systems have been criticized is that automated scoring of non-native writing is more difficult than that of native-speaking writers. “Teaching” an NLP system to analyze relatively standard test taker responses is challenging, but requiring a system to handle non-native speaker output—which may often deviate from the norms of the target language—adds an additional layer of complexity to the task (Carr, 2011b). Indeed, AES was not initially developed with non-native writers in mind (see Page, 2003), nor were the three main scoring engines discussed above originally intended for them (Warschauer & Ware, 2006), subsequent research and development work notwithstanding. The accuracy with which AES systems identify language errors bears this out; e-rater, for example, has an overall false positive rate of 10% in identifying writer errors, meaning that 10% of the errors that it identifies are not actually errors. On the other hand, it has a “miss” rate of 60%, meaning that it only detects 40% of the errors that a human rater would identify (Chodorow, Gamon, & Tetreault, 2010). Similarly, IntelliMetric’s false positive rate in one recent study was found to be 27%, and its miss rate 70%, for 16 types of errors (Hoang, 2011).

Two areas of non-native writing which have been found to pose particular difficulty for NLP systems to identify have included articles and prepositions. Chodorow and his colleagues (2010) report, for example, that e-rater has a false positive rate of 20% for finding prepositional errors, and only detects 25% of such errors. They additionally report that Microsoft’s ESL Assistant presently has a false positive rate of 32% for preposition errors in a Web-scraped non-native writing corpus, while missing 82% of errors (Chodorow et al., 2010). Hoang (2011) also reports that scoring engines in general (specifically, both e-rater and IntelliMetric) are unable to identify verb tense errors, a serious shortcoming when dealing with the writing of language learners. On the other hand, her results indicated that IntelliMetric was well able to identify errors with articles, capitalization, spelling (including closed vs. open spellings, such as *every day* vs. *everyday*), and even articles and run-on sentences.

Jones (2006) finds indications that IntelliMetric may have difficulty finding errors such as sentence fragments and comma splices, shifting persons and faulty

antecedents, misplaced modifiers, sentence structure, subject–verb agreement, and verb forms, and that it tends to produce its worst scoring errors when assessing ESL students' essays (as opposed to those of native English speakers). McGee (2006) notes difficulty with identifying word order issues with the KAT engine, and Jones (2006) also reports issues with word choice, wordiness, and missing words for IntelliMetric. Taken together, these two sets of findings suggest that the inability of NLP systems to decipher meaning can cause them to miss a variety of lexical and lexicogrammatical errors (which would be common in non-native writing), and it would appear that this represents a general problem with these systems.

In spite of the issues just discussed, however, AES systems are nevertheless often capable of predicting human essay scores with a relatively high degree of accuracy (see, e.g., Weigle, 2010), although this accuracy does appear to be greater for native speaker writing than for non-native. In light of that, it seems prudent that automated scoring of extended production responses should be accompanied by a human rating as well, taking advantage of the strengths of both (Enright & Quinlan, 2010). This may be less important, of course, in low stakes assessment, or in cases where language assessment per se is not the focus of the assessment (as when language issues take a back seat to concerns with the rhetorical quality of a composition).

Using NLP to Score Limited Production Responses

In addition to its use in scoring extended production responses such as essays, NLP can also be used in the scoring of limited production responses, although these may sometimes stretch the definition of the term, given that such responses may reach paragraph length. Thus far, most of the applications of this approach to CAS have been in the content areas (e.g., history or science), rather than in language assessment per se. This is because most limited production tasks in language testing are used to assess reading comprehension, listening comprehension, or sentence level grammar, which generally only require sentence length responses. In contrast, content-area limited production tasks often require paragraph length responses, which necessitate the greater sophistication of NLP systems. These systems might be useful for language assessments at very advanced levels, however, such as summary writing and other integrated (i.e., reading or listening integrated with speaking or writing) tasks. This is, in fact, the approach used in the PTE Academic for scoring summary tasks, the expected responses for which are 50–70 words long. The scoring is done using the same KAT AES engine as for the PTE's other writing tasks, however, rather than a specialized, simplified system (Pearson Education, 2009).

As for CAS systems specifically designed for limited production tasks, the best known is probably the *c-rater* engine from ETS. Short for "concept rater," *c-rater* is intended to score content-based questions, using some of the same NLP procedures and tools as *e-rater*, but differs in that it ignores rhetorical structure and focuses on logical relations among the elements of each sentence. In addition, it does not require a training sample, merely the instructor's answer key (Burstein, Leacock, & Swartz, 2001).

Another NLP system specifically designed for scoring limited production responses is AutoMark, which appears to be the scoring engine used for that task format in Intelligent Assessment's ExamOnline platform (Intelligent Assessment Technologies, 2011). AutoMark does not use a "full" NLP approach, however, but rather uses NLP tools such as parsers and lexical databases to search test taker responses for specific concepts (see the section on keyword or regular expression matching below). AutoMark uses a set of templates, each with one form of a correct answer (or a particular incorrect answer that is specified). Test taker responses are then parsed and matched to a template, and assigned the relevant score (Mitchell, Russell, Broomhead, & Aldridge, 2002).

Using Keyword or Regular Expression Matching to Score Limited Production Responses

A third type of CAS for written responses involves keyword or regular expression matching. This approach is used in limited production tasks to which the expected responses range in length from one word up to perhaps one sentence. This scoring approach has thus far mainly been used to assess reading and listening comprehension, but it should be relatively easy to adapt it to assessing grammar at sentence level as well.

As Carr and Xi (2010) describe, regular expression matching systems work by using a key that is written as part of the item-writing process. The item writer produces a model answer, and specifies what the key pieces of information are in that response. The author considers synonyms and alternative phrasings for the key pieces of information, and then truncates them as appropriate using wildcards (e.g., *changed* becomes *chang**, which would allow *change*, *changed*, *changes*, and *changing* as correct responses). Points are then assigned for each key term or grouping of key terms. The scoring algorithm will in turn search for these keywords, also referred to as regular expressions, and when it finds them, assigns points to the response as specified in the key. If no regular expressions from the key are found in a particular response, of course, it receives no points (Carr, 2008).

Surprisingly, there appears to be little operational use of this CAS technique in language assessment at present. Ockey (2009) predicts, however, that this will change in the near future. One likely reason that it will gain in popularity is the relative ease of implementation for such systems—all that is really necessary is the means to construct and deliver Web-based tests, collect the responses, and use relatively simple algorithms to score them (Carr, 2008).

Current Research

Much of the research currently being undertaken regarding CAS for written responses involves validation, or the articulation of assessment use arguments (see Xi, 2010, for a recent overview of the subject; Keith, 2003, for a discussion of the types of validity evidence appropriate in evaluating the use of AES; and Yang, Buckendahl, Juszkievicz, & Bhola, 2002, for a framework for validating CAS). As

with the preceding section on current practices in CAS, this section will approach the subject by considering separately systems that employ NLP for AES, NLP for limited production tasks, and regular expression matching for limited production tasks.

Research Directions for Automated Essay Scoring

As Chung and Baker (2003) note, one area that is the current subject of research in AES is exploring ways of increasing the degree to which scoring is based on a construct definition of writing ability, as opposed to simply trying to predict human scores. Coverage of the writing construct could be improved in terms of both breadth and depth by, for example, developing or improving measures of rhetorical content and organization, as well as by improving the accuracy with which existing features operate (Quinlan et al., 2009).

Another area on which current research focuses is the effort to reduce the size of the training sample required for an AES engine to score a new essay prompt (see, e.g., Elliot, 2003; Attali & Burstein, 2006; Attali, 2011). An expansion on this concept is the attempt to move to a generic training set that can be used for several essay prompts that are deemed comparable, with the scoring engine being trained on essays addressing a number of prompts, thereby saving large amounts of time and money in scoring the training set (Attali & Burstein, 2006; Attali, 2011). An example would be when a testing program rotates through a set of different prompts from administration to administration, but still uses the same rating scale to score them. Taking the idea even further, investigations are also taking place into ways of building models into scoring engines, eliminating the need for a training set beyond a small set of benchmark essays such as what might be given to a group of human raters, for the purpose of setting appropriate scoring standards (Attali & Burstein, 2006).

Appropriately enough, given the difficulties discussed above, an additional important area of current AES research is improving the performance of systems or procedures for detecting grammatical errors. These include improvements in the detection of errors of general English syntax, as well as usage errors associated with specific words such as prepositional collocations or count vs. noncount noun confusion (Leacock & Chodorow, 2001, 2003). An additional, related area currently of major research interest is the improvement of the automated feedback provided by AES systems in formative assessment contexts (see Xi, 2010, for recommendations in evaluating automated feedback systems). This is an area of major overlap with other studies focusing on the validation of various AES systems, particularly including (but not limited to) studies investigating the accuracy of grammatical error identification (e.g., Attali & Burstein, 2006; Chodorow et al., 2010; Hoang, 2011).

Finally, Phillips (2007) observes that one noteworthy weakness in most of the extant research on AES to date is that it has been conducted by the companies developing the systems, and that there is a marked lack of independent research comparing different systems head to head. It is to be fervently hoped that comparative research of the sort that is largely missing today will be pursued in the foreseeable future.

Research Directions for NLP Scoring of Limited Production Responses

Naturally enough, research into NLP-based scoring of limited production responses focuses on those areas that are the most problematic for current systems to score correctly. For example, Mitchell et al. (2002) identified four areas that led to scoring errors with the AutoMark engine and which require further research. These were misspelled words in test taker responses, difficulty parsing responses (usually because they were poorly written), failing to recognize when a correct response is followed by an incorrect statement (“incorrect qualifications”), and the failure to specify every possible correct response in the scoring key. Of these issues, the authors identified the problem of incorrect qualifications as being the most difficult to solve. Similarly, Pulman and Sukkarieh (2005) also refer to various types of unconventional phrasings, which pose marked difficulties for CAS of limited production tasks. Therefore, in the area of NLP scoring of content-oriented tasks, the primary focus of research is—and needs to be—on ways of systems, techniques, or procedures that can better unravel the relationships among concepts, even (or particularly) when they are written unclearly.

Research on CAS Using Keyword or Regular Expression Matching for Limited Production Responses

Current research on regular expression-based CAS for limited production tasks has focused primarily on the impact of various implementation decisions on construct definitions and how they are operationalized in the test (Carr, 2008; Carr & Xi, 2010). In particular, Carr lists seven overlapping categories in which decisions need to be made for any given test using this scoring approach:

1. exactness of responses, or how “picky” to be in setting up the key;
2. whether to assign partial credit for some items, and if so, how much, and how the decisions are to be made;
3. how to handle “undesirable” responses, which contain some or all of the same regular expressions as keyed responses, but which are nevertheless incorrect and must therefore be flagged so that the scoring engine does not mistakenly count them as correct (e.g., if *Earth is a planet* is the model answer, *Earth is not a planet* contains *Earth* and *planet*, yet is inaccurate, and therefore be excluded a priori as an undesirable response);
4. how to handle synonyms;
5. how to handle paraphrases;
6. spelling errors; and
7. whether and how to penalize for extraneous information (e.g., if an examinee quotes five words from the passage when one word is sufficient to answer the question).

These are topics that clearly require further study as this scoring approach becomes more widely adopted.

One additional area of inquiry on this topic has involved the quality of scoring keys, particularly those created by language teachers. Since CAS of short answer questions using regular expression matching represents the approach most amenable to adoption in small- and medium-sized programs, it is important that research take into consideration the keys generated by language teachers, rather than those generated by language testing experts. To that end, Carr (2011c) examined the areas that proved problematic for teachers producing regular expression-based scoring keys, and estimated the dependability resulting when particular keys were viewed as samples from the potential universe of scoring keys that might be used (Carr, 2011d). Given the results of these two studies—that keys were often problematic, and that they were not very consistent one to another—this is another area in definite need of further research.

Future Directions

Future research, development, and operational use will likely follow in the direction of improving the understanding, measurement, and modeling of the construct of writing, in connection with AES, leading to reducing training set requirements for AES; more widespread use of CAS; and, potentially, the use of automated scoring in course management systems.

Improving the Understanding, Measurement, and Modeling of the Construct of Writing

It seems likely that the quality of CAS systems will continue to improve, as it has since their introduction in 1966 (Page, 2003). In particular, improvements in the accuracy with which errors of syntax and vocabulary are identified are an absolute necessity in AES. Given the efforts being made to this end, the now decades-long ubiquity of continuous improvement in computer technology, the competition among the major players, and the concomitant amount of money at stake, improvements seem highly likely, although they may occur incrementally. Similar improvements are probably likely as well in the evaluation of essay content and organization, as well as the ability of systems to parse mangled prose and detect semantically unreasonable propositions such as *eggs lay chickens*.

These improvements are likely to enable the use of smaller training sets for essays addressing the same type of prompt, or even prompts of different types that are intended to be rated comparably (as discussed above). In particular, as the ability to spot linguistic errors improves, along with sensitivity to content and rhetorical organization, the training needs for AES systems will presumably begin to more closely approximate those of human raters. Of course, this would only be enhanced further by parallel improvements in the ability to handle unclear writing and semantically problematic writing.

More Widespread Use of Automated Scoring

Given the trend of increasing—even accelerating—use of AES over the last decade, it seems a fairly safe assumption that its use will continue to grow.³ This is neither an unmitigated benefit nor a drawback, of course. It will, however, be important to establish the appropriacy of a particular system for a particular use, rather than relying on which company makes the most expansive claims, has the best marketing program, and offers the best price. In other words, as with any test, an argument must be made for each particular use of a given assessment (Bachman & Palmer, 2010). Prospective users should also consider whether a commercial AES system will best fit their needs, or, alternatively, whether they might be better served by refocusing their efforts on improving their human scoring procedures (Carr, 2010). It may be in some cases that a combination of AES and improved human scoring will best support the usefulness of the test.

On a separate note, given the relative ease of implementation (as compared to AES, for example), it seems likely that CAS will become more widespread in the area of limited production tasks for comprehension and grammar, for “larger,” higher stakes tests, such as placement and proficiency tests, as well as for smaller and more frequent tests such as tests for individual classes, and even routine quizzes. This will give rise to a need for greater teacher training—even if the design, setup, and operation of the system are handled by computer specialists, the tests and scoring keys will have to be created by teachers. That, in turn, will probably require further research into what the training needs of language teachers *are* in terms of both test writing and key authoring. Both of these would be good things, as proficiency in language assessment is an important part of the professional skill set of any language teacher, notwithstanding its unfortunate scarcity in many cases.

An additional likely expansion in the use of CAS is its application to languages other than English. Very little research, at least in English, appears to have been published on this front (but see Granfeldt et al., 2005, for an example of AES for French writing), notwithstanding statements that IntelliMetric can score essays written in a number of different languages (Vantage Learning, *n.d.d*). As the technology continues to mature, however, it seems implausible that it would *not* be implemented broadly in other languages as well.

Increased Use of Automated Scoring in Course Management Systems

Finally, course management systems such as Moodle, and online workbook packages such as Quia, already offer quiz tools which include short answer questions as options. These typically allow for automated scoring of the short answer questions using an exact text match approach. Specifically, while they may tolerate additional spaces between words, and may not be case sensitive, they are otherwise rigid in their scoring. Any misspellings must be specified in the key, and a phrase or sentence with one word wrong—or even a word that is misspelled, or out of order, or an answer with an extra word inserted—will be counted wrong.

It can be hoped, however, that as time goes by, these systems might move to more flexible regular expression-based systems.

Conclusion

To conclude briefly, the computer-automated scoring of written responses involves several different approaches, from the most complex (natural language processing) to the simpler (regular expression matching). It can be applied to both full length essays and questions eliciting as little as one word in response. CAS systems are growing more and more common in their use, and their capabilities seem to be increasing as well. They do not remain without controversy, however, for philosophical as well as practical reasons. Current and future developments seem likely to lead to even more widespread use, as well as to enhanced capabilities.

Notes

- 1 Interestingly enough, these two uses of IntelliMetric do not appear to be mentioned anywhere on the College Board or GMAT Web sites, although indirect references to the GMAT and WritePlacer can be found by searching the Vantage Learning Web site.
- 2 Dimensionality reduction methods (e.g., factor analysis) identify a set of dimensions which account for a larger number of variables—here, essay characteristics (Landauer, Laham, & Foltz, 2003).
- 3 AES appears to be in no danger at present of suffering the fate of computer adaptive testing—a brief period of prominence, followed by a drop-off due to its resource-intensive requirements.

Introduction to Volume III

The chapters in this volume focus on the conceptual issues regarding assessment evaluation and the methodology to conduct research on language assessments. Specifically, the chapters are on designing evaluations and validation, fairness and justice, accommodations for test takers, consequences, impact, and washback. This is followed by two parts on quantitative analysis and qualitative and mixed method analysis. The quantitative part includes chapters on classical test theory, reliability, dependability, generalizability theory, factor analysis and structural equation modeling, questionnaire development and analysis, item response theory, differential item and testlet functioning analysis, and multifaceted Rasch analysis. The qualitative part includes chapters on content analysis, introspective methods, raters and ratings, spoken and written discourse, mixed methods research, and writing research reports. The volume concludes with interdisciplinary themes from various fields, including philosophy, cognition, language acquisition, bilingualism, classroom-based assessment, program evaluation, forensic sciences, and legal and ethical matters, and a chapter on ongoing challenges.

Evaluation of Language Tests Through Validation Research

Carol A. Chapelle

Iowa State University, USA

Erik Voss

Iowa State University, USA

Introduction

Language test scores are used to make important decisions about people in many different contexts, and consequently the tests that evaluate language users' abilities need to be evaluated themselves. When an applicant for a job or a candidate for university admissions, for example, obtains a score on a language test that is used to decide his or her future, one should ask what kind of evaluation process the test itself has been put through to assess the adequacy of the scores it produces for making such decisions. When a student in a language program obtains a score that places him or her in a particular class level, how has that test been evaluated? One can ask the same question about test scores used to assign final grades to students in a language program. The basic question is the same in each of these cases, reflecting the need to engage in a process of evaluation in order for test users to be confident that the test scores are valid for their intended purposes.

The term *evaluation* is used in a number of ways in language-testing literature. In one sense, the evaluation of assessments and tests can be thought of as a special case of evaluation of materials in language education. It is special because of the specialized techniques and frameworks that have been developed to guide the process. Such specialized practices are called "validation" rather than evaluation, to be distinguished from other forms of evaluation, which are less focused on test scores, and from other summaries of students' performance. Validation is defined as the justification of the interpretations and uses of testing outcomes. In this sense validation appears at first to be a one-sided evaluation, if the aim is solely to produce justifications; but the idea is that, in the process of attempting to justify something, one confronts both sides of an argument. Despite the intended aim of justification, validation is supposed to entail inquiry into the meaning of test

scores, their use, and their consequences. In this chapter evaluation will refer to language assessment validation approaches.

Validation practices vary across testing contexts, but in this chapter we will describe the overall concept of validation and will give two examples of validation, one in high stakes testing and one in low stakes testing. In order to explain the approaches used, we describe the actors involved, the analytic frameworks chosen, and the evaluative data obtained in the process of validation. We begin with a discussion of definitions and frameworks for validation used in the past, some of which continue to be used today.

Previous Views of Validation

Test developers and researchers work in many different contexts to conduct validation research for a variety of tests. Of all of this work, the published studies appearing in *Language Testing* and *Language Assessment Quarterly* are perhaps the most worthy of examination if we wish to get an idea of validation from a scholarly perspective. With the aim of compiling an empirically based chronological description of validation, we conducted a search of articles published in these two journals by using the advanced search feature on the Web pages for each journal. The search terms “validity,” “validation,” “validating,” “evaluation,” “usefulness,” and “argument” were used to find any mention of validation in either the title or abstract of a publication. The terms were chosen to find studies that focus on validation research from any of the variety of perspectives that have appeared since the journal *Language Testing* first appeared in 1984.

The results of the searches were compiled in an Excel document and duplicates, book reviews, and a regional seminar announcement were deleted. Each of the studies was then examined in order for us to determine whether or not it was actually an empirical validation study pertaining to test interpretation and use. Some of the initial results were omitted because the paper did not report an empirical study, or because the key word was used in a manner that did not refer to the validation of test interpretations and uses. The final list contained a total of 123 titles, from 1984 through 2011.

We classified each of these papers under one of four approaches to validation that have been outlined in language testing (e.g., Chapelle, 2012): (1) one question and three validities, (2) evidence gathering, (3) test usefulness, and (4) argument-based. In addition, we created a category where we placed each study for which an approach to validation was not explicitly expressed; and the majority of studies for each of the periods fell in this category. For each of these periods, the counts for each category appear in Table 65.1.

One Question and Three Validities

“Does the test measure what it claims to measure? If it does, it is valid” (Lado, 1961, p. 321). This means of conceptualizing validity and introducing validity research seemed to resonate with testing researchers for some time. It appeared, for example, in Henning’s textbook: “A test is said to be valid to the extent that it

Table 65.1 Results from a search of validation studies in *Language Testing* and *Language Assessment Quarterly*, with validation approach tabulated

<i>Time period</i>	<i>No. of articles</i>	<i>Not explicit % (n)</i>	<i>One question % (n)</i>	<i>Gathering evidence % (n)</i>	<i>Test usefulness % (n)</i>	<i>Argument-based % (n)</i>

measures what it is supposed to measure” (Henning, 1987, p. 89). Books such as Lado’s and Henning’s in the United States described procedures associated with demonstrating three “types of validity.” Content validity referred to expert opinion systematically gathered, indicating that the test items or tasks were appropriate for assessing specific aspects of the construct to be measured. Concurrent and criterion-related validity were investigated through the use of correlations between the test and other tests intended to measure the relevant construct. Construct validity referred to other quantitative evidence showing that the data obtained from examinees conformed to theorized expectations when these data were analyzed statistically.

In 1984–90, when the results came from the only journal that existed at that time, *Language Testing*, many papers reflected the “one question” approach to validity. A paper by Hudson and Lynch (1984), for example, introduced the authors’ approach to validity by stating: “Validity is usually defined as the extent to which a test is actually measuring what it claims to be measuring” (p. 182). They described their study as an initial investigation of content validity and construct validity.

Despite the persistence of the “one question, three validities” approach among nonspecialists today, measurement specialist Sireci pointed out that it is an artifact from the past:

to claim that validity refers simply to demonstrating that a “test measures what it purports to measure” or that it is an inherent property of a test is to ignore at least 70 years of research on validity theory and test validation as well as the consensus Technical Recommendations and Standards that have existed since 1954. (Sireci, 2009, p. 28)

Sireci is referring to the fact that current sources present validity as one overarching concern, and do so with the aim of using a variety of content-related, correlational, and other statistical and qualitative evidence in support of test interpretation and use. Sources that capture this professional consensus include the *Standards for Educational and Psychological Testing*, published jointly by the American Educational Research Association (AERA), the American Psychological Association

(APA), and the National Council on Measurement in Education (NCME) (1999). Another such source is an edited collection, now in its fourth edition, called *Educational Measurement* (Brennen, 2006). According to such sources, the problem for evaluating any particular test interpretation and use would more aptly be characterized as a problem of gathering the appropriate evidence.

Evidence Gathering

In the period 1991–5, papers in *Language Testing* began to refer to Messick's (1989) presentation of evidence gathering in support of construct validity, and from 1996 to 2000 studies continued to adopt an evidence-gathering approach and dropped the terminology "content validity and criterion-related validity." Messick (1989) defined validity as "an overall evaluative judgment of the degree to which evidence and theoretical rationales support the adequacy and appropriateness of interpretations and actions based on test scores" (p. 13). This perspective was presented in Bachman's (1990) seminal book. On the basis of these sources in the 1980s and 1990s, validation research should consist of gathering evidence about the meaning of test scores. In a study published in *Language Testing*, Shohamy and Inbar (1991) explicitly framed their research as gathering evidence, through hypothesis testing, about the type of text and questions in a listening comprehension test—rather than from the perspective of types of validity.

During the period 2001–5, when the first issues of *Language Assessment Quarterly* were published (this happened in 2004), authors continued to adopt an evidence-gathering approach. For example, Snellings, van Gelderen, and de Glopper (2004) applied Messick's (1989) framework to their validation of measures of written lexical retrieval. Their paper illustrates some of the types of construct validity evidence that can be gathered. They collected reliability estimates as evidence of internal structure and used correlational and regression methods as evidence of external structure. Their framework states that "different kinds of validity evidence are not alternatives but supplement each other in assessing the unifying concept of construct validity" (Snellings et al., 2004, p. 178).

Another important strand from Messick's perspective is what, in language assessment, Davies and Elder (2005) called the social turn in the conception of validity. This turn included adopting critical forms of inquiry as part of the validation process, with the aim of uncovering the values and social consequences underlying test interpretation and use. This presentation of validity as an evidence-based judgment continues to be important for validation researchers, despite the fact that what evidence to gather, and particularly how much evidence needs to be gathered, is not at all straightforward. Davies and Elder expressed the frustration of many who attempt to conduct validation research within this frame of reference:

If the notion of test validity and the process of test validation . . . are to be regarded as credible rather than dismissed as the arcane practices of a self-serving élite, they need to be simplified or at least rendered more transparent to test users. (Davies & Elder, 2005, p. 810)

Test Usefulness

In language assessment, Bachman and Palmer (1996) presented such a simplification, which responded to the need for a more transparent framing of the validation process, and this framing was adopted by some researchers in the early 2000s. It is consistent with the perspective of validation that advocates gathering evidence that can be used in an overall evaluation of test use. The phrase “test usefulness” is in this sense a shorthand way of saying “validity of test score interpretation and use.” The types of analysis Bachman and Palmer include pertain to construct validity, reliability, authenticity and interactiveness, impact, and practicality. In language-testing research, this perspective and the practices that these two authors suggest were used in materials aimed at practitioners (e.g., Stoyloff & Chapelle, 2005). The journal articles show that this framework gained some traction: a course-based assessment was evaluated by Spence-Brown (2001) through the use of authenticity and interactiveness, which are components of Bachman and Palmer’s (1996) test usefulness framework. Chapelle, Jamieson, and Hegelheimer’s (2003) evaluation of a Web-based ESL proficiency test was conducted by outlining, for each of the qualities of test usefulness, the evidence suggesting positive results and limitations, or the evidence yet to be gathered. Use of such a framework illustrates how the problems of endless evidence gathering can be addressed in a practical setting, where parameters of time and money have to be considered. Many more such cases exist than those that appear in the journals.

Argument-Based Approach

Within the period of 2006–11 another praxis-oriented approach to validation appeared—namely an argument-based one. The principal characteristics of an argument-based approach are as follows: (1) the interpretive argument that the test developer specifies in order to identify the various components of meaning that the test score is intended to have and its uses; (2) the concepts of claims and inferences that are used as the basic building blocks in an interpretive argument; and (3) the use of the interpretive argument as a frame for gathering validity evidence. These tenets of the validity argument are presented in a number of papers by Kane (2006), most notably in his chapter in the 4th edition of *Educational Measurement*; but they also appear in the influential work of Mislevy (e.g., Mislevy, Steinberg, & Almond, 2003; Mislevy & Chengbin, 2009). In language testing, the approach is also evident in Bachman (2005), Bachman and Palmer (2010), and Chapelle, Enright, and Jamieson (2008). Several studies in the most recent issues of the journals also use an argument-based approach. These studies are discussed in the sections dealing with current research.

Overall, the results reveal an increase in the variety of explicitly identified approaches taken in validation research, especially over the most recent period, 2006 through 2011. From 1996 on, the “one question, three validities” approach seems to be left as a thing of the past. Once evidence-gathering approaches and usefulness approaches were introduced, they continue to be used through the most recent period, even as argument-based approaches appear. As a consequence, it is difficult to identify a one and only current view and practice in

validation, even within the community of scholars who publish their research in the two primary journals in the field.

Current Views and Practices in Validation

Language assessments are used for a wide variety of purposes, and many different people are responsible for their development, use, and validation worldwide, encompassing contexts beyond the journals we examined. Given the variety of testing contexts and test uses, Norris (2008) argues that a single approach to validation would not be appropriate. Instead an approach to validation needs to take into account the context in which tests are used, which includes:

- (a) who uses them, (b) what kinds of information they provide about whom or what, (c) why and how the information is sought, (d) what decisions and actions are taken on their basis, and (e) what consequences are intended (and not intended) to occur as a result . . . (Norris, 2008, p. 73)

One might add that validation practices for language assessments also vary according to the knowledge and beliefs of those responsible and according to the resources available for the validation process. Generally speaking, validation processes are expected to be more thorough and rigorous for tests whose results are used to make high stakes decisions, such as job certification or university admissions decisions, than for low stakes tests whose results are used to provide information to students and teachers in language classes and programs.

Across this variety of contexts and purposes, a fundamental similarity exists: all assessments produce results that need to be accurate reflections of the knowledge and abilities of the test takers and appropriate for their respective uses. The fundamental similarity means that test developers and researchers need to be able to demonstrate that the interpretations and uses of test scores are valid. The evidence used to support validity differs across contexts, as does the manner and place of its presentation. To illustrate the way in which argument-based validity can be used and to highlight some of the differences in validation practices across contexts, we outline the validity arguments for a test used for high stakes decisions and one used for low stakes decisions.

A High Stakes Test

In high stakes testing, scores are used to make highly consequential decisions about test takers and programs, and therefore a need is recognized for rigorous validation practices. The actors involved in the process include government agencies or testing companies, the latter needing to earn the confidence of test users. Such agencies and companies should employ individuals who have been educated specifically in the practices of validation research and therefore have the expertise required to conduct credible research. These professionals are responsible for formulating analytic frameworks required for deciding what research should be done and what data are relevant to constitute evidence for the validity

of test score interpretation and use. The other actors in this process are the test takers and the test score users. In theory, they are the ones who need to be convinced of the credibility of a validity argument; however, in practice, tests are typically chosen for students by score users who count on the professionals to provide appropriate tests.

The validation conducted in one high stakes English language testing program, the TOEFL iBT® (Test of English as a Foreign Language, Internet-based test), serves as an example of an argument-based validity argument. This research is described in an edited volume entitled *Building a Validity Argument for the Test of English as a Foreign Language*TM for an intended audience of other researchers in language testing and applied linguistics more broadly. The purpose of the validation process was to provide research results that would help to justify the interpretations and uses of the TOEFL iBT scores for their intended purpose. The interpretation to be made from test scores is about the examinee's level of academic English language proficiency. The use of the test is for decisions about admissions to English-medium universities as well as for decisions about the appropriate curriculum choice for test takers.

Chapelle et al. (2008) present the validity argument by first stating an interpretive argument containing the following claims: (1) that the tasks on the test were appropriate for providing relevant observations of performance from the examinees on relevant tasks; (2) that the evaluation of examinees' performance resulted in accurate and relevant summaries (test score) of the important characteristics of the performance; (3) that the observed scores were sufficiently consistent to generalize to a universe of expected scores; (4) that the consistency of the expected scores can be explained by the construct of academic language proficiency; (5) that the construct of academic language ability predicts a target score indicating performance in the academic context; and (6) that the meaning of the scores is interpretable by test users, who therefore use it appropriately. An outline of this interpretive argument is shown in Figure 65.1; the claims are marked by a word or expression, and a number refers to the claim indicated above it. The inferences, which are described more fully below, are indicated by nominalizations with "-tion" suffixes.

Each of the claims is different, and therefore the research needed to support each one will be different—that is, tailored specifically to the assumptions underlying the claim. For example, to support the first claim—that the tasks on the test were appropriate for providing relevant observations of performance from the examinees on relevant tasks—it was necessary to examine the language and tasks that students are required to perform in English-medium universities. The research required to support the second claim, about the evaluation of responses, involved studies of the scoring rubrics. To support the third claim, estimates of

Figure 65.1 Schematic diagram of the interpretive argument for the TOEFL iBT (numbers refer to the claims listed in the text)

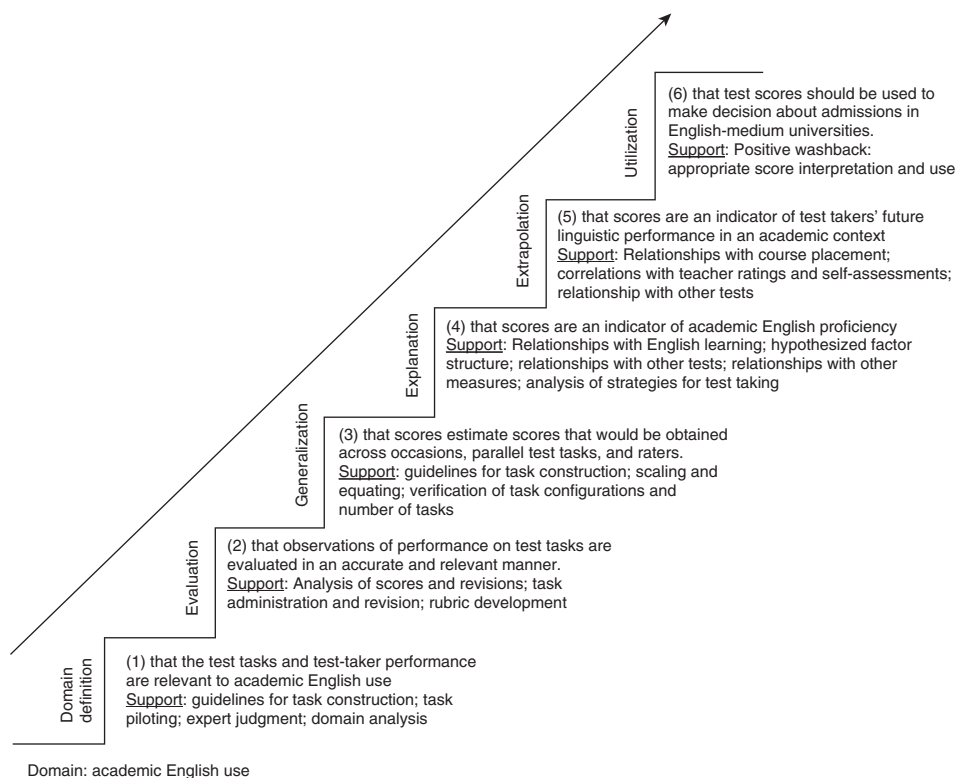

Figure 65.2 Steps in the TOEFL validity argument (adapted from Chapelle, 2008, p. 349). © Routledge. Reprinted with permission

generalizability were calculated and performance from the examinees was examined. The fourth claim was supported through several studies including a factor analysis that showed the test data conformed to the hypothesized component structure. The extensive research is presented in the book outlining the TOEFL iBT validity argument (Chapelle et al., 2008), which describes the multiple research questions and analyses that were used to support the inferences that form the basis of the interpretive argument.

The types of studies are noted briefly in the summary in Figure 65.2, which provides a schematic diagram of the validity argument using a staircase metaphor (Chapelle, 2008, p. 349). The advances in the argument appear as steps that one ascends as inferences are supported. The first step, which makes credible the first claim about the relevance of task performance, is considered to be an inference (called domain definition), and it is supported only with the backing of the appropriate research. It is necessary to have those research results in order to make that inference, in other words take the step up to the next level. Only by getting to that next level can the next inference (evaluation) be made with the appropriate research results, and so on. In this way the argument can be seen as incremental and additive. A gap in the support for any one of the steps reveals a weak stair, which may preclude a continuation to the final intended conclusion.

Low Stakes Tests

In a low stakes testing context, test scores can be used to make diagnostic, progress, or achievement decisions. Frameworks for low stakes tests are unique to the testing situation, and the actors involved in evaluating the tests are instructors and program administrators rather than an external, more public audience. The amount of resources available determines who is involved and how much time is spent on collecting evidence to support test score interpretation and use. The instructors are the ones who need to be convinced of the validity of the tests in order to convey a sense of importance to the test takers. These test takers are usually students in the context of a language classroom.

Although the validation approaches taken in low stakes tests vary widely, an argument-based approach can be applied. The test development and validation underway at an intensive English program at a university in the Midwest United States provides an example. It is a computer-delivered achievement test consisting of five subtests that correspond to instructional objectives for the course. It was developed for an intermediate reading course, as part of an initiative to incorporate into the program a system of assessment for learning. The purpose of the validation process was to provide evidence to justify the interpretations of the test scores as indicators of test takers' level of ability, represented in instructional objectives for the intermediate course. The score is used to make decisions about the students' readiness to advance to the next proficiency level of the reading course in the program. This is an important decision, but it is considered relatively low stakes by comparison with some other uses of language tests (e.g., for certifying job qualifications or for supporting university admissions).

The interpretive argument, which is presented in the same notation used to express the interpretive argument for the high stakes test, is shown in Figure 65.3. The starting point for this test is the intermediate-level reading classroom, because test scores need to be interpreted in relation to this domain. The scores on the tests are intended to indicate how well the test takers have learned the content of that course. The claims in the argument are given in Figure 65.4, but some similarities and differences with the high stakes test are evident from the outline in Figure 65.3. Like in the high stakes test, the interpretive argument for the low stakes test contains the inferences of domain definition, evaluation and generalization, and utilization. Unlike the high stakes test, this low stakes test has an inference called "objectives reflection," which is designed to indicate the need to demonstrate that the course objectives have been well reflected by the test tasks and the abilities that the test measures.

Figure 65.3 Schematic diagram of the interpretive argument for the intermediate reading achievement test (numbers refer to the claims in Figure 65.4)

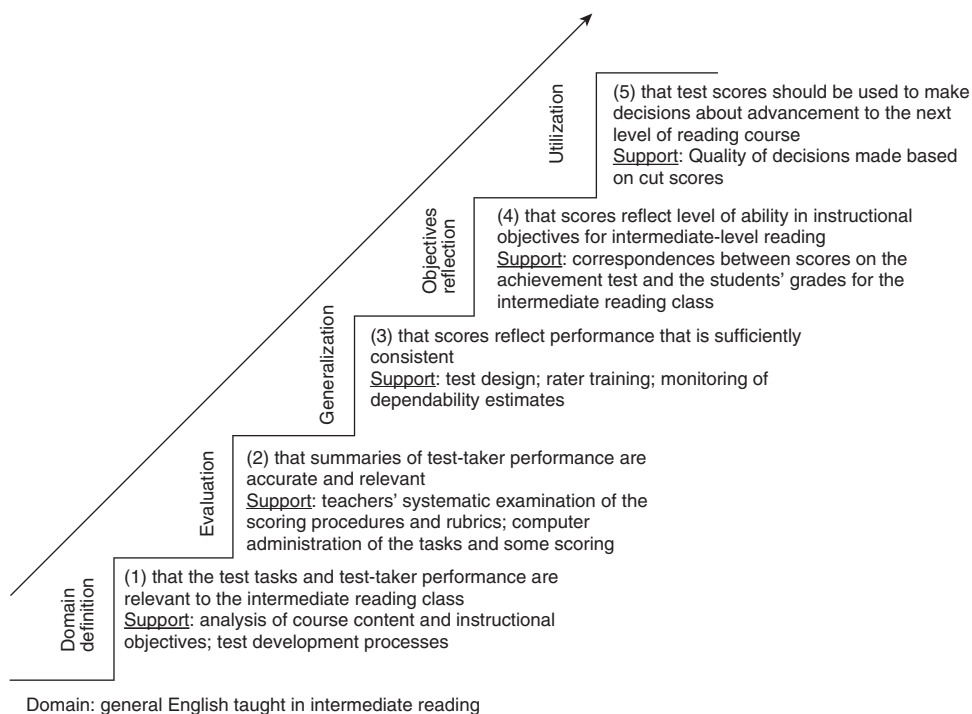

Figure 65.4 Steps in the validity argument for an intermediate reading achievement test in an intensive English program

The validity argument for the low stakes test is outlined in the staircase notation introduced in Figure 65.4. Unlike in the high stakes test, for which extensive documentation exists to explain the support for each of the inferences, the support for the validity argument in the low stakes test remains in the form of data that are kept by the test developer and are known by those working in the testing unit of the language program.

The first step in the argument, domain definition, needs to be supported in order to make the first important claim: that the test tasks and test-taker performance on the reading tests are relevant for eliciting an observable sample of language on intermediate reading tasks. Support for this claim comes from work carried out during test development. First, an analysis was conducted of the course content and instructional objectives by examining the textbooks and online resources used in the course. Second, tests were developed using language characteristics that were identified in the preliminary analysis.

The next step is needed in order to move from a claim about the relevance of the performance sample to one about the relevance and accuracy of the manner used to evaluate the performance. This step of the argument can be taken if an evaluation inference is supported. Support comes from the systematic examination of the scoring procedures and rubrics by the instructors, at the beginning of the course. Instructors also discuss criteria for correctness at meetings before instruction, and again before rating the items not scored by the computer. Their

comments are used to verify the soundness of all procedures or to inform about any revisions in the scoring procedures. The consistency of administration and scoring also gives important support, which is needed to make the inference. A standardized computer-delivered administration of the tests supports further consistency. In addition, automated scoring provides consistent scoring procedures for some of the test items.

Accurate and relevant summaries of test-taker performance offer a basis for making the next claim in the argument—namely that scores reflect a kind of performance that is sufficiently consistent to make the basis for a good estimate of future expected scores, which test takers would receive on a different occasion, on parallel forms, or from different raters. The tests were designed to yield such consistency through a design that included a sufficient number of test items for each subtest and consistent scoring that used automated scoring and rater training. During test scoring and test data analysis, raters are trained on how to use the rubrics. Dependability estimates for the subtests were found to vary from .22 to .88.

Consistent test scores form the basis for the next claim—objectives reflection—that the test can be interpreted so as to indicate that the test scores reflect a level of ability represented in instructional objectives for intermediate-level reading for the class. However, to progress to this next claim, the inference (explanation) needs to be supported by an explanation of how test scores reflect students' knowledge of the instructional objectives for the intermediate reading course. These objectives are the following: to identify supporting details in paragraphs, to summarize a narrative, to understand pronoun reference, to interpret simple bar graphs and pie charts, and to know vocabulary at the 2000 word level. This inference is being supported through examination of the correspondence between scores on the achievement test and the students' grades for the intermediate reading class, which are assumed to reflect students' knowledge of the objectives.

Test use needs to be supported by evidence indicating that the scores are useful for making accurate decisions about test takers' readiness to advance to the next level of instruction. In order to make such decisions, cut scores are needed, and the appropriateness of the cut scores needs to be demonstrated. For the intermediate reading test, a 70% cut score was decided upon as a starting point, and data are being collected and examined to assess the appropriateness of this cut score. The cut score will be determined on the basis of a longitudinal examination of students' and teachers' satisfaction about student end-of-course placements.

Validation in High and Low Stakes Tests

Frameworks for validation across testing contexts can draw upon the same argument-based concepts, but they differ in the specific score meanings that the claims make, in the nature of the support that is provided for each of the inferences, and in the form that the documentation on the validation process takes. The high stakes proficiency test's validity argument includes a theoretical construct of academic language proficiency, in addition to a statement claiming that the score can be extrapolated to performance in the academic domain. In contrast,

this aspect of the validity argument for the low stakes test concerns the need to make a link between the test and the classroom objectives. Support for the inferences is commensurate with the stakes of the test: high stakes necessitate a substantial research program, whereas low stakes are typically carried out with less rigorous research backing. Finally, the public presentation of research results is typical for high stakes testing but less common in low stakes testing.

Current Research

As shown in Table 65.1, recent papers that explicitly present an approach to validation are split between an evidence-gathering approach to validation (13.33%), a usefulness framework (8.89%), and an argument-based approach (11.11%). However, given the recentness of argument-based validation, one might speculate that this approach may appear more in the future; it is therefore worth taking a closer look at the current validation studies that take an argument-based approach. The argument-based approach appears in validity arguments for both high and low stakes assessment, which is consistent with the section “Current Views and Practices in Validation.”

In a high stakes test, Enright and Quinlan (2010) present an argument-based approach to contextualize their research, which collected evidence in the evaluation of the human and electronic rater (e-rater) scoring of a writing task. The authors develop their argument for the TOEFL iBT writing task by using the following four inferences: evaluation, generalization, extrapolation, and utilization. Support for each inference comes from their empirical studies of the relationship between the scoring of human raters and e-rater scoring, of reliability estimates for combinations of human and computer scoring, of correlational studies with other measures and other nontest criteria, and evidence that will be collected regarding the consequences of using automatic essay scoring. In another test intended for high stakes use, Bernstein, Van Moere, and Cheng (2010) presented an argument-based approach for their validation of a test of speaking ability, which used automatic scoring of spoken language. While the authors do not use the same terminology for inferences in the interpretive argument, they gather evidence related to (1) the accuracy of the test score (evaluation inference), (2) test score consistency (generalization inference), (3) the relationship between the automated test and score on other communicative tests (explanation inference), and (4) the target domain (extrapolation inference). In addition, the authors present counterclaims and support in case of a potential rebuttal.

Other recent articles describe validation procedures for low stakes testing. For example, Pardo-Ballester (2010) applied Bachman’s (2005) assessment use argument approach to a Spanish listening test, to support the score interpretation and use for the placement of students in Spanish classes at university. The claims about test score meaning included three of Bachman and Palmer’s (1996) qualities of usefulness: reliability, construct validity, and authenticity. Another example of an argument-based approach in a low stakes test is a test of productive grammatical ability (Chapelle, Chung, Hegelheimer, Pendar, & Xu, 2010). The validity argument outlined in that paper provides support for five inferences: evaluation,

generalization, explanation, extrapolation, and utilization. Finally, a study by Koizumi et al. (2011) offers an example of a validity argument for a low stakes diagnostic test of grammar designed for Japanese learners of English. The evidence from the research supported three inferences in a validity argument; statistical characteristics of test items were appropriate for making the right decisions (evaluation inference); reliability was high (generalization inference); and test scores were consistent with the difficulty of certain grammatical features like noun phrase (NP) groups (explanation inference).

Current studies show the many possible arguments that can be constructed from the basic idea of inferences and claims. These studies do not include all of the steps in the examples shown above, from domain definition through utilization; they include the claims and inferences that are important for the score meaning of a particular test. Alternatively, the formulation of the argument and the evidence presented may be due, in part, to the length restriction of the publication. Another reason for the partial validity arguments in many studies may be that authors chose to write about the inferences that needed attention most, rather than about all the evidence pertaining to the complete argument. "Validity evidence is most effective when it addresses the weakest parts of the interpretive argument" (Kane, 1992, p. 530). Some authors may therefore focus on these more challenging links—for instance those made on the basis of automated scoring. In fact the formulation of an interpretive argument may help test developers and researchers to better deal with the challenges in validation.

Challenges

A number of challenges are inherent in the validation of language tests. One appears at the most basic level: that of defining the relevant domain of language use in a manner that can help develop the test and interpret test results. The relevant domain, be it an academic context, a reading classroom, or any other context, is dynamic and complex. In the case of the achievement test for the reading class, for example, changing materials regularly makes it necessary to redesign the test and to support that the test scores reflect the objectives across time. For example, in the case of the low stakes reading test described above, prior to the summer of 2010, students were using books for reading and vocabulary development that could be examined in order for test developers to identify a pool of vocabulary words to be tested. However, an online source for vocabulary development replaced the book, which made it difficult to define the domain of actual words studied.

A second challenge comes from the variety of professional perspectives that can come into play in the validation process. In a high stakes proficiency test, the construct of language proficiency can be defined in many different ways. Establishing a meaningful basis for interpreting test scores can therefore open up many interesting but complex issues in applied linguistics. The validation of tests in a language program is integrally tied to teaching, which is carried out by many different people with varying degrees of interest in the testing process. Even with set instructional objectives, teachers interpret the objectives differently, and therefore there is variety in how objectives are addressed and in how much time each

objective is given in the classroom. For an instructional objective such as summarizing a short text, for example, one teacher might require a student to write a summary while another might be satisfied if a student can identify the main idea of the text.

A third challenge arises from the use of technology in test administration. Potentially technology offers significant advantages for standardizing test administration, which is one means of supporting the claim that relevant performance is obtained from the test taker. At the same time, however, the reality of human-computer interface issues and glitches, as well as limited familiarity with the keyboard on the part of some students, can create some problems for the validity of individual test scores. Some teachers also raise concerns about the comparability of the performance obtained in an online test with the performance of interest in both online and face-to-face contexts.

These and other challenges are sharply delineated in an argument-based approach to validation because each aspect of the score's meaning needs to be stated and potential threats to the validity of making such interpretations must therefore be identified. In the terms used in argument-based validation, rebuttals need to be identified, and research is required in order to assess the extent to which rebuttals are supported. The clarity of this approach promises to pinpoint some areas of challenge in the process of test validation, in a manner that should allow for fruitful discussion of solutions. For example, when the validation argument makes claims about the correspondence between test tasks and tasks in the domain of interest, support for such claims may need to be stronger and more principled than simply claiming authenticity. Another example comes from examining the support for an evaluation inference in a validity argument. Such support needs to come from a demonstration that the aspects of performance evaluated are relevant to the construct to be measured. In language assessment, such a justification needs to be based on scoring rubrics and their use, as well as on a description of automated response analysis systems. Both forms of justification present challenges for applied linguists.

Future Directions

It seems evident that, in the immediate future, work in language test validation will seek to better understand the use of argument-based approaches to validity, as they can help to yield useful information across a variety of contexts. Language assessments are used by many different people and for many different purposes in language education and research. Therefore the need exists to better understand and conceptualize how principles and methods in validation research can best be used to investigate the quality of assessments for their respective purposes. Like language testing, the process of validation itself is conducted for many different purposes. Norris (2008) points out that, in view of the variety of reasons for conducting validation research, appropriate variations in validation practices need to be formulated. "Accountability, knowledge generation, development, improvement, learning, advocacy, and other rationales each may be posited as the primary driving force behind a validity evaluation" (p. 73). Each of these purposes is likely

to be served by a distinct set of data collection procedures during validation. Moreover, in each situation where validation work is conducted, validity arguments need to stand up to the analysis of critics. In other words, validity arguments themselves need to be evaluated for their completeness, coherence, and degree of support.

The historical perspective outlined above relied on an analysis of published work on validation, but this is only a small selective subset of all of the validation work being conducted. It is an important subset in that it reflects professional perspectives. A more representative view would be considerably more difficult to capture, because it is revealed through the work of testing programs that publish tests and their technical manuals as well as assessments used in language programs and the work that goes into their development, use, and revision. In short, test validation work takes a wide variety of forms in practice. But it is likely that there remains plenty of language testing that has not benefited from validation. Therefore many test developers see the need for an education of the profession at large in the principles and practices of validation. It remains to be seen whether or not argument-based approaches will gain traction in the many testing programs that would benefit from their use.

Fairness and Justice in Language Assessment

Antony John Kunnan

Nanyang Technological University, Singapore

Introduction

The concept of *fairness*, as related to assessment and assessment practice, has been debated regularly since the late 1980s by researchers and practitioners. In the field of educational assessment, the concept of fairness was first introduced in employment-related testing of the General Aptitude Test battery (Hartigan and Wigdor, 1989). In language assessment, the term was first discussed at the Language Testing Research Colloquium in Finland when Kunnan (1997) presented a case for a fairness research agenda. Fairness also soon made its way into the influential *Standards for Educational and Psychological Testing* (APA, AERA, & NCME, 1999) with a section titled “Fairness in Testing” and subsections on fairness in testing and test use, the rights and responsibilities of test takers, testing individuals of diverse linguistic backgrounds, and testing individuals with disabilities. Codes of ethics and practice based on this pioneering work have now been established by many assessment agencies such as the International Language Testing Association, Educational Testing Service, Princeton, University of Cambridge, and the Association of Language Testers of Europe, among others. Since 2000, there have been frequent publications on fairness as a concept (Kunnan, 2000, 2004, 2008; Walters, 2012), situated ethics (Kunnan & Davidson, 2004), how to investigate fairness (Kunnan, 2010; Xi, 2010), differential item functioning as a method for detecting biased items (Ferne & Rupp, 2007), accommodations for test takers with disabilities (see Chapter 67, Accommodations in the Assessment of English Language Learners), the intersection of fairness and justice (McNamara & Ryan, 2011), and legal matters related to fairness (see Chapter 92, Language Testing in the Dock).

Disagreements, however, have regularly surfaced in these debates. The first is to do with the interpretation of the term. Depending on the researcher’s

perspective, fairness has meant “absence of bias,” “equal opportunity,” “equitable treatment,” “similar outcomes in terms of scores,” and so on. Additionally, the scope of the term has been contested (Kane, 2010; Xi, 2010): Does fairness include validity or does validity include fairness? Or are they two separate entities? This has led many researchers to set aside the concept of fair assessments as inferior to validation efforts. Davies (2010) even asked whether it was worth paying attention to. Finally, no foundational principles that drive the concept have been articulated; as a result, critics have argued that fairness studies are incoherent (e.g., Bachman, 2005). As a result, fairness is often invoked with ad hoc and post hoc investigations after assessments are written and launched but it is not part of the assessment design, development, administration, and standard-setting processes. A good example is the class of DIF/bias studies that examine test performance, often with no a priori hypotheses.¹

The term *justice*, on the other hand, is rarely mentioned in the assessment literature, although the idea of justice has been discussed in writings from Plato to recent work by John Rawls and Amartya Sen. Once again, the term is difficult to define. A few interpretations include “distributive justice,” which refers to institutions providing benefits that are distributed to a society in a just manner, “retributive or corrective justice,” which refers to whether punishments are just, and “compensatory justice,” which refers to fair compensation for injuries. In language assessment, Kunnan has tied the two concepts of fairness and justice together (Kunnan, 2004, 2008) and McNamara and Ryan (2011) have wrestled with the two concepts to offer separation and clarity to the concepts.

This chapter attempts to provide principled bases for fairness and justice as applied to the institution of assessment. It does this by applying the *idea of fairness as relating to persons—how assessments ought to be fair to test takers*—and the *idea of justice as relating to institutions—how institutions ought to be just to test takers*.

Preliminaries

Despite the disagreements regarding the concept of fairness, the very concept of the public examination (or assessment) includes notions of fairness and justice. This can be seen as the main goal of such examinations, which is to bring about a level playing field in awarding benefits through a process that assesses desired abilities; not to award benefits based on privilege and patronage. This was the main goal of the civil service selection process in China centuries ago, and in France, Germany, the UK, and colonial India in the late 18th and early 19th centuries. In more recent times, related concepts of equality, equal protection, and equal representation have become part of public discourse in most parts of the world, although such discussions have not always resulted in the active promotion of fairness, equality, and civil rights. Thus, in many countries fairness in schooling and employment has been advanced through fair assessments and just institutions.

The more practical aspects of fairness are noticeable. For example, anonymizing examination responses by removing test takers’ personal information so that test takers cannot be identified; the use of topics in test materials that are familiar to test takers; investigations regarding biases toward test

takers from different language, gender, age, and ethnic backgrounds and biases of raters and ratings; checks regarding whether test takers have had the opportunity to acquire the knowledge or skills prior to the assessment, and the use of appropriate accommodations for test takers with disabilities. Therefore, in many contexts, the practical aspects of fairness are not new. With this background, a few preliminary questions can be articulated:

1. Does every test taker have the right to a fair assessment? Is this rule inviolable? Are rights of test takers to a fair assessment universal or only applicable in states that provide equal rights?
2. Is it adequate that most test takers are assessed fairly while a few are not? Would it be appropriate to use a cost-benefit analysis to evaluate whether assessments should be improved or not? And, if harm is done to test takers, does such harm need to be compensated?
3. Would the rights of test takers to a fair assessment be supported in authoritarian states that do not provide for equal rights? Would institutions in such states feel less compelled to provide a fair assessment?
4. Should an assessment be beneficial to the society in which it is used?
5. Should assessment developers and users be required to offer public justification or reasoning?

The chapter continues with hypothetical vignettes and real-world examples and reflections on these scenarios. These vignettes exclude concrete realistic details so that we can focus on a limited number of issues. Arguments from normative ethics regarding fairness and justice are then discussed in order to provide appropriate background for the proposed principle of fairness and principle of justice. The chapter concludes with how these principles can be used to advance fairness and justice in language assessment.

Vignette 1: Pretesting of assessment tasks

Imagine a new staff member has joined a large professional language assessment organization (university or commercial) that develops assessments for high stakes contexts. After she had worked at the organization for three months, she began to be concerned about many of the agency's practices. She took note of them: First, they did not pretest or trial their test tasks; instead, they used the non-pretested tasks in a real administration and did not delete the scores from those tasks when they computed the scores for the test takers. In other words, the test takers received scores that included tasks that were not pretested. The staff member approached her supervisor who was head of assessment development. He was at first disinterested in the staff member's concern but later admitted that pretesting tasks would cost too much money for the organization, and, if they conducted a pretest, the assessment would also cost the test taker much more.

The main questions here are: Did the staff member do the right thing in bringing to the attention of her supervisor the lack of pretesting? Is pretesting of tasks for high stakes assessments a requirement? Is the head of assessment development's

lack of understanding of the situation acceptable? Are his reasons for not conducting any pretesting justified? Would people of any persuasion (teachers, test takers, business leaders, etc.) be able to defend such a practice? Is there a violation of an accepted code of ethics and practice? Would this be an example of an unfair assessment?

Vignette 2: Checks for biased assessment items/tasks

Continuing with Vignette 1 . . . The staff member also found that the organization did not conduct any review or investigation to examine whether the assessment was fair to all test takers in terms of content, dialect, test delivery, or test performance. She brought this matter up with her supervisor too. The supervisor said that, while these are important matters, the organization did not have staff with expertise to conduct such investigations. He also reminded her that, once again, these investigations would cost the organization a lot of money and the final result would be that the assessment would cost the test taker more.

Once again, the main questions here are: Did the staff member do the right thing by bringing to the attention of her supervisor the lack of any investigations regarding fairness? Are such investigations required in an assessment that is a high stakes assessment? Are the supervisor's reasons for not conducting these investigations defensible? Is there a violation of an accepted code of ethics and practice? Would this be an example of an unfair assessment?

Arguments From Philosophy

One way to understand the concept of fairness and justice is to step back from its current theory and practice in assessment, and to examine how the concept is used in normative ethics (an important branch of philosophy). In this field, there have been numerous attempts at debating the concept of moral reasoning from normative ethical theories. Ethical dilemmas that we face include right and wrong, fair and unfair, equality and inequality, just and unjust, and individual rights and common good. The main theoretical perspectives and proponents in philosophy are: utilitarianism (Bentham, Mill) and social contract/deontology (Kant, Rawls, Sen).²

Utilitarianism

The dominant Western philosophical doctrine for many centuries until Rawls's work appeared was that of *utilitarianism* advanced by Bentham and Mill.³ Its thinking is that the highest principle of morality is to maximize utility and to balance pleasure over pain. It promotes the notion of the greatest happiness of the greatest number of people. As a result, the utility principle trumps individual rights. Related to this, the most important aspect of utilitarianism is *consequentialist* thinking in which outcomes of an event are used as tools to evaluate an institution. Thus, implementing utilitarianism in the assessment context would

mean that decisions about an assessment would be made solely on the basis of utility and consequences.

Rawls's *Justice as Fairness*

Rawls's (1971, 2001) theory and arguments of justice and fairness have been the basis for wide discussions in moral philosophy/reasoning from the 1970s onwards. His main focus is on inequalities in citizens' life prospects. In formulating a theory and principle of fairness and justice, he argues that *fairness is prior to justice* but foundational and central to justice, and that *fairness relates to persons* and *justice relates to choice over institutions*. In this chapter, these two terms will be used accordingly. To quote from Sen's (2009) summary of Rawls's work:

In the Rawlsian theory of "justice as fairness", *the idea of fairness relates to persons (how to be fair between them)* whereas the Rawlsian principles of *justice apply to the choice of institutions (how to identify "just institutions")*. The former leads to the latter in Rawls's analysis. (p. 72, emphasis added)

The case for justice as fairness that Rawls makes is a moral philosophy for a "well-ordered society" that has a "fair system of social cooperation" and has "citizens who are free and equal persons." Rawls's intention here is that, for his theory to work, society has to be well ordered—in other words, democratic—with a representative government and, as Sen puts it, with a "government by discussion" and not just with elections and balloting. Further, Rawls argues that members of such a society should accept the concept of justice and be free and equal to have the moral capacity to do this.

Rawls presents a procedural plan for how a just institution can provide social arrangements that promote justice. He introduces three inter-related concepts: the hypothetical thought experiment which he called "the original position and the veil of ignorance," "public justification," and "reflective equilibrium." In Rawls's original position and veil of ignorance, members of a society are not allowed to know their social position in society, any of their backgrounds (race, ethnicity, or gender), or their endowments (capabilities, talents). Therefore, as members do not know anything about themselves, they will not be able to gamble to become beneficiaries of any benefits. This setup, Rawls argues, would give members a way to derive principles of justice without any biases or prejudices as they know any decisions they make could affect them.

The principles of justice Rawls posits that would emerge from such a procedure would have unanimous agreement, although he amended this later (2001, p. 32) to accommodate the idea of "overlapping consensus," as he recognized the limits of agreement on justice in pluralistic democracies where conflicting religious, philosophical, and moral doctrines may make unanimity unlikely. Finally, for justice as fairness to work, Rawls contends, public justification is a necessary part of the process. He argues that it is necessary to justify political judgments to fellow citizens so that public consensus can be reached. He also suggests the use of the methodology of "reflective equilibrium" to help in the public justification process. In this methodology, initial ideas, beliefs, or theories are subjected to reason,

reflection, and revision until the ideas, beliefs, or theories reach a state of equilibrium in public justification.⁴

Rawls offers two principles of justice as way of guidance in the design of just institutions. The *first principle of justice* states:

Each person has the same indefeasible claim to a fully adequate scheme of equal basic rights and liberties, which scheme is compatible with the same scheme for all. (2001, p. 42)

This principle includes five sets of basic liberties: liberty of conscience and freedom of thought, freedom of association, equal political liberties, the rights and liberties that protect the rights and liberties of the person, and rights and liberties covered by the law.

The *second principle of justice* has two parts: The first part, the *equal opportunity principle*, is familiar as examinations in general provide fair equality of opportunity. The institution of examination by assessing abilities opens up opportunities that would otherwise be available only in terms of heredity, nobility, and social position by birth. The second part, the *difference principle*, refers to economic opportunities in which the least advantaged members of society are better off when primary goods are unequally distributed (between least advantaged and more advantaged members) than when primary goods are equally distributed between the two groups.

In summary, in Rawls's theory of justice as fairness, the focus is on developing ideal just institutions by identifying what just institutions would look like. This, Rawls proposes, can be achieved in a well-ordered society with free and equal citizens interested in social cooperation to bring about justice as fairness. By using the original position and the veil of ignorance, principles of justice can be publicly justified by the process of reflective equilibrium.⁵ When this is done, principles of justice would emerge as guidance to build a just institution.

Sen's Idea of Justice

Sen advances Rawls's thinking significantly with some major ideas. First, he contends that Rawls's theory of justice as fairness is primarily aimed at the ideal of establishing just institutions (which Sen terms "transcendental institutionalism") and that it does not have any mechanism to evaluate human transgressions that bring about unjust societies through public reasoning.⁶ Sen (2009) contends that Rawls's approach is *arrangement-focused* (justice conceptualized in terms of organizational arrangements like institutions, regulations, behavioral rules, and the active presence of these would indicate that justice is being done). This is in contrast to Sen's view of justice as *realization-focused* understanding of justice (examining what emerges in society, the kind of lives people can lead, given the institutions and rules, but also actual behavior that would inescapably affect human lives).

Second, Sen (2009) invokes Adam Smith's thought experiment of the "impartial spectator." This device, Sen argues, could be used "when judging one's own conduct, 'to examine it as we imagine an impartial spectator would examine it'" (p. 124). Sen argues that this approach of the impartial spectator has a major advantage over Rawls's original position with a veil of ignorance in arriving at principles of justice. Although both approaches attempt to remove the vested interests and goals of individuals, spectators or disinterested people from other societies can participate in deliberations in Smith's approach whereas outsiders are restricted in the Rawlsian approach. Sen argues that Smith's open impartiality—including the voice of the people who do not belong to the focal group—is superior to Rawls's closed impartiality—restricting the voice of the people to focal group members—as it provides the opportunity for cross-societal and crossborder deliberations.

In a related point, the nonparochial, global perspective view is a central part of Sen's thesis. He is concerned about the parochial nature of nations when it comes to the service of justice for two reasons: First, what happens in a particular country in terms of how its institutions operate can have huge consequences on the rest of the world, and, second, each country or society may have parochial practices that need to come under examination and scrutiny from others with distant judgments who are impartial spectators.⁷ Further, the global reach of justice is necessary in a world where globalization is taking place in other areas: trade, commerce, business, travel, technology, and so on.⁸ Similarly, Sen also criticizes the view of Asian government leaders from Singapore, Malaysia, and China regarding "(East) Asian values." Their leaders argue that the denial of political and personal freedoms and suppression of media freedoms in exchange for economic growth are part of "Asian values," different from those of the West. This is defective reasoning, Sen argues, as Asian countries have a tradition of democratic values and principles as well.⁹ Recall Martin Luther King's warning: "Injustice anywhere is a threat to justice everywhere."¹⁰

Third, Sen argues that public reasoning is a critical component in advancing justice. His requirements are similar to those of Rawls: in this case, a well-ordered society—in other words, a democratic state (in the sense of "government by discussion" with political and personal freedoms)—with free and equal persons (who are capable of challenging injustice) that would be able to safeguard principles of fairness through public justification and reasoning. Such states would have in place transparent mechanisms for the fair selection and use of assessments, public reasoning of the assessment in use (in public forums), and regulations and laws that have adequate provisions for appeals and redress. An authoritarian regime, on the other hand, with few or no political and personal freedoms, will be less compelled to need or allow public justification and reasoning of principles of fairness. The lack of such reasoning along with inadequate accompanying regulations and laws for appeals and redress would make it difficult for such institutions to be just.

In summary, Sen argues that the focus of justice must be on the advancement of the cause of justice through the methodology of public reasoning. His methodology for doing this is through the distant judgment of the impartial spectator in his open partiality mode with outsiders and the world examining and scrutinizing

the practices of just institutions. He also indicates the need for a global reach of justice.

Applying Fairness and Justice

General Issues

Drawing on insights from Rawls and Sen on fairness and justice, we can now consider how their ideas and arguments can be applied to language assessment. First, individual rights and inequalities in test takers' life prospects have to be the central focus of the application. The main idea is that assessments ought to be fair and assessment institutions ought to be just to all test takers. Second, Rawls's idea of public justification and Sen's public reasoning have to be part of this application.

Two Principles of Fairness and Justice

Based on Rawls and Sen, two general principles and subprinciples of fairness and justice are proposed:¹¹

Principle 1—*the principle of fairness*: An assessment *ought* to be fair to all test takers, that is, there is a presumption of treating every test taker with equal respect.

Subprinciple 1: An assessment *ought* to provide adequate opportunity to acquire the knowledge, abilities, or skills to be assessed for all test takers.

Subprinciple 2: An assessment *ought* to be consistent and meaningful in terms of its test score interpretation for all test takers.

Subprinciple 3: An assessment *ought* to be free of bias against all test takers, in particular by avoiding the assessment of construct-irrelevant matters.

Subprinciple 4: An assessment *ought* to use appropriate access, administration, and standard-setting procedures so that decision making is equitable for all test takers.

Principle 2—*the principle of justice*: An assessment institution *ought* to be just and bring about benefits in society and advance justice through public reasoning.

Subprinciple 1: An assessment institution *ought* to bring benefits to society by making a positive social impact.

Subprinciple 2: An assessment institution *ought* to advance justice through public reasoning of their assessment.

A few remarks regarding the principles are necessary here. To begin with, the first principle, the principle of fairness, is prior to the second, the principle of justice, because if the first principle is not satisfied, then the second principle cannot be satisfied. In other words, if the presumption that treating every test taker with equal respect in an assessment is not satisfied, then the assessment will not succeed in being beneficial to society and bring justice to society. In terms of the relationship between the general principles and the subprinciples, the respective subprinciples provide the framings for the two general principles, and

therefore the subprinciples have to be individually satisfied in order for the general principle to be satisfied.

Second, the principles and subprinciples are written as obligations (obligatory actions signaled with the use of *ought*) and not as categorical or unconditional imperatives, but the assumption is that there will be universal application. As argued earlier, justice should be nonparochial and impartial beyond one's society as everyone should be treated in the same manner. This is particularly true of current globalized assessment institutions that operate in numerous countries. It does not seem defensible to propose otherwise, despite the objection of being imperialist as to how there could be different approaches to fairness and justice.

The Principle of Fairness: Grounds and Objections It is necessary to explicitly make a general case for this principle by articulating the grounds and rejecting some common objections. First, the principle states that an assessment ought to be fair to all test takers, which includes a presumption of treating every test taker with equal respect. This emphasis on the test taker rather than an assessment or its scores should be sufficient to reject the argument that validity of an assessment (or valid score interpretations or validity arguments) guarantees that all test takers will be treated with equal respect. The focus of validity concerns has either been on the assessment itself or at most on various aspects of assessment practice; the focus has never been on the individual test taker.

Second, the subprinciples provide guidance for detailed investigations of assessments so that a number of grounds for the compliance or noncompliance with the principle can be arrived at. Researchers could conduct investigations relevant to the subprinciples to build arguments regarding the general principle of fairness. The subprinciples focus on the test takers' opportunity to learn, the meaningfulness of the assessment to the test taker, and whether the assessment is free of bias and standard setting has been conducted in an equitable manner. These matters are relevant to the individual test taker and affect the test taker positively or adversely depending on the qualities of the assessment. Thus, they are essential components of the general first principle.

The Principle of Justice: Grounds and Objections As mentioned earlier, this principle follows the first principle but it is a necessary component. First, the principle states that an assessment ought to bring about benefits to society and that such institutions promote just institutions. The overall benefit to society should be the primary motivation to build any assessment in society; that is, if the motivation to build an assessment is not to resolve some difficulties and bring about benefits to society, one could conclude that there may not be a need for the assessment. This is particularly the case if an assessment is likely to cause adverse effects on test takers and society.

Second, the institution of assessment is not any different from institutions like banks or universities. But assessment institutions have a higher responsibility in society than the Department for Beautiful Gardens as assessment institutions are responsible for awarding benefits to test takers that can alter their life prospects. If such institutions bring benefits and just institutions, then the principle of justice is satisfied.

Finally, while it is possible that assessment institutions may have different ways of defending their assessments, it is essential that there is public reasoning of assessments. This can be offered through public forums such as conferences or research reports available to the public.

Challenges From Vignettes

Let us now consider vignettes from different assessment contexts that illustrate some real-world challenges. These challenges need to be resolved by assessment developers, administrators, score users such as administrators, teachers, and test takers, and decision makers. Some of the vignettes are related to the principle of fairness while others are related to the principle of justice.

Vignette 3: Defective tasks

Imagine there were two forms of a paper and pencil assessment—Forms A and B. The forms belonged to a high stakes university admissions assessment. It was known previously through pretesting that there were a few defective tasks in the two forms: 10 tasks in Form A and 5 tasks in Form B out of a total of 100 tasks in each. But the administrator went ahead and used both forms as a cost–benefit analysis conducted earlier showed that only 10% of the test takers who took Form A and 5% of the test takers who took Form B were misclassified as failed due to the defective tasks. She felt these figures were within the usual margin of error. The administrator also wrote in her report that the cost of replacing the defective tasks (designing and writing new tasks, pretesting them, assembling them into the forms, and printing the new assessments) would be much higher than that of errors in classification, although she did not assign a monetary value to the misclassified test takers’ lost opportunities due to the errors.

If we consider the different philosophical persuasions, each may take a view that supports or criticizes the actions of the administrator. The utilitarian could take the view that the cost–benefit analysis provided the basis for the administrator’s decision, and that such decisions have to be made in order to run a profitable business. The utilitarian could also concede though that the administrator should have preferred Form B to Form A as it had utility. The contractarian could argue that the administrator did not act morally as she did not uphold the rights of all test takers to a fair assessment by holding defective assessments. These arguments could lead us to some important questions: What should the administrator have done? Which of these perspectives appeals to us? What is the right thing to do?

Vignette 4: Compensation for misclassification

Continuing with Vignette 3 and expanding it . . . Imagine further that the administrator was convinced of her error and agreed to pay compensation to the test takers who were misclassified as failed. She offered a free retake of the assessment at a later date (as per the contract issued by the agency) but the results would be available only after the completion of the university

admissions cycle. The test takers were not satisfied with the remedy offered: Some test takers wanted more compensation, while others planned to file a law suit in court against the assessment agency.

This action raises additional questions regarding the right thing to do. The utilitarian could claim that the consequences of the assessment were mostly successful as most test takers were assessed appropriately, thus satisfying the principle of maximizing utility and the maxim of “greatest good for the greatest number of people.” Further, as the assessment did not provide sufficient utility for these test takers who were erroneously misclassified, they were offered compensation as per the contract. The contractarian could argue that the administrator did not carry out her duty and therefore should be tried for dereliction or breach of duty, as she did not uphold the rights of all test takers to a fair assessment. The argument could then be made that the administrator and her agency should face a tort, product liability, or a similar lawsuit that would be available in a just institution. These are simplified arguments from different perspectives, but they nevertheless indicate how difficult it is to do the right thing. Both the vignettes above pose problems for the principle of fairness and in particular subprinciples 3 and 4, and the principle of justice and in particular subprinciple 2.

Vignette 5: Selecting an assessment

Now imagine a school teacher—or a group of teachers—were authorized by the school principal to choose an assessment for a grade 8 reading class in English. The teachers had to choose from three assessments that were commercially available: Test A was developed by a well-established company known for its quality products, the test was traditional and was broadly suitable in terms of content, it was normed for the national population, and it cost \$500 for a class of 40. Test B was developed by a small local company, it was highly suitable in terms of content, it was normed for the local population and checked for fairness, it was proven to offer accurate results and useful diagnostic information, and it cost \$800 for a class set of 40. Test C was an innovative test developed by teachers from another local school, it had not been analyzed yet but was available for free for the class.

The main question is: On what grounds should the teachers choose from these assessments? Should the decision be based on cost? If the decision were to be made on this ground, the choice would be Test C even though the assessment had not been analyzed; the argument could be that the assessment was not high stakes in grade 8. Another consideration would be consequences and fairness—whether the assessment would have consequences that were beneficial to the students and the community. If the decision were to be made on this ground, the choice would be Test B. This would appeal to the consequentialist doctrine. Yet another consideration would be the quality of the organization developing the assessment. If this was the ground, then it would be Test A. You will see that the choice is not straightforward and the teachers have to weigh several factors such as quality, cost, and so on in order to make their choice.

Vignette 6: What was the quality of the assessment?

Imagine a high stakes high school exit examination that is conducted by the ministry of education in a country. The examination had been in use for many years and students worked hard during the months prior to the examination. After the examination, some students got together and exchanged thoughts on the examination. They concluded that some of the questions were tasks and topics that were new to them. When the results were announced, it turned out these students had received low grades. Apart from feeling upset, the students could do nothing else (there was no review or appeal process in place) but their parents went to the ministry and complained that something was wrong with the examination. The ministry officials said that there could not be anything wrong as their examinations were written by expert senior teachers who had been doing this for decades. When pressed to show that the examination was an appropriate assessment procedure, the ministry officials defended their examination by saying there were no prior complaints and therefore no analysis of the examination was conducted as it was not necessary.

The main question here is whether the ministry had the motivation and expertise to provide the best possible examination. There were numerous problems with the examination from an equal rights perspective (a Rawlsian concern): Did some of the students not have the opportunity to learn all the material? Did their school or teacher perhaps not cover all the topics? In which case, did the assessment have utility (a utilitarian concern)? Did the ministry's regulations not have any provision for review or appeals? Further, were there no analyses of the examination tasks conducted although they were written by experts? Were there no research studies that examined the quality of the assessments and the test performance? Was the examination providing a beneficial service to the community? Did the ministry owe the student community public justification (Rawlsian requisites)? Finally, was the ministry acting responsibly? In general, Rawlsian theorists would in particular be up in arms with the ministry's lack of provision for basic rights to the students and its dereliction of duty to the students and community.

Vignette 7: Public reasoning of the assessment

Continuing with Vignette 7 and expanding it . . . Imagine that the parents of the students who received low grades protested against the ministry's approach and demanded that they provide a public justification of the assessment. The ministry replied with a firm NO as it had never responded to such a request before and did not consider it necessary to do so.

Once again, the test takers were denied basic freedoms such as the basic right to be treated with respect and dignity, to have fair assessments and assessment practice. They could also argue that public reasoning (in public forums) would be the only way to ensure that the assessment is fair and the institution is just. Both these vignettes pose problems in terms of the principle of fairness and all its subprinciples. Vignette 7 in particular poses a problem for the principle of justice and its subprinciple 2.

Vignette 8: The role of differential pricing

Imagine you received a questionnaire from a well-known assessment developer and publisher who is planning on introducing differential pricing to test takers for different services. Which of these would you find acceptable? The proposal is higher test-taker fees for new services. Thus, there would be two levels of pricing: regular pricing for regular assessment and premium pricing for additional services. Here are the additional services for premium pricing: Better assessments with higher reliability and thorough validation and fairness studies, individual diagnostic feedback instead of generic feedback, better raters who are experienced and not severe in their ratings, faster turn-around time for results, front row seating for the listening section (where audio speakers are in front of the test room), fast-track line for speaking tests/interviews, better test room facilities (air-conditioning, heating, plus seats), relaxed time conditions (more and frequent breaks), assistance from spell and grammar checks for the writing test, upgraded technology (computers, monitors, keyboard and mouse, color photos, and video), accommodations for test takers with disabilities, no experimental section included in the assessment, repeat assessment within a few days, re-evaluation of assessment performance by two human raters, and return of responses to tasks to test taker (selected and constructed responses on items/tasks).

The main questions are: For which of these services would we consider differential pricing appropriate? On what grounds would we accept or not accept differential pricing? Is the market forcing us to change our ethical behavior? Is there an obligation on the part of the assessment developer to offer some of these services without differential pricing? Would the differential pricing for some of these services violate the principles of fairness and justice?

Advancing Fairness and Justice

The earlier section considered how Rawls's and Sen's ideas can be applied to language assessments in order to design and establish just institutions by examining hypothetical vignettes. But it is also important to simultaneously explore how institutions can advance the principles of fairness and justice and remove existing unfairness and injustice in current society. Any example of unjust practice should motivate skeptics about the need for action should such practices be identified. For example, recall the discriminatory practice behind the dictation test given to immigrants in Australia in the 1900s during the country's White Australia policy (McNamara & Ryan, 2011). If such a policy were to be in place now, we could ask on what moral principles such an assessment could be defended. One real-world example from language assessment for immigration and citizenship that presents a serious challenge to fairness and justice is important to consider.

Assessing Immigrants in the Netherlands

A new real-world example is unfolding in the Netherlands (see Kunnan, 2012, for the context). Immigrants to the Netherlands now have to pass three stages of

testing in order to become citizens: admission to the country, civic integration after arrival, and naturalization to citizenship. The Law on Integration Abroad passed in 2006 described what applicants for admission to the Netherlands need to do—they have to take a computerized phone test of the Dutch language called the *Toets Gesproken Nederlands* (using Versant's computer-scoring technology) and a test of knowledge of Dutch politics, work, education, health care, history, and living. This type of requirement is the first in the modern world as it clearly presents barriers to family unification (particularly for women in Morocco and Turkey) and has been criticized on grounds of human rights. Extra and Spotti (2009) cite a Human Rights Watch (2008) report that considered this testing regime as discriminatory "because it explicitly applies to particular 'non-Western' countries and because it violates the qualified human right to marry and start a family" (p. 133). A legal challenge in a Dutch court in 2008 of this regulation resulted in a Dutch court providing relief to a Moroccan woman plaintiff who challenged the admission tests in Morocco because she failed the test and thus was not admitted to the country. After an appeal by the state, a higher state court ruled in February 2010 that applicants for admission to the Netherlands will no longer face a Dutch language test and questions about knowledge of Dutch society. The court's decision now will allow immigrants from Turkey and Morocco to apply for temporary residence on the basis of family reunification, and Dutch citizens would be able to bring their spouses from outside the country without having to pass the test of Dutch language and knowledge of Dutch society. Such testing was already considered to be in violation of the equality principle because citizens from European countries and others (such as Australia, Canada, Japan, New Zealand, the USA, etc.) do not need to take these tests.

This example highlights the right of a sovereign state to demand certain abilities (including language and knowledge of history and civics or culture),¹² on the one hand, and the right of an individual to join his or her family based on marriage (irrespective of any abilities that may be needed excluding any moral grounds). The decision of the Dutch government to deny this basic freedom demonstrates that they are denying respect for human dignity. Further, the law only applies these requirements to some groups of immigrants, but allows others to immigrate without the required Dutch language ability.

Leaving aside legal issues, what are the ethical issues here? Is this institution's requirement that a spouse demonstrate a certain level of language ability prior to traveling and living in the receiving country a violation of human rights? Is it appropriate to relax this law for citizens of certain countries? How is this policy beneficial to the community? Is this an example of an unjust institution? If this is the case, what could language assessment professionals do about this?

Conclusion

This chapter has provided a principled foundational basis for fairness and justice in language assessment by drawing on work from Rawls and Sen. Applying arguments from Rawls and Sen to language assessment has provided the background that led to the principles of fairness and justice as instruments being used

to evaluate assessments and assessment institutions. The methodology of how principles of fairness and justice may be derived by assessment agencies remains a concern. Rawls and Sen offer ways in which this can be done through the original position/veil of ignorance and the impartial spectator. These or other methods should help put in place mechanisms that enable the development of fair assessments and just institutions.

As Sen argues, it is not sufficient to use principles to design and establish just institutions: efforts should be made to remove manifest injustice that exists in the world today. He argues that a nonparochial global justice view would be best suited to establish and review unjust institutions. This is critical with globalized assessment institutions. These institutions need to be evaluated by enforcing categorical imperatives with obligations and *ought-to* principles, particularly general principles. The chapter also put forth the idea that there should be public reasoning of assessments. This would mean that whether an assessment is fair or not and whether an institution is just or not should be a matter of public discourse for which public reasoning is necessary. This is a critical part of justifying fair assessments and just institutions.

Finally, the main point of this chapter is not to debate whether the putative principles of fairness and justice (proposed in this chapter) are appropriate or workable for all contexts but to find principles that can guide us to right action when we encounter examples of unfair assessments and unjust institutions. We hope therefore the answers to the preliminary questions that were raised at the beginning of the chapter can now be answered by focusing on the right thing to do in setting up fair assessments and just institutions and the right thing to do to remove any unfairness and injustice.

Notes

- 1 ETS, Princeton, is one of a few agencies that have publicly declared they have a sensitivity review phase in which all items are subject to careful review.
- 2 Other perspectives include virtue ethics, cosmopolitanism, communitarianism, and postmodernism.
- 3 This does not include traditional and theological ethics such as the divine command theory or the natural law theory.
- 4 Rawls's reflective equilibrium is remarkably similar to Habermas's idea of discourse ethics in which principles are not mirrors of truth but something that emerges from fair argumentation by members in a society.
- 5 Rawls is a secular theorist and his theory is in this tradition. There are traditional virtues from religion-based ethics that might overlap with the major secular theories. These could include virtues of consciousness, benevolence, and self-restraint (from Buddhist ethics), humanity and goodness, rightness and duty, consideration and

- reciprocity, loyalty and commitment (Chinese ethics), neighborly love, natural morality (Judeo-Christian ethics), social and individual duties (classic Hindu ethics), and charity, kindness, and prayer (Islamic ethics).
- 6 This idea is similar to the thinking of Schopenhauer, although Sen does not mention him.
 - 7 Although Sen does not put it this way, we can assume he advocates, in Cohen and Sabel's words, "equal concern, equal respect, and equal opportunity regardless of any background conditions" (2006, p. 148). Sen cites many examples of this parochial nature: the common practice of the murder of newborn infants in ancient Greece despite the presence of Aristotle and Plato in their midst; more recently, stoning of adulterous women in Taliban Afghanistan, selective abortion of female fetuses in China, Korea, and parts of India, female genital mutilation in parts of Africa, capital punishment in China and the USA and restrictions of personal and media freedoms in North Korea and China.
 - 8 Nagel (2005) argues against global justice: that outside the state, there is no justice, and therefore as there is no global state, there can be no global justice. But does this mean that a state does not have any humanitarian obligations to its citizens even if the obligations do not lead to egalitarian justice?
 - 9 Sen (1999) illustrates this through a variety of examples that show the use of democratic ways from the past in Asian states. Examples include democratic Buddhist councils in the first and second century AD; Japanese Prince Shotoku's "Constitution of 17 Articles" in the seventh century AD; Emperor Ashoka of India in the third century BC; and the Moghul Emperor Akbar in the 16th century. It is also not true that all Western or European states are liberal democracies with media freedoms and all Asian states are authoritarian. There are counterexamples too: the early to mid-20th century saw authoritarian regimes in Germany, Italy, Spain, and apartheid South Africa. In contrast, in the mid- to late 20th century, there have been Asian democracies with full media freedoms in India, Japan, South Korea, and Taiwan.
 - 10 But Sen, like Rawls, for different reasons shies away from a full cosmopolitan approach to justice which holds moral universalism as paramount to moral value.
 - 11 Previous versions of the principles were presented in Kunnan (2000, 2004). This revision is more extensive.
 - 12 Whether these abilities as assessed currently around the world can contribute to social integration of immigrants is an important but different question.

Accommodations in the Assessment of English Language Learners

Jamal Abedi

University of California, Davis, USA

Introduction

Accommodations are provided to English language learner (ELL) students to make assessments more accessible to these students. To provide valid assessment outcomes for ELL students, these accommodations must have certain characteristics. They must (a) be effective, that is, they should increase the accessibility of assessments for the students; (b) be valid, not altering the focal construct; (c) have a differential impact, fitting an individual student's needs; (d) be relevant, serving the ELL student population by addressing their linguistic needs; and (e) be feasible, that is, be practical in their administration. Existing research suggests that many of the accommodations that are used for ELL students lack one or more of these essential characteristics; therefore they may be less helpful to these students than they could be. For example, they may alter the construct being measured or have major logistical issues in their implementation phase.

This chapter presents a summary of research related to the five major characteristics of accommodations mentioned above. This discussion will be followed by a brief description of accommodations currently in use in the USA, along with recommendations on how to choose accommodations on the basis of students' background characteristics, and how to interpret accommodated test scores for these students. Particular attention will be given to the research focusing on the validity of accommodations. The chapter will also elaborate on why the outcomes of assessments under invalid accommodations cannot be aggregated with the assessment outcomes for students tested under standard testing conditions with no accommodations provided. Thus, the main question in the provision of accommodation is how, and to what extent, decision-making policies on the use of accommodations are influenced by research results and whether there is enough research to inform accommodation decisions and use.

Previous Views or Conceptualization

What Is the Notion of Accommodation?

The term “accommodation” is defined in the 1988 *Webster’s New World Dictionary* as “willingness to do favors or services” or “a help or convenience.” However, in an assessment context, accommodations are used as a means to help students, particularly those with challenging academic lives, and make the assessment conditions fair and accessible for these students. The term “accommodations” itself refers to changes in the test administration conditions or to the test itself (Acosta, Rivera, Willner, & Fenner, 2008). The following example may help clarify the concept of accommodation for an ELL student.

This example focuses on the academic performance of an ELL student who was among high-performing grade 7 students in a Spanish-speaking country. He moved to the USA and enrolled in a school under an English-only instruction and assessment policy. This student graduated from grade 7 in a middle school in his country with high grades (all “A” grades) and enrolled in a grade 8 that offered English-only instruction and assessment. On entering school in the USA, he was tested for his level of English proficiency and received a “far below proficient” (poor) status in English proficiency. According to the No Child Left Behind (NCLB) Act, all students must be assessed in NCLB Title I contents (reading/language arts, mathematics, and science). He took the state assessments in the three content areas in English, and performed at the lowest level (far below proficient) in all three contents. His teacher realized that his low performance might be due to lack of English language proficiency, and therefore requested that he be tested in his native language (Spanish). His test scores were quite high when tested with the Spanish version of the state assessments. In this case, *native language testing* was used as an accommodation for the student.

Current Views or Conceptualization

Who Is Eligible to Receive Accommodations?

In general, all students who are faced with a challenging academic career can receive accommodations. However, traditionally ELLs and students with different types of disabilities receive accommodations. For students with disabilities, accommodations must directly address their needs according to their disabilities. For example, Braille is used as a form of accommodation for blind students. The focus of this chapter is on the accommodations given to ELLs and the justification for the use of accommodations for these students.

Unlike students with disabilities, who have different types of disabilities and different needs for assistance in their academic career, ELL students mainly share a common characteristic: their need for assistance in the language of instruction and assessment. Therefore, accommodations that address their English language needs and make assessments more linguistically accessible for them are more likely to have positive impact on their academic career.

While the history of accommodations for ELL students is relatively new as compared with the history of accommodations for students with disabilities, there has been substantial attention to the issues of accommodations for ELL students in more recent years (e.g., Francis, Rivers, Lesaux, Kieffer, M., & Rivera, 2006; Abedi, 2007; Acosta et al., 2008). Currently, different states use many different accommodations for their ELL students. Some of these accommodations that help ELL students with their linguistic needs are shown to be effective in making content-based assessments more accessible to ELL students (Abedi, 2010). However, more evidence is needed on the effectiveness and validity of other types of accommodations that are used for ELL students. Below is a short discussion of the criteria used to evaluate accommodations in improving the validity of assessments for ELL students.

What Criteria Are Used to Evaluate Accommodations?

There are several different criteria for evaluating the accommodations in making assessments more accessible for ELL students. These criteria include: (a) effectiveness, (b) validity, and (c) differential impact. Below is a brief discussion of each of these features.

Effectiveness How effective is the accommodation in making assessments more accessible for ELL students? To be effective, an accommodation should improve the performance of ELL students without altering the focal construct of the assessment. For example, research on accommodations shows that ELL students perform better on assessments that are less linguistically complex (Maihoff, 2002; Solano-Flores, 2008; Abedi, 2010). (This is also true for non-ELL students, particularly those at the lower performance level in content areas such as mathematics [Abedi & Lord, 2001; Oller, Chen, Oller, & Pan, 2005].) Therefore, linguistic modification can be used as an effective accommodation for ELL students to help make assessments more accessible for them. Different studies have examined the impact of unnecessary linguistic complexity of assessments and found that ELL students who took the linguistically modified version of the test performed significantly better than ELL students who took the original test with no linguistic modification (Abedi & Lord, 2001; Abedi, 2010).

The best way to examine the effectiveness of accommodations is to assign them randomly to ELL students and to compare performance outcomes of ELL students who received accommodations with those were tested under the standard testing condition without accommodations. Native speakers of English from different backgrounds can also be added to the sample to demonstrate that the accommodations can help everyone if they do not alter the focal construct. Random assignment of ELL students to accommodated and nonaccommodated groups is key to measuring the effectiveness of accommodations. In practice, however, accommodations are assigned to ELL students on the basis of their academic needs. For example, ELL students who are at the lowest level of English proficiency are usually accommodated, and those at the higher level of proficiency are tested with their native English-speaking peers without receiving any accommodations. Therefore a direct comparison of the performance of these two groups

under accommodated and nonaccommodated conditions may not be productive, since there are potentially major initial differences between those who are receiving accommodations and those who are not. The random assignment of ELL students into the accommodated and nonaccommodated groups controls for such initial differences, and any significant differences between the two groups may be interpreted as the direct impact of the accommodations used.

Validity How valid are the accommodated assessment outcomes as compared with the nonaccommodated ones? Literature on the accommodations for ELL students has provided information on the validity of accommodated outcomes in two ways: (a) experts' review of the existing accommodations for any sign of accommodations altering the focal construct, and (b) experimentally controlled field studies in which the performance of non-ELL students has been compared across accommodated and nonaccommodated testing conditions. A major issue with currently used accommodations is the possibility that they provide an unfair advantage to the recipients. That is, they do more than what they are supposed to do. These validity concerns are illustrated in the example of providing a *dictionary* as a form of test accommodation. While a dictionary provides direct linguistic support for these students (Willner, Rivera, & Acosta, 2008), it may compromise the validity of assessment outcomes by helping the student arrive at the correct answers to the questions.

The study done by Willner et al. (2008) can be discussed as a prime example of examining the validity of accommodations on the basis of expert opinion. In this study, using a Delphi method, experts were asked to identify accommodations that are relevant to ELL students and that are ELL responsive. Among the many accommodations listed, several were identified as "direct linguistic support." Among these were glossaries and both English and bilingual dictionaries. As it will be elaborated below, some of these accommodations may provide unfair advantage to the recipients.

Experimentally controlled studies can provide convincing evidence on the validity of accommodated assessments by measuring the impact of accommodations on the assessment outcomes for non-ELL students. In these studies, it is hypothesized that accommodations used to make assessments more accessible for ELL students should not have any impact (or less impact) on students who are proficient in English (non-ELLs) for whom accommodations are not intended. To examine this hypothesis, non-ELL students are randomly assigned to either a treatment group, where they are tested under an accommodation, or a control group, where they are tested under the standard testing condition with no accommodation provided. If non-ELL students in the treatment group (receiving an accommodation) perform significantly better than non-ELL students in the control group (no accommodation), then one may conclude that the accommodation impacts the measurement of the focal construct. As such, the accommodation should not just be used for one group, but rather should be provided to everyone (both ELL and non-ELL students).

Evidence on the validity of accommodated assessments can also come from valid external criteria (Abedi, 2007). For example, the measurement outcomes from the accommodated and nonaccommodated assessments can be compared

with a valid external criterion such as a student's state test scores or classroom academic indicators. The structural relationships between the assessment outcomes and the external criteria should be consistent across the accommodated and nonaccommodated assessments.

The literature has also suggested the use of multiple group confirmatory factor analyses for the external validation of accommodations (Abedi, 2002, 2010). This process involves creating a latent variable of the accommodated assessment outcomes along with a latent variable of the external criterion and then estimating the correlations between the two. These latent variables can be created by grouping test items into parcels and using those parcels to create an overall composite score of the test. The process then involves testing a set of hypotheses on the invariance between ELL and non-ELL students (for a detailed discussion of this approach in assessing the validity of accommodated assessments, see Abedi, 2002).

As indicated earlier, there are many different forms of accommodations for ELL students that lack validity evidence (Abedi 2007; Solano-Flores, 2008; Willner et al., 2008; Young & King, 2008). It would be a challenging task to provide any indication of the validity of interpretation of test scores with information missing on the effectiveness and validity of accommodations used in state assessments (Kane, 2006).

Differential Impact The effectiveness and validity of accommodations depend, to a great extent, on students' background variables. An accommodation that is effective and valid for a student with certain background characteristics may not be beneficial to another student with different ones. For example, ELL students who are proficient in their native language and have been instructed in it may benefit substantially more from the native language testing than do ELL students who are proficient in their native language but have been in the USA for a longer period of time and have been instructed in English. Therefore, background characteristics must be considered when assigning accommodations to ELL students. Among the most important background variables to consider for ELLs is their level of English and native language proficiency. The ELL population is quite a heterogeneous group in many respects, particularly when it comes to their levels of proficiency in English and their native language. Research has demonstrated that some ELL students have a higher level of English proficiency than some of their native English-speaking peers (Abedi, Leon, & Mirocha, 2003). Other background variables to consider when assigning accommodations to ELL students include the number of years a student has been in this country, the number of English-only classes students have taken, and the language of instruction. The language of instruction and language of assessment must be aligned in assigning any bilingual or native language accommodations.

Current Research

What Are the Commonly Used Accommodations for ELLs?

Among the most commonly used accommodations for ELL students are use of a dictionary (both English and bilingual), use of English and bilingual glossaries,

native language or bilingual testing, having test items read aloud, and providing linguistically modified assessments (Abedi, 2007; Acosta et al., 2008). These accommodations all provide direct linguistic support for ELL students. There are, however, other commonly used accommodations that are not language based and may not be directly relevant for ELL students. Examples of these accommodations include an extension of testing time, small group testing, individual student testing, and having the test administered by a person familiar to the student.

There are other accommodations that are used for ELLs in state assessment that are even less relevant. These accommodations include providing breaks during the test administration, extending the test schedule, administering the test at the time of day most beneficial to the test taker, having the test taker mark answers in a test booklet instead of on a Scantron form, providing copying assistance between drafts, and having the test taker indicate the answers by pointing or a similar method (Rivera, 2003).

Do the Commonly Used Accommodations for ELL Students Help Make Assessments More Accessible?

As discussed above, some of the accommodations that are currently used in the assessment of ELL students may not be effective or may not provide valid assessment outcomes for ELL students. Abedi (2007) found that of the 73 accommodations listed for ELL students in the nation, 47 (64%) were deemed “not related” to ELLs, 7 (10%) were remotely relevant, 8 (11%) were moderately relevant, and only 11 (15%) were highly relevant in the assessment of ELL students.

Accommodations that are not relevant to ELL students are not only a nuisance in the assessment process, but introduce a substantial amount of content-irrelevant variance into the assessment process. Many of these accommodations are not being used in classroom instruction and therefore students may not be familiar with them. This unfamiliarity with the application and purpose of accommodations creates frustration and anxiety during the assessment process, which in turn affects student performance. Furthermore, many of these ineffectual accommodations take a significant amount of testing time, which could otherwise be spent in a more productive way in the assessment process. More importantly, accommodations that are not relevant to ELL students and that cannot help them with their real academic needs may prevent these students from receiving more appropriate accommodations.

What Are the Research-Supported Accommodations?

This section presents a summary of studies that were conducted to examine the major characteristics of accommodations, including the effectiveness and validity of accommodations currently used by states. Accommodations that are not supported by experimentally controlled studies may not produce desirable assessment outcomes. As indicated earlier, accommodations that may alter the focal construct can produce invalid assessment outcomes. Similarly, accommodations that are not shown to be effective in making assessments more accessible to ELL students may not serve the purpose.

Of the many accommodations that are used for ELL students across the nation (see, e.g., Rivera, Stansfield, Scialdone, & Sharkey, 2000; Thurlow & Bolt, 2001; Rivera, 2003; Sireci, Li, & Scarpati, 2003; Abedi, Hofstetter, & Lord, 2004; Willner et al., 2008), many may not actually be relevant. For some, there is no research evidence to support their use on assessments. Accommodations that are created and used for ELLs are referred to as ELL-responsive accommodations (Willner et al., 2008). The main characteristics of these accommodations is that they address a common theme of increasing the accessibility of the linguistic structure.

The ELL-responsive accommodations help reduce construct-irrelevant variance on assessments that is due to language (Acosta et al., 2008). These accommodations include providing the following: an English glossary with definitions or glosses; English and bilingual dictionaries; read-aloud test items; directions in plain English; bilingual glossaries; and test items and directions presented in the native language and English, with the option of responding in either language on written portions of tests. However, while the goal of these accommodations is to reduce the construct-irrelevant variance due to unnecessary linguistic complexity, some of them may actually alter the focal construct. A good example of an ELL-responsive accommodation that may alter the focal construct is the use of a dictionary. The dictionaries, regardless of the type of language (English or bilingual), may help students to find the correct assessment response; they therefore give an unfair advantage to the recipients (see, e.g., Abedi, 2007).

Therefore, it is essential to continue to research the effectiveness and validity of accommodations that are currently being used to ensure that they are effective in making assessments accessible for ELL students, and provide valid assessment outcomes. They must also be logistically feasible and relevant for ELL students with different academic backgrounds.

To shed light on some of these important characteristics of accommodations used for ELL students, this chapter provides a summary of research on some of the accommodations that are ELL-responsive (Abedi, 2007). The accommodations that are selected for this section of the chapter are (a) bilingual tests, (b) an English/bilingual glossary, (c) a commercial English/bilingual dictionary, (d) a customized English/bilingual dictionary, (e) a linguistically modified assessment, and (f) computer accommodation.

Bilingual Version of the Test A bilingual version of the test provides an opportunity to test ELL students in their native language. It is used by many states across the USA to reduce the impact of language factors as a source of construct-irrelevant variance (Abedi, Lord, Hofstetter, & Baker, 2000; Rivera et al., 2000; Sireci et al., 2003; Abedi et al., 2004; Willner et al., 2008). There are, however, issues concerning the validity and effectiveness of native language or bilingual test accommodations. Among these issues is a possible lack of alignment between the language of instruction and language of assessment. If the languages of instruction and assessment are not aligned, then the effectiveness of this accommodation would be questionable. It is not valid assessment if students learn the content vocabulary in English but are asked to deliver these concepts in their native language no matter how fluent they are in their native language.

Native language and bilingual testing may also suffer from validity issues due to the translation. The translated version of the test may turn out to be easier or harder in another language than the original version of the assessment. There may also be some cultural phrases and idioms that may be difficult to translate from the original version (Hambleton, 2001).

Unfortunately, the literature on the translation of assessment instrument as a form of accommodation is scarce. Francis et al. (2006) found only two experiments with Spanish translations, which indicated that the translation positively impacted Spanish-speaking students when they were instructed in Spanish. Kieffer, Lesaux, Rivera, & Francis (2009) suggested that the language of instruction may be a moderator in the effectiveness of native language testing (Pennock-Roman & Rivera, 2011). However, from an extensive review of research on accommodations, Sireci et al. (2003) indicated that a dual-language test booklet may not provide significant improvement in assessment results for students using this accommodation.

English/Bilingual Glossary Glossaries (English or bilingual) provide simple definitions of terms that appear in the test. A glossary is a commonly used accommodation for ELLs in many states in the USA. However, there are major validity concerns in the use of this accommodation. The main one is that it may provide content-related information that may help students reach the correct response for the test items, which could be a source of threat to the validity of the assessment.

Research on the validity and effectiveness of an English glossary confirms that in fact, using an English glossary with extended time raised performance of both ELL and non-ELL students (Abedi, Hofstetter, Lord, & Baker, 1998; Abedi et al., 2000, 2004; Sireci & Scarpati, 2003). The results of these studies suggested that the performance of non-ELL students was increased at a higher rate than that of ELL students. This may be evidence that the accommodation (English glossary with extra time) may have altered the focal construct (Abedi et al., 2000).

Other research, however, found no significant differences between the performance of ELL students using a glossary and non-ELL students tested under standard conditions with no accommodations provided (Francis et al., 2006). Yet the results of this study indicated that the effectiveness of glossary accommodation depends on ELL students' level of proficiency in their native language and in English. For example, students at the higher level of English proficiency benefited more from an English glossary accommodation with extra time than did students with lower English proficiency.

Results of a meta-analysis of data on bilingual glossary use showed mixed results regarding the effectiveness and validity of the accommodation. The analysis results indicated that the effect sizes were not significant in three experimental studies, but were significant in one study. That study was unique in that it was conducted under a quasi-experimental design that used only Spanish speakers in the treatment group but included non-Spanish-speaking ELLs in the control group (see also Kieffer et al., 2009).

Commercial English/Bilingual Dictionary Allowing the use of a dictionary is one of the commonest accommodations for ELLs. Pennock-Roman and Rivera (2011) found that a dictionary is an effective accommodation for ELLs when combined

with extra time. Francis et al. (2006) cited the use of an English language dictionary as the only one of seven empirically tested accommodations to produce a small effect size that was both positive and significant.

Dictionaries are published in different forms and languages and are different in many aspects, including content coverage. While dictionaries could help ELL students with their language needs, they may give unfair advantages to the recipients by providing information above and beyond what they are supposed to provide. For example, explanations, definitions, pictures, and examples of terminology can help students reach the correct answer to the test questions without prior knowledge of the correct answer (Abedi, 2007). To deal with the validity issues concerning dictionaries, the literature has proposed the use of customized dictionaries in which content-related terms are not included. Below is a short description of the customized dictionary as a viable alternative to the commercial ones.

Customized English/Bilingual Dictionary As indicated above, providing a dictionary as a form of accommodation for ELL students may affect the validity of the assessment, as it may provide information related to the focal construct. A customized dictionary may be a more valid alternative to the commercial English/bilingual dictionary. A customized dictionary provides terms and definitions that are not content related, and its provision is an easier accommodation to administer (Abedi et al., 2004). It has been found to be a highly effective and valid accommodation for ELL students (Abedi, Hoffstetter, et al., 1998; see also Abedi et al., 2004; Rivera et al., 2000; Sireci & Scarpati, 2003).

Linguistically Modified Assessment Unnecessary linguistic complexity is a major threat to the reliability and validity of assessments for ELLs. Revising test items to reduce linguistic complexity improves the content and psychometric properties of assessments for the general student population, and more so for ELL students. Research on assessment of and accommodations for ELL students have found linguistic modification of the assessment to be an effective and valid accommodation for ELL students (Abedi, Lord, & Hofstetter, 1998; Abedi et al., 2000; Rivera & Stansfield, 2001; Maihoff, 2002; Abedi, 2010).

In the linguistic modification approach, a distinction is made between linguistic features that are related to the focal construct and are essential components of the construct, on the one hand, and those linguistic features that are unnecessary and unrelated to the focal construct, on the other. This approach provides the methodology and instruction to modify unnecessary linguistic complexity of the assessments and make them more accessible to ELL students (Abedi, Lord, & Plummer, 1997; Abedi, 2010).

Studies on the effectiveness and validity of the language modification approach can be grouped into two different categories: (a) studies conducted using state and national US data and (b) studies conducted through randomized field trial designs. Findings from the analyses of existing data show ELL students perform significantly better on test items with shorter question phrases and shorter distracters. The results of these analyses also show that ELL students consistently perform better on test items that are judged by content and linguistic experts to be less linguistically complex (Abedi et al., 1997; Abedi & Lord, 2001).

In randomized trial studies, ELL students were assigned either to a treatment group, where they received a linguistically modified version of the assessment with a reduced level of linguistic complexity, or to a control group, where they were tested on the original version with no linguistic revisions. The results of many studies in this area clearly showed that ELL students benefited from linguistic modification of assessments. However, it is important to note that the performance of non-ELL students, particularly at the higher level of academic achievement, did not change with linguistic modification of assessments. Such findings support the notion that the linguistic modification approach did not impact the focal construct (Abedi et al., 1997, 1998, 2000; Kopriva, 2000; Abedi & Lord, 2001; Rivera & Stansfield, 2001; Kieffer et al., 2009). For a more detailed discussion of these studies and the impact of linguistic modification on the assessment of ELL students see Abedi (2010).

The results of these studies (Abedi, 2007, 2010; Francis et al., 2006; Sireci et al., 2003) clearly and consistently suggest that reducing the level of unnecessary linguistic complexity makes assessments more accessible to ELL students and helps to improve the reliability and validity of content-based assessments for all students. However, understanding the basic principles and proper application of this approach is necessary to utilize its full potential. It is neither merely an editorial process nor an expert evaluation of the linguistic structure of the text. Rather, it is a systematic approach that is used to identify features of the assessment that slow down the readers and make the interpretation of assessment content difficult for the student. Several linguistic features have been identified that affect ELL students' level of understanding of assessment questions (Abedi, 2006). Taking the linguistic modification approach, these features are used to guide the modification, and test items are ranked on the level of existence of these features. Test items that contain a high level of these features are then modified to reduce their impact on the assessment outcomes.

Computer Accommodation Computer assessment systems have great potential in making assessments more accessible to ELL students by incorporating many *direct linguistic support* accommodations into the actual system of administration. The computer assessment system provides easier access to these accommodations and keeps track of exactly how a student interacts with the assessment system. Research on the use of computerized assessments among the general student population provides mixed results. Some of these studies found no significant differences between those who were tested with the computer version of assessments and those who took the traditional paper version (Hargreaves, Shorrocks-Taylor, Swinnerton, Tait, & Threlfall, 2004).

Studies on the effectiveness of computer accommodations for ELL students, however, have shown promising results. For example, Abedi (2009) showed that a computer assessment system that incorporated several accommodations was highly effective in improving the performance of ELL students and making assessments more accessible for them. In this study, researchers included several accommodations including a pop-up glossary of noncontent words and a customized dictionary. ELL students in both grades 4 and 8 showed significant performance improvements in mathematics test items.

In a more recent study on computer-based accommodation (Abedi, 2009), the effectiveness and validity of several ELL-responsive accommodations were examined. These accommodations included read-aloud test items in mathematics, pop-up glossaries, and variation in font sizes.

The main advantage of using a computer accommodation system is the use of advanced technologies in presenting a set of accommodations that are shown to be useful for ELL students. Presenting the bundle of accommodations within a paper and pencil format would be logistically challenging. Also, the accommodations for the tests are guaranteed to be given in a consistent manner among all test takers.

One of the many potentials seen in these studies of a computer-based assessment and accommodation system for ELL students was the extensive use of pop-up glossaries by the students. In the paper and pencil version of the assessment, very few students used a customized dictionary (Abedi, 2009). Students assessed on the computer testing approach, however, used the glossary substantially more. The main reason for this higher level is the ease of use of the glossary in the computer format. Rather than searching for an unknown word in an alphabetical glossary, students could use the mouse to point to a word in the test and were presented with a gloss. Another major advantage in the use of a computerized accommodation system is the higher level of motivation and incentives: ELL students enjoyed the computer testing strategy much more than the paper version of the test.

How Are Accommodations Assigned to ELL Students?

Currently, there is no uniform national guideline in the USA for assigning accommodations to ELL students. For students with disabilities, the decision regarding accommodations is based on the student's individualized education program (IEP) team. Different states have different lists of possible accommodations for ELL students. The decision on which accommodations to include in the list is based on the state policy and state assessment guidelines. So far, the findings of research on accommodations have had little impact on the decisions regarding assigning accommodations to ELL students. Instead, input from teachers of ELL students seems to play the largest role in the selection of these accommodations. Teachers often consider a student's level of English and native language proficiency when recommending a particular accommodation, but they are limited to the list of the state-allowable accommodations. If none of the accommodations on the list fits the student's background, then the teacher has to make a choice between those that are available.

Thus, the policy of selecting accommodations at the state and district level without research-based evidence may lead to inappropriate decisions for some students. It is important that state policy be based on sound evidence including findings of studies that have been cross-validated.

Challenges and Future Directions

In the USA, federal and state legislation (e.g., the Elementary and Secondary Education Act) mandates the inclusion of all students, including ELLs, in the state and national assessment and accountability system. However, mere inclusion does

not necessarily provide fair assessments to these students. A fair assessment system for them includes test items that are culturally and linguistically accessible and provide appropriate accommodations. Inappropriate accommodations in the ELL assessment system may cause two different but quite serious problems. If accommodations are not relevant and are not effective for these students, then they may cause fatigue and frustration and take attention away from the assessment. On the other hand, if accommodations alter the focal construct by providing unfair advantage to these students, then their assessment outcomes cannot be used as valid indexes of their progress.

The history and practice of accommodations originated from the population of students with disabilities in both classroom instruction and assessments (Willner et al., 2008). The policy and practice of accommodation were then expanded to ELLs, and therefore many of the accommodations that are given to ELLs were originally developed and used for students with disabilities, with no or little adjustment or justification. Thus it is clear that many of these accommodations that serve students with disabilities may not serve ELL students' academic needs and objectives. It is therefore essential to examine the content and characteristics of the accommodations that are currently used for ELL students.

Accommodations used in the assessment of ELLs must have several essential characteristics. First and foremost, they must be relevant to these students. Unlike the population of students with disabilities, who have many different types of disabilities and different needs, the ELL student population has a common objective—to reach proficiency in English—and has similar needs for assistance with learning academic English. Accommodations that directly address their language needs (direct linguistic support) would therefore seem to be more relevant to them. However, one must be careful not to generalize this concept. Not all direct linguistic support accommodations can be applied in the ELL assessment and instructional practices, since some of these accommodations may not meet all the requirements of appropriate accommodations for these students.

This chapter has provided information and methodology for examining the effectiveness and validity of accommodations. Accommodations that are not supported by research and are not shown to make assessments more accessible for ELL students should be used with caution. The most important factor to consider in the use of accommodations is the validity of accommodated assessments. If an accommodation does more than it is supposed to do—that is, provides unfair advantage to the recipients—then the outcomes of assessments under such accommodation cannot be used for any high stakes assessment and accountability purposes. Furthermore, the outcomes of such assessments cannot be combined with the outcomes of nonaccommodated assessments. This has major assessment and policy implications in the USA for states and for the nation.

Thus, the main objective of this chapter is to bring these issues in the assessment and accountability system to the attention of assessment policy makers and researchers so that they be cognizant of the potentials and limitations of accommodations for ELL students and use the accommodations wisely.

The author wishes to thank Kimberly Mundhenk for her contribution to this chapter by editing and providing helpful suggestions.

Consequences, Impact, and Washback

Liyong Cheng
Queen's University, Canada

Introduction

The prevalence of large-scale high stakes testing and its impact on its stakeholders have been well documented in education. There is a set of relationships, intended and unintended, between testing, teaching, and learning. The phenomenon of testing consequences is not new; it has existed ever since the birth of modern testing. The core issue of this phenomenon resides in the use (or misuse) of test scores and the values and stakes attached to a test within the society and within the teaching and learning context where a particular test exists. Given the range and extent of testing consequences reported worldwide, it is critical that testing practices yield valid data about student achievement and performance.

The term “consequences” is used as a general concept in educational assessment. It is therefore used in this chapter to discuss testing consequences in general. The terms “impact” and “washback”—both now commonly used in applied linguistics—are, however, used here as specific research concepts. Washback (also “backwash” in early literature) is a term used specifically in applied linguistics since the well-known and well-cited publication of “Does Washback Exist?” (Alderson & Wall, 1993). Bachman and Palmer (1996) define testing consequences as “test impact”—the effect that testing has on individuals (teachers and students), educational systems, and the society at large. They treat “impact” as one of the six qualities of test usefulness—reliability, construct validity, authenticity, interactivity, impact, and practicality. McNamara (2000), however, uses two terms to distinguish between two levels of this phenomenon: “impact”—the effects of tests on macro-levels of education and society, and “washback”—the effects of language tests on micro-levels of language teaching and learning inside the classroom. In this sense, the difference between impact and washback resides in the scope of the effects of testing—which gives us a view of test consequences falling

between the more narrow one of washback and the all-encompassing one of impact (Hamp-Lyons, 1997). These two specific terms are discussed in this chapter as individual researchers use them. In addition, “testing” (or “tests”) is used consistently in this chapter, where it bears a meaning similar to that of “examination,” as cited by individual researchers. To note, the testing and examination practices referred to here are of a large-scale high stakes nature. Consequences, impact, and washback of classroom-based teacher-led formative assessments are not discussed in this chapter as such issues require quite a different consideration (Brookhart, 2004). It is possible that the consequences of large-scale high stakes testing could be lessened if more quality classroom-based teacher-led formative assessments were conducted in combination of large-scale high stakes testing—a combination of assessment *for* learning and assessment *of* learning (see “Future Directions”).

Considering the nature of testing consequences, Messick (1996, p. 243) regards washback as “only one form of testing consequence that needs to be weighted in evaluating validity, and testing consequences are only one aspect of construct validity needing to be addressed.” Messick also points out that the consequences of tests are likely to be a function of factors both within the test itself and within the setting of the test. He recommends the examination of the two threats to construct validity—construct under-representation and construct-irrelevant variance—in order to enhance the quality of the test and thus promote positive washback. Bailey (1996, p. 268), however, argues that any test, whether good or bad (in terms of validity), can have either negative or positive washback, depending on whether “it impedes or promotes the accomplishment of educational goals held by learners and/or program personnel.” She focuses on the specificity of this phenomenon, which could induce differential impact on test stakeholders within a range of teaching and learning contexts—a view increasingly shared by many language testers (e.g., Cheng, 2008). In a sense, positive or negative washback is likely defined by test stakeholders, possibly differentially, as they see how a test serves its purposes and uses from their own points of views. More recently, Bachman (2005) proposes a validity framework with a set of principles and procedures for linking test scores and score-based inferences to test use and the consequences of test use—an area in which he argues for more research to be conducted.

In addition, testing consequences have increasingly been discussed from the point of view of critical language testing (Shohamy, 2001), which focuses on ethics and fairness in language testing (Hamp-Lyons, 1997; Kunnan, 2004). Shohamy (2001) points out the political uses and abuses of language tests and calls for examining the hidden agendas of the testing industry and of high stakes tests. Kunnan (2004) discusses the role of tests as instruments of social policy and control, drawing on research in ethics to link test validity and test consequences to create a test fairness framework. Hamp-Lyons (1997) argues for an encompassing ethics framework to examine the consequences of testing on language learning at the classroom and the educational, social, and political levels. The study of testing context is highlighted from this point of view.

The above literature has examined testing consequences either by using a theoretical framework focusing on test validity or by using a philosophical framework illustrating the social concerns of language testing. In order to provide a context for the discussion of the phenomenon of testing consequences, I will address

below research literature derived from both the fields of educational assessment and of applied linguistics, where language testing and assessment is situated. Further, in order to understand the relationship between testing, teaching, and learning within a society and a teaching and learning context, it is important to review the previous and the current views of testing consequences, as well as the empirical research conducted in understanding this educational phenomenon. Due to the relatively short history of empirical research on impact and washback in applied linguistics, I will discuss the views and research published prior to and during the 1990s as *previous* and those in the 2000s as *current* views and research. The timing of this division is arbitrary, yet significant to the field of applied linguistics, because the research in the 1990s had just started to explore the existence and nature of the phenomenon and its potential relationship with teaching and learning. The research in the 2000s has provided increasing empirical evidence about the nature and scope of the phenomenon from a range of teaching and learning contexts around the world. After that, I will present the current conceptualization on testing consequences, pose the challenges for conducting empirical research, and point out future research directions in the end.

Previous Views and Research

Testing consequences have been an issue of long-standing concern in education. The earliest literature can be traced back to Latham (1877), who referred to an examination system as an “encroaching power” and pointed out “how it influences the prevalent view of life and work among young men, and how it affects parents, teachers, the writers of educational books, and the notion of the public about education” in the UK (p. 2). Indeed, the use of examinations for selection purposes in education and employment has existed for a very long time. In many parts of the world, examinations were valued by society as ways to encourage the development of talent, to upgrade the performance of schools and colleges, and to counter to some degree nepotism, favoritism, and even outright corruption in the allocation of scarce opportunities, such as in the case of the imperial examinations in China (Eckstein & Noah, 1992). If the initial spread of examinations can be traced to the above, the very same reasons appear to be as powerful today as ever. Linn (2000) classified the use of tests and assessments as key elements in relation to five waves of educational reform over the past 50 years in the USA: their tracking and selecting role in the 1950s; their program accountability role in the 1960s; minimum competency testing in the 1970s; school and district accountability in the 1980s; and the standards-based accountability systems in the 1990s. Clearly, tests and assessments have played a crucial and critical role in education and society. Testing consequences are influenced by the ideological, social, and political milieu surrounding particular educational systems.

In spite of its long and well-established place in educational history, the use of tests has been constantly subject to criticism. Nevertheless, tests continue to occupy a leading place in the educational policies and practices of most countries around the world. Aware of the power of tests, policy makers in many parts of the world continue to use them to manipulate the local educational systems, to

control curricula, and to impose (or promote) new textbooks and new teaching methods. Testing is “the darling of the policymakers” (Madaus, 1985, p. 5), and it would not be too much of an exaggeration to say that testing has become the engine for implementing educational policy despite the fact that tests have been the focus of controversy for as long as they have existed. One reason for their longevity in the face of such criticism is that tests are viewed as the primary tools through which changes in the educational system can be introduced without other educational components, such as teacher education and curricula, having to change—a naive and simplistic view of the power of testing practices. Shohamy, Donitsa-Schmidt, and Ferman (1996, p. 299) pointed out the strong authority of external testing in a study conducted in Israel:

the power and authority of tests enable policy-makers to use them as effective tools for controlling educational systems and prescribing the behavior of those who are affected by their results—administrators, teachers and students. School-wide exams are used by principals and administrators to enforce learning, while in classrooms, tests and quizzes are used by teachers to impose discipline and to motivate learning.

It is because of the potential and actual misuses of tests that washback has become a well-known concept in applied linguistics (now appearing in education literature). It is an increasingly prominent phenomenon in education, as what is assessed becomes what is valued and taught. Since the early 1990s we have seen an increasing number of washback research studies conducted. There seem to be at least two major approaches of empirical studies to this phenomenon: an approach that relates to traditional, multiple choice, large-scale high stakes tests, which are perceived to have had mainly negative influences on the quality of teaching and learning; and one where a specific test or examination has been introduced, modified, or improved upon in order for it to exert a positive influence on teaching and learning, e.g., communicative language teaching (see Wall & Alderson’s 1993 study in Sri Lanka). Studies in earlier applied linguistics literature in the 1990s fell mostly into this latter category. In this approach, researchers investigated how and what happened when a new or revised test was used to bring about changes in teaching and learning (see Cheng & Watanabe, 2004—a collection of studies conducted in all major parts of the world). Further, most of these studies were conducted within the context of teaching English as a foreign language.

The work of Alderson and Wall (1993) and Wall and Alderson (1993) marked a significant development in shaping the constructs of washback studies for the field of language testing in this period. Alderson and Wall (1993) explored the potentially positive and negative relationships between testing, teaching, and learning. They questioned whether washback could be a property of test validity, as suggested by Messick (1989). They subsequently proposed 15 hypotheses regarding the potential influences of language testing on various aspects of language teaching and learning and posed the intriguing question: “Does washback exist?” Of the 15 hypotheses, half are about teaching and half on aspects of learning.

Prior to their major work, only a few empirical studies on washback had been published. Li's (1990) work is the first piece well known to the field of language testing for its delineation of how powerful a test can be in China. Morrow (1986, p. 6) adopted the concept of "washback validity" to describe the quality of the relationship between testing, teaching, and learning. He claims that "in essence an examination of washback validity would take testing researchers into the classroom in order to observe the effect of their tests in action." Accordingly, most of the earlier washback research had responded to the call by focusing on the classroom—most specifically on teachers, their teaching practices, their materials, and their methodology.

In 1996 a collection of the six most cited washback works was published in a special issue of *Language Testing*, volume 3, issue 3, edited by Alderson and Wall. Messick linked washback with validity, as mentioned above. Bailey, employing a model of washback, explored the nature of the phenomenon, the mechanism by which it worked, and how it could be investigated. The next three empirical studies were conducted by Alderson and Hamp-Lyons, who investigated how washback likely changed what teachers taught and how they taught; by Shohamy and colleagues on the differential stakes of testing; and by Watanabe on teacher factor in washback research. The last paper, by Wall, explored why tests do not always have the effect as we desire or fear they would have. Indeed, most of the studies conducted in the 1990s investigated the perceptions and practices of teachers (e.g., Alderson & Hamp-Lyons, 1996; Shohamy et al., 1996; Watanabe, 1996). However, much remains unknown about the washback effects of tests on learners and their learning processes. Of the 15 washback hypotheses proposed by Alderson and Wall (1993), eight are related to learners but very few of them were empirically examined in the 1990s. Meanwhile, empirical studies of testing consequences on parents and employers are almost nonexistent. These areas are, however, seen to be researched increasingly in the 2000s.

Current Views and Research

The 2000s have witnessed an increasing number of research studies on the phenomenon of testing consequences. Major works include:

- Cheng & Watanabe, 2004;
- another special issue on "investigating washback in language testing and assessment" in *Assessment in Education*, volume 14, issue 1, 2007, edited by Pauline Rea-Dickins and Catriona Scott;
- a number of large-scale empirical studies published in the *Studies in Language Testing* (SILT) series (e.g., Cheng, 2005; Wall, 2005; Hawkey, 2006; Green, 2007).

In addition, roughly more than 20 doctoral dissertations and 10 journal articles have been completed and published in applied linguistics journals including *Language Testing* and *Language Assessment Quarterly*. All these studies continued to investigate the influence of testing on various aspects of teaching, and increasingly on various aspects of learning. These studies have also expanded our

understanding of test impact on other testing stakeholders like parents (Cheng, Andrews & Yu, 2011), employers (Pan, 2010), and publishers (Hawkey, 2006). In addition, more studies are seen to investigate the issue of test use using a validity framework (Cheng, Klinger, & Zheng, 2007; Abdul Kadir, 2008; Wang, H., 2010; Xie, 2011).

Cheng and Watanabe (2004) is the first systematic attempt to capture the essence of the washback phenomenon and has, through its collection of washback studies from around the world, responded to the question “what does washback look like?” (p. ix)—a step further from the question “does washback exist?” posed by Alderson and Wall (1993).

Four major sources of evidence are produced over this period of time, predominantly in response to the question of what washback looks like in teaching and learning. First of all, we have empirical evidence that testing influences teaching. Language tests are seen to have a more direct washback effect on teaching content than on teaching methodology. For example, Alderson and Hamp-Lyons’s (1996) washback study in the context of Test of English as a Foreign Language (TOEFL) preparation courses found out that the TOEFL affected both *what* and *how* teachers taught; but the effect was not the same in degree or kind from teacher to teacher, and the simple difference between different types of courses—e.g., TOEFL versus non-TOEFL courses—did not explain why teachers taught the way they did. Over the years, a great number of studies continued to investigate the influence of testing on teachers (including teaching assistants: see Saif, 2006), on teaching practices (see the works of Burrows, Ferman, Hayes, & Read, and Qi in Cheng & Watanabe, 2004),¹ and on textbooks (Hawkey, 2006; Tsagari, 2007). Although the studies of textbooks are not encompassed by Alderson and Wall’s 15 hypotheses, these studies indirectly investigated the *rate* and *sequence* as well as the *degree* and *depth* of teaching and learning (Alderson & Wall, 1993). However, these studies have not yet produced sufficient and direct evidence about the relationship between testing, teaching, and learning. Watanabe (1996; also in Cheng & Watanabe, 2004) was the first to point out that teacher factors, including personal beliefs, past education, and academic background, seemed to be more important in determining the teaching methodology a teacher employs. It is the teacher (who s/he is and what s/he brings as a teacher), rather than the testing, that decides how s/he teaches. In addition, washback studies have investigated other teacher- and teaching-related factors such as teacher ability, teacher understanding of the test and of the approach the test was based on, classroom conditions, lack of resources, and management practices within the school (Tan, 2009; Wang, W., 2009; Yu, 2010; Wang, J. 2011). Among other teaching factors also studied are: the status of the subject being tested in the curriculum, feedback mechanisms between testing agency and the school, and the time elapsed since the introduction of the test (Tan, 2009; Yu, 2010); teacher style, commitment, and willingness to innovate (Cheng, 2005); teacher background (Watanabe in Cheng & Watanabe, 2004); the general social and political context (Wall, 2005; Wang, W, 2009); and the role of publishers in material design and teacher training (Cheng, 2005; Wall, 2005; Hawkey, 2006).

Second, compared with washback studies on teaching and teachers, the studies on learning and learners are still limited. Wall (2000) pointed out that, while it would be useful to continue to study the effects of tests on teaching, it is extremely

important to investigate the effects on student learning, as students receive the most direct impact of testing. This reminds us that, if we wish to establish the relationship between testing, teaching, and learning, it is not sufficient only to study, indirectly along with other instructional variables, teaching and the instructional context where learning is studied. So far we have seen a number of research studies conducted on the relationship between testing, learners, and their learning (Andrews, Fullilove, & Wong, 2002; Qi, 2007), students' attitudes toward testing (Cheng, 2005), and test preparation behaviors (Stoneman, 2006). For instance, in a recent investigation of stakeholder perceptions of test impact on learners in the primary school context in the UK, Scott (2007) found that the degree of test impact varied in different grades. The higher the grades, the more intensive the testing effects felt among the students. In another recent study, Qi (2007) examined students' perceptions of writing in comparison with those of the test constructors embodied in the writing task of the national matriculation English test in China. A mismatch was identified in relation to perceptions concerning writing. The test constructors' intention, as reflected in the input of the writing tasks, was that students would be encouraged to learn to write for communicative purposes. However, students were found to focus only on those aspects of writing that they believed would help achieve better scores, while neglecting the development of the ability to write communicatively in real-life situations. Andrews et al. (2002) studied a major examination change intended to bring about positive washback on teaching and learning. They found that the introduction of the Use of English oral examination as a requirement for university admission in Hong Kong appeared to lead to general improvements in students' spoken performance; however, some students' inappropriate use of transitional words and discourse markers seemed to indicate a rote-learning of exam-targeted strategies and formulaic phrases rather than meaningful internalization. What needs further research in that context is the reason why students think that memorization can help them to cope with a speaking exam. Though not discussed in the above two studies, these findings seem to suggest that students may not always fully understand the construct of a test. This may happen especially in the public exam context, where test-related information may not be directly accessible to students. In addition, students' perceptions of tests are likely to be shaped by the school context, for example, by students' teachers and peers. Therefore it is important to examine not only what students understand about a test, but also how they obtain such knowledge.

In recent years, more attention has been paid to test impact on students' learning practices and test preparation activities. Ferman (in Cheng & Watanabe, 2004), in a study investigating the washback of an oral examination on teaching and learning in Israel, found that intensive learning for the test is prevalent among students and that low ability students tend to learn for the test more intensively than their high ability peers (see also Cheng et al., 2011), believing that cramming can help them achieve a better score. Also, not surprisingly, more students with low language ability than with high language ability turn to private tutors for help. Such findings have resonance in Gosa's (2004) study within the Romanian context, which reports that students feel a strong need to practice exam tasks intensively and actually do so in their personal learning environment. Stoneman's

(2006) study in Hong Kong provides further evidence that students faced with a high stakes exam tended to choose activities mainly intended for test orientation or test-specific coaching. A contribution of her study to our knowledge about washback on learners is that students' past learning and test-taking experiences have a major influence on their choice of types of test preparation activities. Green (2007) emphasizes that it is important for us to know how students understand test demands and whether/how that understanding is related to the test preparation practices they undertake. These studies discussed above suggest that washback on learners does not seem to be any simpler than it is on teachers. Tests used as an agent to promote desirable changes in learners and their learning may not necessarily be efficient tools for change and may not have the desired consequences predicted. The unpredictability of test washback on learners may be due to our lack of understanding about learners' beliefs and expectations in a testing situation (Stoneman, 2006). We need more direct research evidence, for example student behavioral and test performance data, to demonstrate the relationship between testing and learning.

Third, another area that lacks empirical research is washback on parents (also on other stakeholders). The limited research in the literature shows that very often parents see the evaluative and normative values in the test results more than anything else (James, 2000; Scott, 2007). According to Scott (2007), most parents have very little understanding of what tests usually entail and what the test information they receive actually means. James (2000) argues that the function of tests in reporting to parents about their children's learning progress remains unfulfilled. Contrary to what teachers believe, parents have been found to have an interest in knowing more about assessments and to feel responsible for helping their children prepare for exams. A recent study by Cheng et al. (2011) linked parent and student questionnaire responses toward an assessment change and found that parents' views were directly associated with the views of their children and with their children's perceptions of what they did in schools.

Lastly, since Shohamy et al. (1996) first pointed out that the degree of impact of a test is often influenced by several other contextual factors—the status of the subject matter tested, the nature of the test (low or high stakes), and the uses to which the test scores are put—a number of studies investigated the impact of test use (Cheng et al., 2007; Abdul Kadir, 2008; Wang, H., 2010; Xie, 2011). These studies adopted the framework that testing consequences are part of test validity, and they responded to the call launched by Bachman (2005) when he proposed a framework with a set of principles and procedures for linking test scores and score-based inferences to test use and to the consequences of test use. For example, Cheng et al. (2007) conducted a multiphased mixed method study investigating the impact of a large-scale literacy test on second language students in the province of Ontario in Canada. These second language students come to the Ontario secondary school system from other countries and learn their school subjects in English as their additional language. Employing large data sets of student literacy test performance, the study has shown that testing constructs—represented by test formats, text types, skills and strategies of reading, as well as by different writing tasks—impacted second language students differently and significantly in comparison with first language students (those who were born and grew up

in Canada). The study also showed the direction of test impact and the specific areas of performance gaps of second language students. In addition, these students' after-school reading and writing activities predicated their reading and writing performance differently. Apart from linking learners' variables with their test performance, the researchers also used cognitive verbal protocols to listen to student accounts of their test-taking processes (Fox & Cheng, 2007). The findings can be used to inform test validity and to ensure that testing practices yield valid interpretations and uses of test data on the basis of student achievement and performance. This multiphased study investigated a wider range of cognitive and sociocultural variables in relation to test impact on students and on their literacy test performance. The study has investigated far more issues than the 15 washback hypotheses proposed by Alderson and Wall (1993) and has explored the relationship between testing, teaching, and learning by attempting to link test validity, test use, and the consequences of test use.

Current Conceptualization

Empirically, as mentioned above, researchers have studied washback of existing tests and have also explored the use of testing in bringing about new changes in language teaching and learning. The latter approach takes into account the value and stakes of testing in a particular social, teaching, and learning context. The consequences of testing have been closely associated with test validity (consequential validity) and, specifically, with the consequences of test use. Theoretically, the concept of consequential validity has been well argued for in Messick (1989, 1996; see also Cronbach, 1989; Kane, 2002). Messick's (1989) validity framework remains the most influential current theory of validity in language testing and assessment (McNamara & Roever, 2006). This framework details two interconnected facets of the unitary validity concept. One facet is the source of the justification of testing, which is based on the appraisal of either evidence or consequence. The other facet is the function of the test score, which is either interpretation or use. Drawing on Messick's facets of validity matrix (1989),² Haladyna and Downing (2004) echoed the importance of collecting evidence that contributes to construct under-representation and construct-irrelevant variance in test performance. *Construct under-representation* involves error in test performance that is attributed directly to measurement of the specific test construct, whereas *construct-irrelevant variance* involves factors that are disconnected from the test construct but influence test performance. For example, when a test designed for English for academic purposes and for university admission is used for job or professional certification purposes, construct under-representation could occur. When a test taker is too anxious due to social (e.g., family pressure), educational (e.g., entrance to university pending the score), and economic reasons (e.g., costly test registration fee), construct-irrelevant variance would likely contribute greatly to test performance. Construct-irrelevant variance also occurs when cultural and linguistic bias could potentially disadvantage certain subgroups of students (Fox & Cheng, 2007). However, as pointed out by Loevinger (1957) more than 50 years ago, every test under-represents its constructs to some degree and contains sources of

construct-irrelevant variance. What is needed in empirical research is the evidence on what specific constructs are under-represented and on what the sources of irrelevant variance are from multiple stakeholder perspectives.

Contemporary validation practices rely on multiple frameworks to establish evidence to justify score interpretation and test use. While some of these frameworks focus on establishing internal validity through an examination of psychometric processes within testing programs (Bachman, 2005), others maintain a broader scope, considering contextual factors and social consequences on test validity (McNamara & Roever, 2006). Across these frameworks there is a growing emphasis on collecting validity evidence from multiple stakeholders and by using multiple methods. For example, Moss, Girard, and Haniford (2006) have suggested a hermeneutic methodology to access teachers' perspectives toward large-scale and classroom assessment practices. Kane (2002) has used an argument-based model to systematically collect validity evidence at various assessment stages. Focusing on the assessment of language ability, Bachman (2005) has expanded upon this argument-based approach and has proposed the assessment use argument (AUA) framework, which links test scores to interpretations about language ability, and also explicitly links these interpretations to test use.

Challenges

Researchers have not yet been able to establish methodological frameworks for *how* to link test validation with test use in language testing and assessment. Further, the majority of previous studies on consequential validity have been conducted from the perspectives of test designers (Bachman, 2000), which focus on test validation and on the cognitive dimension of testing (McNamara & Roever, 2006). Studies have rarely included the social dimension of language testing, despite the fact that washback is likely to be a function of factors both within the test itself and within the setting where the test is situated (see Messick, 1996). In fact, even fewer studies have considered both the cognitive dimension of language testing (e.g., the interaction of motivation and test anxiety with test takers' test performance) and its social dimension (e.g., potential test uses/misuses within a context) (Cheng, 2008). These two dimensions can result in construct under-representation and in construct-irrelevant variance. So the challenges facing researchers as to how to empirically examine the link between test validation and test use remain.

Given the range and the extent of testing consequences, it is critical that testing practices yield valid data about student achievement and performance. Research in language assessment has demonstrated strong evidence of test validation from the perspective of test developers, albeit with foci exclusively on intended test uses and consequences (Bachman, 2000). However, validity evidence from the perspectives of test takers is still limited in language assessment. Even fewer studies have included the perspectives of parents, employers, and other stakeholders. For example, the impact of public media on a testing context—the impact of how schools are ranked by newspapers—has rarely been studied. Further, only a few language assessment researchers have attempted to draw a link between

test validation and test use. Bachman (2005, p. 7) observes that “the extensive research on validity and validation has tended to ignore test use, on the one hand, while discussions of test use and consequences have tended to ignore validity, on the other.” The application of contemporary validity theory in educational assessment contexts (e.g., classroom assessment, large-scale achievement assessment, and dynamic assessment) has established grounds for the inclusion of consequences and uses within validation studies (Messick, 1989, 1996; Kane, 2002, 2006). Specifically, there is an increasing recognition that construct under-representation and construct-irrelevant variance, together with their attending factors—social consequences, test-taking experiences, and multiple test uses—contribute towards test validation (Haladyna & Downing, 2004). Thus it is critical that the link between test validity and consequences of test use be established from multiple stakeholder perspectives within language assessment. Only then can we better justify the use of test scores in pedagogical practices. Moss et al. (2006) argue that validation studies must include multiple stakeholder perspectives in order to expose sources of evidence that would otherwise stand to invalidate test inferences and uses. If increased, and therefore more informative, measures of validity are desired, an under-representation of test takers’ perspectives in language assessment contexts is clearly problematic. Validation evidence from test takers should include, for instance, an analysis of “how test-takers interpret test constructs and the interaction between these interpretations, test design, and accounts of classroom practice” (Fox & Cheng, 2007, p. 9). The same argument should apply to research on other testing stakeholders. The challenge remains as to how to delineate evidence that was collected from multiple stakeholders and by using multiple methods so as to justify the use of test scores. Criteria for such delineation could be epistemology, paradigms, methods, and funding, just to mention a few.

Future Directions

The phenomenon of testing consequences has existed for a long time and will remain for many years to come. Although empirical research on impact and washback is relatively recent in the field of applied linguistics, it is likely that such effects have occurred for an equally long time. It is also likely that these testing, teaching, and learning relationships are to become closer, more complex, and more contextual in the future, for example, with the increasing research on classroom assessment (see the two special issues, in *Language Testing* in 2004 and *Language Assessment Quarterly* in 2007). How can teaching and learning be understood in the current test-oriented pedagogical and assessment culture? And how can learner-centered and constructive learning take place in the test-oriented culture? What is the relationship between large-scale high stakes testing and classroom-based teacher-led formative assessment? Research evidence in this area, though still limited to the field of applied linguistics, points out that classroom assessment (or assessment outcomes that are used formatively), when used appropriately, can better inform teachers for their curriculum planning and instruction and can better support student learning (Andrade & Cizek, 2010). If

this is true, such assessment practices should be able to minimize the negative consequences of our assessment practices. Teachers could be more willing to adopt quality formative assessment practices than simply to accept and mirror large-scale testing, which in many cases serves purposes beyond classroom practice. It is therefore essential that the members of the educational community (including all testing stakeholders) work together to understand and evaluate the consequences of testing on all of the interconnected aspects of teaching and learning within different education systems around the world. As pointed out earlier, the impact and washback of classroom-based assessments will likely be different from those of assessments derived from large-scale high stakes testing, yet they may be equally complex, if not more so.

Researchers who are interested in conducting research in this area will first of all make deliberate attempts to understand the test they investigate, e.g., by working with the test developers and in the context where the test exists. Their studies need to go beyond the micro-level of the classroom (washback) to the macro-level of society (impact), to analyze the social factors that lead to assessment practices in the first place and to explain why some forms of assessment practice (such as large-scale testing) are valued more than others. Their studies also need to link the use/misuse of test scores with what happens at the micro- and macro-levels of the context. The future research directions, based as they should be on contemporary validation practices, should employ multiple theoretical and conceptual frameworks to establish evidence to justify test score interpretation and test use. This means that empirical studies need to be conducted not only to establish internal validity through an examination of psychometric processes within a testing program (see Bachman, 2005), but also to consider contextual factors and social consequences of test validity (see McNamara & Roever, 2006). Only by doing so can we link test scores to interpretations about language ability within the teaching and learning context, and also explicitly link these interpretations to test use. Further, researchers will need to collect validity evidence from multiple stakeholders, and also by using multiple methods—including mixed method explanatory, exploratory, and concurrent design. Methodologically, researchers must collect sufficient data; they must also attempt to link them from multiple stakeholder perspectives and by using multiple methods. Only then can we confidently make the claim that the testing consequences we find at the micro- and macro-levels are exclusively the results of a testing program, and confidently say what these consequences are.

Classical Test Theory

Yasuyo Sawaki
Waseda University, Japan

Introduction

Classical test theory (CTT) is a measurement theory that developed over the last century and has been used widely ever since, as a framework for examining the precision of measurements obtained from various types of tests. While other complex measurement theories have been developed more recently, knowledge of CTT remains fundamental to their understanding. Quite often, a CTT analysis of assessment data provides us with valuable information as to whether examinee performance data for a target ability of interest, obtained from a given test, are of high enough quality for further score interpretation. Accordingly, CTT data analyses play important roles in constructing and validating tests as well as in interpreting and using test scores in practice. This chapter gives a brief overview of CTT and aims to offer the reader a good conceptual understanding of CTT basics.

Key CTT Concepts

Fundamental CTT Equations

Suppose that you are a non-native speaker of English just starting a degree program at a university in an English-speaking country. Suppose, further, that you need to take a placement test for the university's ESL (English as a second language) program the day after you arrive on campus. In such a situation you might not perform as well as usual: fatigue from the long trip may mean that you cannot concentrate on the test. If the score you have earned is unexpectedly low, you might conclude that this is not because of your English ability but because you happened to take the test on a bad day. As can be seen from this example, a

test score reflects not only the ability we purport to assess, but also other factors that might affect test performance, such as fatigue. The greater the contribution of factors other than the target ability (in this case, English language ability is of interest), the more difficult it is to interpret a given candidate's test score as a measure of his/her ability (in this case, English language ability). This is because the effects of such "extraneous" factors make the candidate's score discrepant from the score that would reflect his/her "true" English language ability.

The example above illustrates the relationship among three key CTT concepts: observed score, true score, and measurement error. The observed score is the score we actually obtain when we test a candidate. The true score is the score reflecting a given candidate's true ability. Note that the true score is a hypothetical entity, because we can never observe someone's true language ability. Measurement error is the difference between the observed score and the true score, reflecting the effects of various factors other than the target ability. In CTT, the relationship between the observed score (X), the true score (T), and the measurement error (E) is expressed in Equation 1 below:

$$X = T + E \quad \text{(Equation 1)}$$

Equation 1 communicates some fundamental ideas of CTT. First, a score that we actually observe is a linear combination of a true score and a measurement error. That is, the smaller the measurement error, the closer the observed score is to the true score. Any measurement that we obtain in real life includes some degree of measurement error. Thus E in Equation 1 above is never equal to zero in practice.

Equation 1 above is extended to explain the variability of test scores across examinees as well. A measure of score variability often used in assessment research is variance, which is the average of squared differences between individual test scores and the mean score across all examinees being analyzed. When we administer a test, we often expect that candidates will differ from one another in terms of the ability being tested. However, parallel to what we have seen in Equation 1, the score variance that we observe reflects not only candidate ability differences, but also various sources of measurement error. Accordingly, CTT defines the observed score variance (σ_x^2) as a linear combination of score variance due to true ability differences (true score variance; σ_t^2) and score variance due to measurement error (error variance; σ_e^2):

$$\sigma_x^2 = \sigma_t^2 + \sigma_e^2 \quad \text{(Equation 2)}$$

Equations 1 and 2 serve as the basis for various CTT concepts that evaluate the consistency of measurement described in this chapter. Before moving on, however, a discussion of two important assumptions of CTT is in order. First, the CTT true score is defined as the theoretically expected score, which is the average score across all scores one would obtain when measurements of a person were taken an infinite number of times under the same measurement conditions. An important assumption here is that each testing is independent, in other words, a candidate's performance on one testing occasion does not affect his/her performance on another. As shown above, the concept of the true score in CTT is math-

emational. Thus the definition is not directly associated with how one conceptually defines the ability of interest, although this point is often confused (Willse, 2010).

Secondly, measurement error is treated as random in CTT. That is, error in CTT is conceptualized as the random variation of an examinee's score from his/her true score unrelated to his/her ability. A random error is temporary in nature. In the ESL placement test example above, the score you obtain the day after you arrive on campus might be lower than usual because you happen to be extremely tired and lack focus during the test session. Alternatively, you might score better on the same test if you happen to take the test when you are in a good physical and mental condition.

It is worth noting that the concept of CTT measurement error above does not make a distinction between random (unsystematic) sources of measurement error that affect individuals differently and systematic sources of error that affect multiple individuals systematically. Bachman (2004) distinguishes two general types of systematic sources of measurement error: those associated with the personal characteristics of candidates; and others, associated with the test method. An example of a systematic source of error concerning personal characteristics is knowledge about the topic of a text used in a reading comprehension test. Candidates who are familiar with the topic—a specific physics theory, for instance—may score systematically better than others on a reading task about this theory. Sources of measurement error pertaining to the test method include those related to the test design, how the test is administered, and how candidate responses are scored. An example is the severity of raters who score candidates' responses in performance assessments. Scores assigned to essays by a harsh rater may be systematically lower than those assigned by a lenient rater. Language assessments often involve these systematic sources of error. Thus the lack of distinction between unsystematic and systematic sources of error is often considered a limitation of CTT, as discussed in more detail later.

Definition of CTT Reliability

The fundamental equations of CTT above extend to defining the notion of reliability of measurement. Reliability refers to the consistency of measurement across different test occasions, different test forms, and different raters, among other things. The notion of reliability is closely related to how we interpret test scores. Two major types of score interpretation often distinguished in the literature are norm-referenced testing (NRT) and criterion-referenced testing (CRT). A primary goal of NRT is to rank-order candidates for decision making (e.g., admission, placement, hiring, and certification), where decisions about candidates are made on the basis of how well they perform in relation to others. Selecting the top three candidates on the basis of their English-speaking test scores as trainees of court interpreters, no matter how high or how low they score, is an example of an NRT situation. In contrast, in a CRT setting, candidate decisions are based on whether their performance levels satisfy a predetermined criterion of performance. In such a situation, only those candidates whose speech samples have earned the rating of "fully functional English speaker" as trainees of court interpreters, for instance, would be selected, regardless of how many candidates pass the exam.

The distinction between the types of test score interpretation above is critical in a consideration of reliability, because reliability of measurement is defined differently in NRT and in CRT. In NRT, reliability means how consistently candidates are rank-ordered no matter when they take the test, what forms are used to test them, and who judges their performance. This definition is distinct from the notion of reliability in CRT, in which reliability concerns how consistently candidates are classified into different performance levels of interest, again, no matter when they take the test, what forms are used to test them, and who judges their performance. Various CTT-based reliability coefficients discussed below are more closely associated with NRT, while CRT reliability coefficients have been developed outside of CTT. Thus CRT reliability coefficients are not discussed further in this chapter. (See Bachman, 2004, and Brown and Hudson, 2002, for more details about CRT.)

Equation 2 above serves as the basis of the mathematical definition of CTT reliability. In CTT, reliability, denoted as $r_{xx'}$, is defined as the proportion of observed score variance that is explained by true score variance. Equation 3 provides the formal definition of reliability, which is denoted as $r_{xx'}$:

$$r_{xx'} = \sigma_t^2 / \sigma_x^2 \quad (\text{Equation 3})$$

Following Equation 2, Equation 3 can be rewritten as Equation 4 below:

$$r_{xx'} = \sigma_t^2 / (\sigma_t^2 + \sigma_e^2) \quad (\text{Equation 4})$$

Given that reliability is a measure of proportion, it ranges from 0.0 to 1.0. Reliability takes its maximum value when the true score variance equals the observed score variance—a situation that is virtually impossible in practice, where the target ability is measured without measurement error. In contrast, reliability approaches 0 as the error variance increases. In language assessment we normally expect our measurements to tell us about candidate ability differences. Thus our goal is to maximize the reliability of our tests.

It should be noted that the definition of reliability above is only a theoretical one, because the true score variance (σ_t^2) is unknown, and thus reliability cannot be obtained directly from Equation 3 or 4. For this reason we need an operational definition of reliability, so that reliability can be estimated. CTT reliability is defined operationally as a correlation between observed scores on at least two sets of parallel measures. In CTT, two measures are considered parallel to each other when they satisfy the following four criteria: (1) the measures must be based on the same test specification, so that they are equivalent in content and the ability being measured; (2) they must have the same mean and variance; (3) their correlations to a third measure must be the same; (4) individual sets of scores must be independent of one another—that is, an examinee's performance on one test does not affect his/her performance on another.

Types of CTT Reliability Coefficients

There are various ways in which CTT reliability estimates are obtained operationally. Table 69.1 provides selected CTT reliability coefficients in three broad catego-

Table 69.1 CTT reliability coefficients for norm-referenced tests

<i>Reliability coefficient</i>	<i>Definition</i>	<i>Features</i>
<i>A. Reliability coefficients based on data obtained from two test sessions</i>		
1. test–retest	Correlation between two administrations of the same test given to the same examinees	<ul style="list-style-type: none"> • Advantage: The coefficients are transparent, closely reflecting the operational definition of CTT reliability
2. parallel forms	Correlation between two parallel forms given to the same examinees	<ul style="list-style-type: none"> • Limitation: Both require testing examinees twice
<i>B. Internal consistency reliability coefficients</i>		
3. split half (Spearman–Brown)	Based on the correlation between halves of a single test (e.g., random split, odd–even, first/second)	<ul style="list-style-type: none"> • Advantage: Only a single test administration is required
4. split half (Guttman)	Based on variances of halves of a single test (e.g., random split, odd–even, first/second)	<ul style="list-style-type: none"> • Limitations: Split half methods are relatively less stable; all coefficients under this category ignore performance difference across occasions and may overestimate reliability
5. Cronbach’s α	Based on variances of individual items treated as parallel measures	
6. KR-20	A special case of Cronbach’s α (for dichotomous data only)	<ul style="list-style-type: none"> • Reliability is underestimated when the parallel measure assumption is not met for the Spearman–Brown split half reliability coefficient and when the essential tau-equivalence assumption is not met for the other four coefficients listed under this category.
7. KR-21	A short-cut estimate of KR-20 (for dichotomous data only)	
<i>C. Rater consistency reliability coefficients</i>		
8. intra-rater reliability	Correlation between scores assigned to a set of examinees by the same rater	<ul style="list-style-type: none"> • Advantage: The coefficients are transparent because they closely reflect the operational definition of CTT reliability
9. inter-rater reliability	<ul style="list-style-type: none"> • Only two raters: correlation between scores assigned to a set of examinees by the rater pair • More than two raters: Cronbach’s α where each rater is treated as an “item” 	<ul style="list-style-type: none"> • Limitation: Multiple sources of error that often affect reliability of performance assessments cannot be modeled simultaneously

ries, according to the type of information they offer about measurement consistency. All coefficients in Table 69.1 except KR-20 and KR-21 are applicable to both dichotomous data (examinee responses to test items scored for two categories such as correct and incorrect) and polytomous data (examinee responses to test items scored for more than two categories, such as fully correct, partially correct, and incorrect), while KR-20 and KR-21 are for dichotomous data only. There are

some other important differences within and across the three categories as well, including how measurement error (the error variance, σ_e^2 , in Equations 4) is conceptualized, how strictly the four criteria for parallel measures above should be satisfied, and what statistics are used for calculation. In the circumstances, it is important for researchers and practitioners to carefully choose a coefficient that provides information about measurement consistency that is appropriate for their specific purposes.

As will be noted later, computer programs can be used to obtain the coefficients in Table 69.1. However, the basic formulas for the calculation of these coefficients will be introduced through discussions of conceptual issues of consideration below, in order to help the reader to better understand the meaning behind the statistics. For more details about the coefficients in Table 69.1, see volumes such as Brown and Hudson (2002), Bachman (2004), and Brown (2005). Moreover, note that the list of CTT reliability coefficients in Table 69.1 is by no means exhaustive. Interested readers should refer to Haertel (2006) for information about a wider variety of CTT reliability coefficients. A given coefficient can also be calculated in various ways. For example, Cronbach's alpha in Table 69.1 can be obtained by using other procedures, such as Hoyt's ANOVA (Hoyt, 1941) and generalizability theory (Shavelson & Webb, 1991; Brennan, 2001).

Category A in Table 69.1 includes two reliability coefficients, a test-retest reliability coefficient and a parallel forms reliability coefficient. These two coefficients are similar in that they both provide information about the consistency of candidate performance across two test sessions. While both require examinees to be tested twice, the nature of the measurement error that these coefficients address is not the same. The test-retest reliability coefficient highlights the degree to which the information obtained from a given test is stable across time (testing occasions) when the test content is held constant. Thus the same test is given twice to each candidate, and a correlation coefficient between the two sets of the test's total score is obtained as the reliability coefficient. In contrast, the parallel forms reliability coefficient focuses on the equivalence of information about candidate performance obtained across different test forms. Accordingly, two different test forms, designed to be parallel to each other, are administered to the same candidates. One can then obtain either a correlation coefficient between the two or a Cronbach's alpha coefficient, as discussed below, as a parallel forms reliability coefficient. (See Bachman, 2004, p. 168, for further details.)

Carefully planned test administration is essential for obtaining test-retest reliability and parallel forms reliability coefficients that provide meaningful information about consistency of measurement. A primary issue of consideration, for three reasons, is to allow a long enough interval between the two test sessions when obtaining data required for calculating these coefficients. First, too short an interval (e.g., administering both measures on the same day by making the test session twice as long) would introduce another, unwanted source of measurement error: candidate fatigue. Second, a reliability coefficient based on data collected at once is likely to overestimate consistency of measurement, because the coefficient would not reflect variability of candidate performance across separate testing occasions. Third, allowing a sufficiently long interval between the two sessions is important in order to control for a practice effect. That is, candidates may

remember what was on the test from the first session when the same form is administered for a second time to obtain the test–retest reliability coefficient. This also applies when obtaining a parallel forms reliability coefficient. There is a possibility that candidates will score systematically higher on the second form than on the first, simply because they become accustomed to the test format and procedure. One way to address this issue is to have a random selection of half the candidates start with one form, and to have the other half start with the other form (Bachman, 2004). When data are obtained by taking account of important administration issues such as those above, test–retest and parallel forms reliability coefficients provide useful information about measurement consistency.

Haertel (2006) notes that the parallel forms reliability coefficient is often considered an ideal reliability coefficient if the data used for the calculation are obtained properly. This is because the coefficient shows the extent to which a combination of two important sources of measurement error—testing occasions and test forms—affects measurement consistency. However, obtaining the data required for the calculation of this coefficient is not easy, because it requires two test sessions. This is one reason why reliability coefficients that can be calculated on the basis of data from one test session are used widely. Five commonly used reliability coefficients of this type, called “internal consistency reliability coefficients,” are listed under Category B in Table 69.1. These coefficients indicate the extent to which information obtained about candidate ability is consistent across different parts of a single test. When scored candidate response data related to individual test items are available, these coefficients can be obtained by splitting the test into multiple parts, in different ways.

The first two coefficients in Category B are two types of split half reliability coefficients based on test halves. The Spearman–Brown split half reliability coefficient can be calculated by plugging a correlation coefficient between the total scores on the halves ($r_{hh'}$) into Equation 5:

$$r_{xx'} = \frac{2r_{hh'}}{1 + r_{hh'}} \quad (\text{Equation 5})$$

However, this coefficient assumes that the two halves are strictly parallel measures, which is difficult in practice. Accordingly, reliability coefficients based on a weaker assumption, called “essential tau-equivalence,” have been proposed. When test halves are essentially tau-equivalent, they have the same true score variance but possibly different measurement error variances. The observed mean scores of the halves may also be different. Guttman (1945) and Rulon (1939) proposed equivalent formulas for a split half reliability on the basis of the essential tau-equivalence assumption. The version proposed by Guttman, which was based on the variances of the halves (designated as s_{h1}^2 and s_{h2}^2) and on that of the total score (designated as s_x^2), is presented in Equation 6 because it is often implemented in statistical packages as the Guttman split half reliability coefficient:

$$r_{xx'} = 2 \left(1 - \frac{s_{h1}^2 + s_{h2}^2}{s_x^2} \right) \quad (\text{Equation 6})$$

When calculating split half reliability coefficients, it is extremely important to obtain halves that can reasonably be treated as comparable to each other. Let us take a vocabulary test comprising items that require identification of the definitions of individual words. If the items are ordered according to difficulty (e.g., on the basis of vocabulary frequency measures), splitting the test into odd- and even-numbered items is a reasonable approach. Alternatively, if the items are positioned in the test with no specific order in mind, one might decide to randomly split the items into halves. Unlike in the example above, however, language assessments often include items that share the same stimulus text (e.g., listening comprehension items based on the same lecture; gap-filling items based on the same reading passage). Because candidate performance on items that share the same stimulus text is related across questions, assigning these items to different halves of the test contributes to inflation of the reliability estimate. It is therefore recommended that such items are kept together when calculating split half reliability coefficients.

The remaining three coefficients under Category B in Table 69.1—Cronbach's alpha, KR-20, and KR-21—treat individual items, instead of halves of the test, as measures that are essentially tau-equivalent to one another and offer information about the degree to which consistent information about candidate ability is obtained across items within a single test. The formula for the Cronbach's alpha coefficient is shown in Equation 7, where k is the number of items in the test, s_i^2 is the item variance, and s_x^2 is the variance of the entire test:

$$r_{xx'} = \frac{k}{k-1} \left(1 - \frac{\sum s_i^2}{s_x^2} \right) \quad (\text{Equation 7})$$

KR-20 and KR-21 are versions of Cronbach's alpha applicable to dichotomous data only. The advantage of these coefficients is the simplicity of the calculation. KR-20 can be obtained when the number of items in the test, the variance of the test, and the proportion of candidates answering individual items correctly are known. KR-21, a shortcut of KR-20, requires only the number of items in the test, as well as the variance and the mean of the total test score.

Cronbach's alpha is the most widely used index of test reliability. As already noted, it is practical because data from only one test session are required for its calculation. Another advantage is its stability. While the split half reliability coefficients yield different reliability estimates depending on how test halves are obtained, Cronbach's alpha is equivalent to the mean across Guttman split half reliability estimates on the basis of all possible ways in which halves of the test are obtained (Haertel, 2006). Thus Cronbach's alpha offers more stable reliability estimates than the split half reliability coefficients.

While these advantages make Cronbach's alpha attractive, caution should be exercised concerning its interpretation and application. First, given that Cronbach's alpha treats individual items as essentially tau-equivalent measures, using this coefficient is appropriate only when individual items are comparable in test design, the ability being assessed, and statistical functioning. When different parts of a test are not essentially tau-equivalent to one another, the coefficient underestimates reliability. For example, a language test often comprises parts designed

to assess different aspects of language ability (e.g., grammar, vocabulary, and reading). Examinee performance on this test may not be consistent across the different parts. Likewise, it is not appropriate to use Cronbach's alpha for obtaining reliability estimates for speed tests. This is because it is likely that at least some of the candidates do not perform well on items toward the end of the test due to lack of time. This instability of candidate performance across items leads to an underestimation of reliability. Thus, when a test is speeded, it is more appropriate to use either a test-retest or a parallel forms reliability coefficient. Finally, it is often said that Cronbach's alpha is a conservative estimate of reliability, offering a lower-bound estimate of internal consistency reliability. As noted by Haertel (2006), however, internal consistency reliability coefficients, including Cronbach's alpha, ignore candidate performance consistency across time. In this sense, Cronbach's alpha can overestimate reliability as well.

While the reliability coefficients discussed so far are often applied to tests in traditional formats comprising a fairly large number of items, some approaches to obtaining CTT reliability estimates for candidate responses scored by human raters have also been discussed in the literature. Human raters are often used to evaluate speech and writing samples in language performance assessments (e.g., oral interview tests and writing tests requiring candidates to write essays). This introduces human judgment into the scoring process, yielding another source of measurement error: consistency of ratings assigned by raters. (See McNamara, 1996, for a detailed discussion on the role of human rater scoring in measurements obtained in language performance assessments.) Even after careful training and monitoring of the raters, the ratings they provide fluctuate for various reasons. Previous research has shown that rater training may help raters to apply scoring rubrics consistently but that such training may not necessarily eliminate systematic differences among them, such as harshness or leniency (e.g., Weigle, 1998).

In NRT approaches to estimating rater reliability for performance assessments, two aspects of the reliability of ratings provided by human raters are widely recognized. One is called intra-rater reliability, which is the extent to which a given rater assigns ratings to a set of candidates' responses consistently across rating occasions. The other is called inter-rater reliability, which is the extent to which ratings assigned to a given set of candidates' responses are consistent across raters. Category C in Table 69.1 offers some approaches to calculating inter- and intra-rater reliability coefficients within the CTT framework. For calculation of an intra-rater reliability coefficient, one can have a given rater score the same set of candidate responses twice. What has been said above on the careful planning of the test administration when obtaining the test-retest and parallel forms reliability coefficients also applies here. It is thus important to secure a sufficient interval between the two rating sessions in order to control for fatigue in the rater, and to present candidate responses to the rater in a different order across the two rating sessions in order to minimize practice effects. A correlation between the two sets of scores obtained from the two rating occasions can then be calculated as an intra-rater reliability coefficient for the specific rater. Meanwhile, a few approaches are possible when examining inter-rater reliability. If there are only two raters involved in scoring examinee responses, a correlation coefficient can be calculated between two sets of scores obtained from the pair of raters on the

same set of candidate responses. By contrast, when there are more than two raters, Bachman (2004) recommends calculating Cronbach's alpha by treating ratings obtained from different raters as different "items" (see Equation 7).

The CTT approaches to rater reliability investigation discussed above provide useful information about how consistently raters assign scores to examinee responses. However, a few words of caution are in order for the appropriate interpretation of the rater reliability information. First, a correlation coefficient tells us how consistently a set of candidate responses are rank-ordered by the same rater across different occasions, or by different raters. Accordingly, as long as the rank ordering of the candidates is the same across the two sets of scores, a perfect correlation ($r_{xx'} = 1.0$) can be obtained between two sets of scores, even when the scores assigned to a given candidate response are not the same. Thus it is recommended that correlation-based inter- and intra-rater reliability coefficients are examined, along with rater agreement information. (See Xi, 2007, for a sample of a study reporting rater agreement information.) Second, the inter- and intra-rater reliability coefficients focus on one source of error at a time, despite the fact that other sources of error, including task difficulty and rater background such as native language and professional training and experience (e.g., Brown, 1995; Johnson & Lim, 2009), are often thought to affect the reliability of language performance assessments as well. This issue will be revisited in the "Challenges" section below.

Spearman–Brown Prophecy Formula

Another important notion developed within CTT is a formula called "the Spearman–Brown prophecy formula," which is often used to estimate how score reliability changes by adding/reducing the number of items in a test. The assumption here is that the items to be added to lengthen a test, as well as those that are already in the test, parallel one another. This formula is also useful in order for us to understand how score reliability is related to test length. The Spearman–Brown prophecy formula is presented as Equation 8, in which $r_{xx'}$ refers to the reliability estimate of the shortened or lengthened test, N refers to the factor by which the original test is lengthened, and $r_{yy'}$ refers to the reliability estimate of the original test:

$$r_{xx'} = \frac{Nr_{yy'}}{1 + (N-1)r_{yy'}} \quad (\text{Equation 8})$$

It should be clear from Equation 8 that the longer the test, the higher the test reliability becomes. For example, imagine that you have constructed a 30-item grammar test with an internal consistency reliability estimate of 0.75. You may wonder to what extent the reliability of your test may improve if the length is doubled. The reliability of a test containing 60 items, which is twice as long as the original (hence $N = 2$), can be estimated by plugging the appropriate numbers into Equation 8 above:

$$r_{xx'} = \frac{Nr_{yy'}}{1 + (N-1)r_{yy'}} = \frac{2 \cdot 0.75}{1 + (2-1) \cdot 0.75} = \frac{1.5}{1.75} = 0.86 \quad (\text{Equation 9})$$

As this example illustrates, the Spearman–Brown prophecy formula is useful for test construction and revision. The formula can be used, for instance, to estimate the number of items required to secure a certain level of reliability in a test based on pilot test data. In such a case, the reliability estimate of the pilot test and the desired level of reliability of the actual test can be plugged into the formula as $r_{yy'}$ and $r_{xx'}$, respectively. The equation can then be solved for N to calculate the number of additional items required.

Standard Error of Measurement

While reliability estimates provide us with information about the consistency of measurements obtained from a test as a whole, they do not tell us how one might go about interpreting individual test scores. Standard error of measurement (SEM) is a measure developed to do just that. SEM refers to the standard deviation of error scores (a square root of the error variance) across repeated independent testing with the same test or a parallel test, assuming that the error is the same across all candidates. Equation 10 shows the formula for calculating SEM:

$$\text{SEM} = S_x \sqrt{1 - r_{xx'}} \quad (\text{Equation 10})$$

S_x in Equation 10 is the standard deviation of the observed scores, and $r_{xx'}$ is the reliability estimate. Equation 10 tells us two things. First, the larger the standard deviation of a test, the larger its SEM. Thus a test that spreads candidates widely across a given scale would yield a relatively large SEM. Second, as $r_{xx'}$ becomes larger, the SEM becomes smaller. One would normally want an SEM to be small, and a test with a high reliability helps us minimize it.

SEM is often used to construct a confidence interval around an observed score of interest in order to estimate the true score with which it is associated. The confidence interval can be set by using the statistical notion of a normal curve and a z score, a standardized score that tells us the location of a specific score in the score distribution. When scores on a given test are distributed normally, 95% of the scores fall between the z scores of -1.96 and $+1.96$ under the normal curve. This concept allows us to estimate where a given person's true score falls. Suppose, for example, that a student earns a score of 50 on a test. If S_x for the test is 10 and $r_{xx'}$ is 0.90, then the SEM for this test can be obtained as in Equation 11:

$$\text{SEM} = 10\sqrt{1 - .90} = 10 \cdot .37 = 3.7 \quad (\text{Equation 11})$$

The 95% confidence interval for the score of 50 can be obtained by using Equation 12, in which the observed score is denoted as X and the absolute value of the z score associated with the 95% confidence level as $|z_{.95}|$:

$$\text{CI} (.95) = X \pm \text{SEM} \times |z_{.95}| = 50 \pm 3.7 \times 1.96 \quad (\text{Equation 12})$$

Equation 12 shows that the lower bound of the 95% confidence interval is 43.8 and its upper bound is 56.2. This suggests that the true score of a person who has scored 50 on the test lies somewhere between 43.8 and 56.2, with the probability

of 0.95. The 95% confidence interval is often used when accurate estimates of true scores are required. Similar confidence intervals can be constructed for other desired levels of confidence by referring to a z-score table available in basic statistics references to look up the z scores associated with the specific confidence levels of interest.

Disattenuated Correlations

In language assessment research, correlation coefficients are often obtained to examine inter-relationships among different parts of the same test and between a test and other external measures. As discussed above, however, all measurements we obtain from a test are affected by measurement error. The same applies to an observed correlation coefficient calculated from two sets of observed scores. In other words, an observed correlation coefficient may not present an accurate picture of the relationship between two variables because measurement error masks the true relationship between them. For this reason the observed correlation is often corrected for the reliability of the variables for further interpretation. The resulting correlation coefficient is called “the disattenuated correlation” or “the true score correlation,” which is an estimate of the correlation between two variables measured with perfect reliability, that is, with no measurement error. Equation 13 shows the formula for calculating the disattenuated correlation coefficient (r_{TaTb}), in which the observed correlation coefficient between Variables A and B is denoted as r_{ab} and the reliability estimates of these two variables as $r_{aa'}$ and $r_{bb'}$, respectively:

$$r_{TaTb} = \frac{r_{ab}}{\sqrt{r_{aa'}r_{bb'}}} \quad (\text{Equation 13})$$

Computer Programs

Although there are few computer programs dedicated to CTT data analysis, widely available statistical packages such as R, SAS, and SPSS implement the internal consistency reliability coefficients listed in Table 69.1. Moreover, all basic statistics introduced in this chapter (mean, variance, standard deviation, and correlation) can be obtained from these programs. They can be used for hand calculation of SEMs (Equation 10), disattenuated correlations (Equation 13), and estimated reliability with different test lengths, on the basis of the Spearman–Brown prophecy formula (Equation 8).

Current Practice

In the field of language assessment, the different types of CTT-based information about the quality of measurements obtained from the language tests discussed above are reported routinely. First, reporting test reliability is, in all circumstances, the responsibility of any test developer, and doing so is of paramount importance for maintaining good testing practice. To this end, guidelines for reporting

reliability in a form that is suitable for a specific test purpose and context are provided in professional standards such as the *Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999) and the International Language Testing Association's (2007) *Guidelines for practice*. While high reliability is usually preferred, expected reliability depends on various issues such as the purpose, stakes, length, and design of a given test. Accordingly, there is no "one size fits all" criterion for how high test reliability should be. Nunnally (1978) offers a useful rule of thumb for suggested levels of test reliability for different purposes, ranging from 0.70 to 0.95 (pp. 245–6).

Second, the standard error of measurement (SEM) discussed earlier in this chapter should be reported along with information about test reliability, because it facilitates the interpretation of individual test scores. One context in particular where the availability of SEM is critical is setting standards for making decisions about candidates on the basis of their test scores. Suppose, for instance, that the example cited in the SEM section above is a high stakes test used for admitting candidates to a university. If the institution wishes to accept candidates whose true score is 55 or above, the institution may as well consider accepting a candidate who earns a score of 50 in the example. This is because, as shown in Equation 13, the 95% confidence interval for the observed score of 50 indicates that the candidate's true score lies between 43.8 and 56.2, with the probability of 0.95, which includes the cut score. By following this procedure to construct confidence intervals for different scores, the institution can adjust the cut score.

Finally, disattenuated correlation coefficients play an important role in test validation studies that employ correlational analyses of test data. Some recent studies that have reported disattenuated correlation coefficients include an investigation of the comparability of test scores between paper-based and computer-based administrations, by Choi, Kim, and Boo (2003), and a validation study of the TOEIC® test for South American learners of English by Sinharay et al. (2009).

Challenges

While CTT has wide applications in measurement, it has some notable limitations that have been discussed elsewhere in the literature. A first limitation is the underestimation of reliability through recourse to frequently used indices such as Cronbach's alpha. However, recent research suggests ways to adjust the value of alpha when the assumption of essential tau-equivalence is violated. For example, an approach based on structural equation modeling (e.g., Raykov, 1997; Raykov & Shrout, 2002) is applicable when different parts of the test are congeneric, a situation where the true score variances of the test parts may not be the same, thereby violating the essential tau-equivalence assumption.

A second limitation is that, essentially, CTT treats only one type of measurement error at a time (e.g., Shavelson & Webb, 1991; Bachman, 2004). As we saw in Table 69.1, different CTT reliability indices feature different aspects of measurement consistency, such as the stability of information obtained across occasions (test–retest reliability and intra-rater reliability), across forms (parallel forms

reliability), across different items on a single test (internal consistency reliability), and across raters (inter-rater reliability). Another closely related issue is that CTT does not distinguish between different types of error. As shown in Haertel's (2006) statement about the parallel forms reliability coefficient mentioned above, it is possible to calculate a reliability coefficient reflecting more than one type of measurement error with careful collection of data. The limitation is, however, that the resulting CTT reliability estimate tells us only about the combined effect of the different sources of error; it does not give us fine-grained information about how individual sources of error and their interactions contribute to measurement error. Together with the fact that CTT does not distinguish unsystematic or systematic errors, the lack of fine-grained information about the effects of multiple sources of error on test score variability is a cause of concern. This is because, as already noted, multiple sources of systematic error and their interactions (e.g., rater severity, rater background, task difficulty) are often thought to affect the reliability of language assessments. Understanding the way in which different sources of error affect measurement consistency is essential for controlling the test design appropriately enough to maximize test reliability. A final concern about CTT, often pointed out by various researchers, is that CTT assumes SEM to be equal across all score levels, which is not the case. It is well-known that measurement error tends to be larger at the higher and lower ends of a score distribution. However, CTT provides only a single, average SEM across all score levels.

Recent advances in measurement models have made it possible to address some of the limitations of CTT listed above. For instance, generalizability theory (G-theory) and a special type of item response theory (IRT) called "many-facet Rasch measurement" are often employed in language assessment research to examine multiple sources of measurement error simultaneously. Moreover, both frameworks offer separate estimates of SEMs for different score levels. These measurement models have additional advantages. For instance, G-theory allows score reliability investigation for both norm-referenced testing and criterion-referenced testing. Meanwhile, IRT approaches allow the estimation of score reliability to be unaffected by the sample taking the test. This is considered advantageous, because CTT reliability calculation depends on the test performance of the specific sample on which the calculation of the statistics is based. For further details about G-theory and many-facet Rasch measurement, see the chapters on these topics in this volume, as well as introductory texts such as Shavelson and Webb (1991) and McNamara (1996).

Future Directions

Despite the advances seen in new measurement theories such as G-theory and IRT, it is expected that CTT will continue to serve as a fundamental measurement theory for examining test reliability and measurement error in the future. A discussion of two issues is in order, however, for the effective use of information obtained within the CTT framework. First, while this chapter focused primarily on the statistical aspects of test reliability and measurement error from the perspective of CTT, too much reliance on statistics should be avoided, because they

provide information about only one aspect of measurement consistency. Rather, test reliability should be evaluated from multiple perspectives. As suggested by Bachman and Palmer (1996), there are various types of logical analyses one can conduct to identify and control various test design features that potentially contribute to measurement error. For example, a document prepared by Educational Testing Service (ETS) (2011) summarizes various issues that they attend to in order to ensure the reliability of TOEFL® iBT (Internet-based test), such as standardizing the test administration conditions, developing detailed test specifications, and training and monitoring raters who score speaking and writing responses. Making such documents publicly available would promote the understanding of test reliability from a wider perspective.

Second, argument-based approaches to test validation that are rapidly developing in the field (e.g., Kane, 2006; Chapelle, Enright, & Jamieson, 2008; Bachman & Palmer, 2010) clarify the role of information obtained from CTT analysis of test data in different stages of test development and validation. In the TOEFL validity argument framework proposed by Chapelle et al. (2008), for example, ensuring test reliability is essential for justifying the generalizability of the scores obtained from a test. This in turn serves as the basis for making claims about the extent to which test scores are linked to a theoretical definition of target ability and candidate language performance in real life, as well as about the utility of test scores for making decisions about candidates. The roles of such information about test reliability in the test validation process are expected to be clarified further, as research on those validity argument frameworks accumulates in the future.

Classical Theory Reliability

James Dean Brown

University of Hawai'i at Mānoa, USA

Introduction

When we measure anything, we need that measurement to be consistent. Let's say I go to the post office and hand the clerk a package. She weighs it and says it is one pound, but that I forgot the return address. I write the return address on the package, and she weighs it again saying that it is one and a half pounds. Should I think, *wow, that ink was heavy?* Or should I question the consistency of the scale she is using? This is exactly the sort of problem that this chapter addresses: How consistent are our measurements? However, here I am concerned not with the relatively trivial issue of consistency in weighing packages, but rather with the consistency, or reliability, of the important measurements that language-teaching professionals make in determining students' scores on tests. These measurements are important because they lead to decisions about college admissions, the level of placement in a language program, passing or failing a course, the grade a student will get in a course, and so forth. Clearly, we need these decisions to be reliable because they affect students' lives in important ways that can cost students time, money, opportunities, and so forth.

The purpose of this chapter is to define and discuss classical theory reliability approaches to test score consistency, with the ultimate goal of helping readers decide whether classical theory reliability is appropriate for their particular tests and score interpretations, and if so which classical theory reliability strategy they should use. While several formulas will be presented to illustrate conceptual issues, space precludes me from explaining in detail how to compute each and every reliability estimate that I cover. However, I will present conceptually important equations with example calculations and some explanation; I will also reference language-testing sources that readers can refer to for further explanations of how to compute the relevant statistics. All classical theory equations will

appear in Roman letters and will be the simplest available version of each equation. While this chapter will assume minimal knowledge of descriptive statistics like the mean, the standard deviation, and test variance (i.e., the standard deviation squared), all other statistics will be defined as the discussion develops. To review basic descriptive statistics, see Bachman (2004, pp. 41–77) or Brown (2005, pp. 89–138).

Reliability and Norm-Referenced Testing

Norm-referenced tests (NRTs) focus on spreading examinees out along a continuum of scores so that educators can make grouping decisions about the examinees. Examples include language proficiency testing used to help in making admissions decisions (admit versus deny), and language placement tests used to determine the level that students should enter their language studies (e.g., beginning, intermediate, or advanced). Much program-level norm-referenced testing was developed and is conducted using *classical theory* (CT) statistics and methods of estimating reliability. Since CT formed the basis of psychometrics during much of the first half of the twentieth century and is alive and well today (as argued in Brown, 2012), all language-teaching professionals interested in testing should understand these basics.

Within CT, reliability can be defined simply as the consistency of a set of test scores. CT reliability has typically been conceptualized, examined, and estimated in terms of psychological *constructs*. In language testing, we are usually interested in *language constructs* like overall English language proficiency, academic English ability, and so forth. As a result, within CT, we are often trying to measure differences among individuals in a particular construct. Test scores are then considered reliable if they are shown to be measuring consistently.

It is important to note that, where reliability focuses on the consistency of the scores on a test, validity focuses on the degree to which the interpretations and uses of the scores on the test are appropriately related to the construct that the test designer purports to be measuring. Thus reliability and validity are different but related concepts. In a sense, reliability is a precondition for validity; that is, the scores on a test must first be reasonably consistent (and therefore systematic) before they can be shown to be systematically measuring what they are purported to measure (see Chapter 65, Evaluation of Language Tests Through Validation Research; Chapter 69, Classical Test Theory).

It is also important to note that all of the concepts discussed in this chapter can, and often should, be applied to subtest scores as well as total test scores. Too often test developers look at the reliability of all of the items on a test without considering the reliabilities of the subtests for listening, reading, grammar, and so forth separately. For example, the Test of English as a Foreign Language Internet-based test (TOEFL iBT) score reliability was reported to be .85, .85, .88, .74, and .94 for the reading, listening, speaking, and writing subtests' scores and total scores, respectively (see http://www.ets.org/s/toefl/pdf/toefl_ibt_research_s1v3.pdf). Clearly, subtest and total test reliability estimates are providing different but useful information, so it may be foolish to ignore either.

Some CT Background

Histories of CT usually begin with Pearson's groundbreaking (1896) demonstration that the best value for a correlation coefficient for two sets of numbers can be determined by dividing their covariance (i.e., the degree to which the two sets vary together) by the product of their two standard deviations (i.e., measures of how much each of the two sets of numbers is dispersed). A consensus was developing among scientists at that time that measurements were not perfect, that is, measurements contained error. CT developed out of these notions. A number of other striking moments occurred in the history of CT. Spearman (1904) used reliability estimates to correct for attenuation (i.e., for lack of reliability) for the first time. Brown (1910) and Spearman (1910) described how to calculate reliability from a single set of test items using what is commonly called the split half reliability adjusted with the Spearman–Brown prophecy formula. Spearman (1913) systematized the basic principles of what we now call CT. Kuder and Richardson (1937) critiqued the existing reliability methods (i.e., split half and test–retest) and derived the now famous KR-20 and KR-21 formulas. Guttman (1945) demonstrated that reliability estimates from a single administration of a test can be considered *lower bounds* estimates (i.e., underestimates) of the correlation between the examinees' observed scores and true scores, which means that any error in estimating the reliability should occur on the conservative side, that is, the estimates should be lower than or equal to the actual state of affairs. Cronbach (1951) first presented the famous alpha (α) reliability statistic, and showed that under certain conditions (discussed below) α is equivalent to KR-20. Amusingly, Cronbach (in Cronbach & Shavelson, 2004) points out that:

So many articles tried to offer sets of assumptions that would lead to the [same] result that there was a joke that "deriving K-R20 in new ways is the second favorite indoor sport of psychometricians." Those articles served no function once the general applicability of alpha was recognized. (p. 397)

All of these CT developments are explained at length in Lord and Novick (1968), and the development and nature of CT reliability are also described in depth in Stanley (1971), Feldt and Brennan (1989), and Haertel (2006).

The Basis of CT Reliability Theory

CT score reliability distinguishes between *observed scores*, which are the examinees' actual scores on a given test, and *errors*, which are random effects due to factors that are not being measured. The variation in observed scores, or the differences among examinees, is called *observed score variance*, and the variation in errors among examinees is called *error variance*. Such error variance is considered random because it comes from nonsystematic sources that are extraneous to the testing purposes. Brown (2005, pp. 171–5) lists a number of error sources that may not be accounted for in the environment (e.g., noise, lack of space, high or low temperatures, and lack of lighting), administration procedures (e.g., faulty

equipment, unclear directions, and differences in timing), scoring procedures (mathematical errors in calculating scores, or rater subjectivity and biases), test items (e.g., low item quality, item types unfamiliar to some examinees, and lax test security), or examinees (e.g., poor health, fatigue, and lack of motivation).

True scores are the theoretical results that would be obtained if there were no errors in measurement. *True score variance* is the variation among examinees that would occur if there were no errors in measurement. A *true score* can be conceptualized as follows: “Roughly speaking, the person’s *true score* is the average score he or she would obtain on a great number of independent applications of the measuring instrument” (Cronbach & Shavelson, 2004, p. 395). If a set of observed scores is completely random, the *true score variance* will theoretically be 0% and *error variance* will be 100%. However, since any test is designed to measure some construct, it is much more likely that at least some portion of the observed score variance will be attributable to true abilities in that construct. Hence some portion of the variation in observed scores is likely to be true score variance and some proportion error variance. Conceptually, those relationships are often represented as follows:

$$\text{Observed score variance} = \text{True score variance} + \text{Error variance}$$

The CT framework for reliability is based on the observation that the proportion of observed score variance attributable to true score variance is the *proportion of reliable variance* and the rest is error variance. For example, the reliability for the composite scores on the Academic Module of the International English Language Testing System (IELTS) in 2010 is reported to be .95 (see http://www.ielts.org/researchers/analysis_of_test_data/test_performance_2010.aspx). This means that the proportion of reliable variance was .95 (or 95%), and the rest, .05 (or 5%), is error.

Within this CT framework, two types of approaches are traditionally used to examine reliability statistically: proportions-of-reliability approaches and error-estimation approaches. The remainder of this chapter will be divided into two sections explaining those two approaches (for more information on CT reliability in language testing, see Bachman, 2004, pp. 153–91; Brown, 2005, pp. 169–98).

Proportions-of-Reliability Approaches

Most often, the reliability of a set of scores is reported as a proportion on a scale of 0.00 to 1.00, indicating that the scores are not consistent at all (0.00, or 0%) or completely consistent (1.00, or 100%), or somewhere in between. For instance, say the reliability for a set of scores is .85. That means that the scores are 85% reliable (and by extension 15% unreliable). But is .85 good enough? Shrout (1998, p. 308) suggested some rule-of-thumb standards for interpreting reliability estimates:

.00 to .10	virtually none
.11 to .40	slight
.41 to .60	fair
.61 to .80	moderate
.81 to 1.00	substantial

I personally interpret reliability estimates more conservatively, something like:

.00 to .30	virtually none
.31 to .50	slight
.51 to .70	fair
.71 to .89	moderate
.90 to 1.00	substantial

Since such interpretations depend heavily on additional information like the type of test, test length, testing conditions, and so forth, language professionals will have to decide for themselves how to take all of the relevant factors into consideration in interpreting particular reliability estimates.

Four proportions-of-reliability strategies are commonly used for estimating CT reliability: test–retest, equivalent-forms, internal-consistency, and rater.

Test–Retest Reliability

Test–retest reliability addresses the consistency of a set of test scores over time. The tester begins by administering the items to the same group of examinees twice with testing sessions far enough apart so examinees won't remember the test items, and yet close enough together so they are not likely to have learned anything substantial related to the items. A *Pearson product–moment correlation coefficient* is then calculated between the two sets of scores (henceforth referred to simply as *correlation coefficient*; for more on this concept and instructions for calculating it by hand, see Bachman, 2004, pp. 78–109; or with a spreadsheet program, see Brown, 2005, pp. 139–62). This correlation coefficient provides a test–retest reliability estimate, which represents the proportion of reliable (or true score) variance over time for the scores. This approach is conceptually fairly easy to understand, but it has the drawback that the examinees must take the same test twice.

Equivalent-Forms Reliability

Traditionally, *equivalent-forms reliability* addresses the stability of test items across forms. It requires developing two equivalent tests and administering them to a single group of examinees. Next a correlation coefficient is calculated for the two sets of resulting scores. This coefficient provides an equivalent-forms reliability estimate that indicates the proportion of reliable (or true score) variance on either form of the test. This approach is conceptually fairly easy to understand. However, it has the drawbacks of requiring that the examinees take two very similar tests and that the two forms are equivalent.

Internal-Consistency Reliability

In order to overcome the drawbacks of test–retest and equivalent-forms reliabilities, test designers most often use *internal-consistency reliability*, which has the distinct advantages of being based on only one test form and only one test

administration. Internal-consistency reliability estimates come in many forms, but the most common are split half, Kuder–Richardson formulas 20 and 21, and Cronbach’s alpha reliabilities.

Split half reliability is conceptually the simplest internal-consistency strategy. It is similar to the equivalent-forms strategy except that the equivalent forms in this case are created by separating a single test into two equal parts, usually by scoring the odd-numbered and even-numbered items separately for each examinee. The tester then calculates a correlation coefficient between the odd-numbered and even-numbered scores and that provides an estimate of the reliability for either the odd-numbered scores or the even-numbered scores. However, since testers are normally interested in the full-test reliability (i.e., the scores for all items combined) and since a longer test is typically more reliable than a short one, an adjustment must be made to the half-test correlation using the *Spearman–Brown prophecy formula* (Brown, 1910; Spearman, 1910) in order to estimate the full-test reliability. That formula is:

$$r_{xx'} = \frac{2 r}{1+r}$$

where $r_{xx'}$ = full-test reliability and r = half-test reliability. For example, consider a 30-item test that has a half-test (15-item) reliability of .80. The full-test (30-item) reliability would be:

$$r_{xx'} = \frac{2 r}{1+r} = \frac{2 \cdot .80}{1+.80} = \frac{1.60}{1.80} = .8888 \approx .89$$

A more general version of the Spearman–Brown prophecy formula can be used for estimating the reliability of a test that is increased in length by any number of times (e.g., 3 times, 4 times, 2.5 times, etc.):

$$r_{xx'} = \frac{n r}{(n-1)r+1}$$

where the symbols are the same except for n = number of times length is increased. For instance, for the same example, let’s say that we want to make it a 45-item test and would like to estimate the reliability that we are likely to get if all other factors except length are held constant. In this case, 45 is three times ($n = 3$) as long as the half-test reliability of 15, so the adjustment would be:

$$r_{xx'} = \frac{n r}{(n-1)r+1} = \frac{3 \cdot .60}{(3-1) \cdot .60+1} = \frac{2.40}{(2) \cdot .80+1} = \frac{2.40}{1.60+1} = \frac{2.40}{2.60} = .9231 \approx .92$$

For more on calculating split half reliability, see Bachman (2004, pp. 161–2), Bachman and Kunnan (2005, p. 86), or Brown (2005, pp. 176–9, 190–2).

Rulon (1939) offered an alternative formula for calculating split half reliability that is slightly easier to calculate because it avoids the Spearman–Brown adjustment:

$$r_{xx'Rulon} = 2 \left(1 - \frac{S_{odd}^2 + S_{even}^2}{S_{total}^2} \right)$$

where $r_{xx'Rulon}$ = Rulon's split half reliability for the full test; S_{odd} = standard deviation for the odd-numbered items; S_{even} = standard deviation for the even-numbered items; and S_{total} = standard deviation for the total test scores. Like the regular split half estimate, Rulon's method has the drawback that it requires scoring the test three times: once each for the odd, even, and total scores. Rulon's method also assumes that the two have equal covariances. For example, say the test above turned out to have $S_{odd} = 3.92$, $S_{even} = 4.15$, and $S_{total} = 7.11$. Then:

$$\begin{aligned} r_{xx'Rulon} &= 2 \left(1 - \frac{S_{odd}^2 + S_{even}^2}{S_{total}^2} \right) = 2 \left(1 - \frac{3.92^2 + 4.15^2}{7.11^2} \right) = 2 \left(1 - \frac{15.37 + 17.22}{50.55} \right) \\ &= 2 \left(1 - \frac{32.59}{50.55} \right) = 2(1 - .6447) = .7106 \approx .71 \end{aligned}$$

For more on calculating split half reliability this way, see Bachman (2004, p. 162) and Bachman and Kunnan (2005, pp. 84-5), where it is called the Guttman split half in both cases; or Brown (2005, p. 174), where it was labeled *Cronbach α* because Cronbach (1970, p. 161) called it α_k , which "is really just the first α_k formula, with $k = 2$," and because it was easier to calculate than the original alpha equation.¹

Kuder-Richardson formulas 20 and 21 (KR-20 and KR-21, respectively) are widely taught and used in language testing (for the original derivation, see Kuder & Richardson, 1937). *KR-21* is the easier of the two to calculate because it only requires knowing the number of items (k), as well as the mean (M) and the standard deviation (S) for the total test scores. It can be expressed as follows:

$$KR-21 = \frac{k}{k-1} \left(1 - \frac{M(k-M)}{kS^2} \right)$$

Consider a test where $k = 50$, $M = 24.91$, and $S = 8.12$. The KR-21 reliability in this case would be:

$$\begin{aligned} KR-21 &= \frac{k}{k-1} \left(1 - \frac{M(k-M)}{kS^2} \right) = \frac{50}{50-1} \left(1 - \frac{24.91(50-24.91)}{50(8.12^2)} \right) \\ &= 1.0204 \left(1 - \frac{24.91(25.09)}{50(65.93)} \right) = 1.0204 \left(1 - \frac{624.99}{3296.5} \right) \\ &= 1.0204(1 - .1896) = 1.0204(.8104) = .8269 \approx .83 \end{aligned}$$

KR-20 is somewhat more difficult to calculate because it involves item-level computations, but it does provide a more accurate (sometimes much more accurate) estimate of reliability than *KR-21*. *KR-20* is often given as follows:

$$KR-20 = \frac{k}{k-1} \left(1 - \frac{\sum p(1-p)}{S^2} \right)$$

where k = number of items; Σ = sum, or add up; p = proportion answering each item correctly; and S^2 = total score variance. The hard part is calculating $\Sigma p(1 - p)$, which is done as follows: the item facility (p) must be calculated for each item, then subtracted from 1.00; then the result of $(1 - p)$ is multiplied times p for each item. For example, if $p = .40$, $(1 - p) = .60$ and $.40 \times .60 = .2400$. That needs to be done for each item on the test. Then to get $\Sigma p(1 - p)$, the individual item results must be added up. With that sum in hand, the tester is ready for the final steps in calculating KR-20. For example, for a test with 50 items (k), where $\Sigma p(1 - p) = 8.99$, and $S = 7.94$, KR-20 would be:

$$\begin{aligned} \text{KR-20} &= \frac{k}{k-1} \left(1 - \frac{\Sigma p(1-p)}{S^2} \right) = \frac{50}{50-1} \left(1 - \frac{8.99}{7.94^2} \right) \\ &= 1.0204 \left(1 - \frac{8.99}{63.0436} \right) = 1.0204(1 - .1426) = .8748 \approx .87 \end{aligned}$$

Both KR-20 and KR-21 have the limitation that they can only be applied to items that are dichotomously scored (i.e., right or wrong). KR-21 additionally assumes that items are of equal difficulty, which is sometimes far from true in language testing. For example, the item difficulties in cloze tests often vary wildly from 0.00 to 1.00 (i.e., everyone answering incorrectly to everyone answering correctly, respectively); such violations of the assumption can cause serious underestimates of reliability when using KR-21 as compared to other strategies (Brown, 2005, p. 181). For more on calculating KR-20 and KR-21, see Bachman (2004, pp. 163–4), or for a spreadsheet approach, see Brown (2005, pp. 179–85, 193–5).

Cronbach's alpha (α) is the most commonly reported internal-consistency estimate in language testing and research, probably because it is flexible (i.e., it can be applied to items that are scored right or wrong, but also to items that are not dichotomously scored, e.g., weighted items, Likert scales, etc.). Other reasons for the apparent pre-eminence of Cronbach's alpha (or simply "alpha") in CT are described by Cronbach (in Cronbach & Shavelson, 2004, p. 396):

One of the bits of new knowledge I was able to offer in my 1951 article was a proof that coefficient alpha gave a result identical with the average coefficient that would be obtained if every possible split of a test were made and a coefficient calculated for every split. Moreover, my formula was identical to K-R 20 when it was applied to items scored one and zero. This, then, made alpha seem preeminent among internal consistency techniques.

Thus, alpha is equivalent to KR-20 when applied to dichotomously scored items, but is also more flexible. The original Cronbach (1951) alpha equation was:

$$\alpha = \frac{k}{k-1} \left(1 - \frac{\Sigma S_i^2}{S_t^2} \right)$$

where k = number of items; Σ = sum or add up; S_i^2 = item variances (item standard deviation squared); and S_t^2 = total score variance (test score standard deviation squared).

If the same dichotomously scored item data were used to calculate α that were used above to calculate KR-20, $\Sigma p(1 - p)$ would equal $\Sigma S_i^2 = 8.99$ and S would equal $S_i = 7.94$, and of course, there would still be 50 items, so the result would be exactly the same for KR-20 and α , as follows:

$$\begin{aligned}\alpha &= \frac{k}{k-1} \left(1 - \frac{\Sigma S_i^2}{S_i^2} \right) = \frac{50}{50-1} \left(1 - \frac{8.99}{7.94^2} \right) = 1.0204 \left(1 - \frac{8.99}{63.0436} \right) \\ &= 1.0204(1 - .1426) = .8748 \approx .87\end{aligned}$$

However, calculating ΣS_i^2 would mean calculating the standard deviation and then squaring it for each and every item, then adding them up. For dichotomously scored items (coded 1 for correct and 0 for incorrect) the result would be the same as for $\Sigma p(1 - p)$. However, if the data were for items with weighted scoring, say 2 for factually and grammatically correct, 1 for factually correct, and 0 for completely incorrect, only ΣS_i^2 could be calculated, and therefore only α is applicable if the items are not dichotomously scored. Note that calculating either ΣS_i^2 or $\Sigma p(1 - p)$ by hand takes inordinate amounts of time (see Brown, 2005, pp. 181–5), but it can be done quickly in a spreadsheet program (as explained in Brown, 2005, pp. 193–5). In addition, for those who have it available, the SPSS statistical program can be used to calculate α and several of the other reliability estimates discussed here (as shown in Bachman & Kunnan, 2005, pp. 83–4). Additional information about alpha is available in Bachman (2004, pp. 163, 170). Note also that, because α can handle weighted scores, it can also be used for ratings, as explained below.

Rater Reliability

Rater reliability is a common concern in language testing because situations are common where raters are asked to make judgments about the language performances of examinees (e.g., examinees' productive speaking and writing skills as in essay writing, oral interviews, role plays, task performance, etc.). Within CT, such reliability estimates typically take the form of inter-rater, intra-rater, or alpha reliability estimates.

Inter-rater reliability is calculated by lining up the scores produced by two raters for a single group of examinees and calculating a correlation coefficient between those two sets of scores. The resulting coefficient provides an estimate of the inter-rater reliability of the ratings of either rater. If the scores are to be added up or averaged and then serve as the basis for decision making, the tester may wish to use the first Spearman–Brown prophecy formula described above to estimate the two-rater reliability (or use the more general formula to estimate reliability for other multiples like three or four raters). Inter-rater reliability coefficients provide estimates of the reliability of judgments between raters. For instance, let's say that the correlation between the ratings assigned to a set of compositions by Randy and Jeanne produce a correlation coefficient of .63. That would indicate that either Randy's ratings or Jeanne's ratings are 63% reliable (and 37% unreliable). If that is not a satisfactory level of reliability in a given situation, they might consider adding their ratings together (or averaging them) for each student, in which case

the Spearman–Brown prophecy formula could be used to estimate the reliability for both raters combined as follows:

$$r_{xx'} = \frac{2}{1+r} r = \frac{2}{1+.63} \frac{.63}{1.63} = \frac{1.26}{1.63} = .7730 \approx .77$$

If they were thinking about the possibility of bringing in more raters, they could also estimate what the reliability would be for three raters, four raters, and so forth, based on their current data, by using the more complex Spearman–Brown prophecy formula discussed earlier in the chapter.

Intra-rater reliability is calculated in a similar manner. However, the two sets of scores are produced by the same rater for a single group of examinees on two separate occasions, followed by calculating a correlation coefficient for the two sets of scores. That coefficient provides an estimate of the intra-rater reliability of the ratings on either of the two occasions. However, if the two sets of ratings are to be added up or averaged and then serve as the basis for decision making, again, the tester may wish to use the Spearman–Brown prophecy formula described above to estimate the reliability for the two ratings taken together. Intra-rater reliability coefficients provide estimates of the reliability of a rater's judgments over time. For instance, let's say that Randy must also rate a set of interviews that he taped with students, but he cannot coerce Jeanne into doing the ratings too. So he rates the interviews on two occasions one week apart. He can then calculate the correlation coefficient between his two sets of interview ratings to determine the single-occasion reliability. Let's say that turns out to be .73. If that level of reliability does not seem satisfactory to Randy, he might consider adding his ratings from the two occasions together (or averaging them) for each student. Again, the Spearman–Brown prophecy formula could be used to estimate the reliability for the scores combined from both rating occasions as follows:

$$r_{xx'} = \frac{2}{1+r} r = \frac{2}{1+.73} \frac{.73}{1.73} = \frac{1.46}{1.73} = .8439 \approx .84$$

Randy could also estimate what the reliability would be for three occasions, four occasions, and so forth, based on his current data, by using the more complex Spearman–Brown prophecy formula discussed earlier in the chapter.

Using *alpha for ratings* is another possibility. If the scores assigned by each rater are viewed as items, then the standard deviations for each rater's scores can be squared and added up as follows:

$$\Sigma S_r^2 = S_{r_1}^2 + S_{r_2}^2 + S_{r_3}^2 + S_{r_4}^2$$

Since ΣS_r^2 is the same conceptually as ΣS_i^2 ,

$$\alpha = \frac{k}{k-1} \left(1 - \frac{\Sigma S_i^2}{S_i^2} \right) = \frac{k}{k-1} \left(1 - \frac{\Sigma S_r^2}{S_r^2} \right)$$

For example, consider a situation in which four raters (so $k = 4$) on a 6-point holistic rating scale for a possible total of 24 points assigned scores to 30 compositions, where the standard deviation for the total scores (S_t^2) was 3.96 for the four raters' scores combined, where the standard deviations for the four sets of ratings separately were 1.11, 1.06, 1.23, and 1.01, respectively, and where the squared values of those standard deviations were 1.2321, 1.1236, 1.5129, and 1.0201, respectively, and their sum (ΣS_r^2) was 4.8887. In that case:

$$\begin{aligned}\alpha &= \frac{k}{k-1} \left(1 - \frac{\Sigma S_r^2}{S_t^2} \right) = \frac{k}{k-1} \left(1 - \frac{\Sigma S_r^2}{S_t^2} \right) = \frac{4}{4-1} \left(1 - \frac{4.8887}{3.96^2} \right) \\ &= 1.33 \left(1 - \frac{4.8887}{15.6816} \right) = 1.33(1 - .3116) = .9156 \approx .92\end{aligned}$$

Clearly, Cronbach's α is very flexible, since it is applicable not only to dichotomously scored tests (as are the KR-20 and 21 internal-consistency estimates), but also to tests with weighted scoring schemes, and to ratings. This flexibility also means that α is applicable to questionnaire data like Likert scales. All in all, α is a very useful tool for language testers and researchers. Unfortunately, it is more difficult to calculate by hand than some of the other reliability estimates, but with minimal skills in a spreadsheet program like Excel, the calculations are relatively easy, and for those who know how to use the SPSS statistical program, α is very easy to calculate (see Bachman & Kunnan, 2005, pp. 83–4). For more on rater reliability, see Bachman (2004, pp. 169–70) or Brown (2005, pp. 185–8).

Error-Estimation Approaches

Reliability estimates help testers examine the proportion of consistent variance on a test. However, another, more practical and perhaps more useful, way to examine the consistency of a set of scores is to estimate the amount of error in test score points by calculating the *standard error of measurement* (SEM):

$$SEM = S\sqrt{1 - r_{xx'}}$$

where S = the standard deviation of the scores on a test and $r_{xx'}$ = the reliability estimate for those scores. Consider a test that has $S = 6.34$ and $r_{xx'} = .87$. The SEM would be:

$$SEM = S\sqrt{1 - r_{xx'}} = 6.34\sqrt{1 - .87} = 6.34\sqrt{.13} = 6.34(.3606) = 2.2862 \approx 2.29$$

The resulting SEM of 2.29 can be used to further estimate *confidence intervals* (CIs) that indicate how many score points of variation can be expected with 68%, 95%, or 98% probability (based on percentages under the normal distribution) around any given point (e.g., a cut point). Let's say that the SEM for that test with the SEM of 2.29 points had a cut point for passing the test of 55. The tester will know that the score for any examinee falling within one SEM plus or minus

($55 + 2.29 = 57.29$; $55 - 2.29 = 52.71$; or a band from 52.71 to 57.29) is likely to fluctuate within that band 68% of the time by chance alone if the test were administered repeatedly. Similarly, any examinee falling within two SEMs plus or minus ($2 \times 2.29 = 4.58$; $55 + 4.58 = 59.58$; $55 - 4.58 = 50.42$; or a band from 50.42 to 59.58) is likely to fluctuate within that band 95% of the time by chance alone, and an examinee falling within three SEMs plus or minus ($3 \times 2.29 = 6.87$; $55 + 6.87 = 61.87$; $55 - 6.87 = 48.13$; or a band from 48.13 to 61.87) is likely to fluctuate within that band 98% of the time. Practically speaking, testers may want to at least consider gathering additional information about any examinees who have scores within the band of plus or minus one SEM of any cut point in order to increase the reliability of the decision making. Whether the tester decides to choose a 68%, 95%, or 98% CI is a judgment call.

For example, let's consider a placement test that has scores ranging from 20 to 80 and a cut point of 60 between the intermediate and advanced level English as a second language (ESL) courses. The test designer dutifully calculates the SEM and finds that it is 4.33. He then informs the decision makers that they should gather additional information (e.g., additional test scores, a writing sample, an interview, etc.) for any examinee falling within the 68% confidence interval between 55.67 and 64.33 (i.e., $60 - 4.33 = 55.67$; $60 + 4.33 = 64.33$) to make reasonably sure the placement decisions for these particular examinees are consistent and accurate.

For additional information on SEM, see Bachman (2004, pp. 171–4) or Brown (2005, pp. 188–90, 193–5).

Conclusions

Table 70.1 summarizes the material in this chapter, but with an eye to helping readers determine which reliability statistic(s) they might want to use in a given testing situation. That said, it is important to first recognize that this chapter, and therefore the table, only cover the reliability of NRTs as analyzed within CT. However, NRTs are common and CT statistics are relatively easy to understand and calculate. For readers who prefer ease of understanding and calculation and who want to analyze the reliability of NRTs from a CT perspective, this chapter and table are perfect. If, however, ease of understanding and calculation are not crucial and readers are interested in (a) analyzing NRTs from a more sophisticated point of view where sources of measurement error can be studied and accounted for, (b) investigating the dependability of their criterion-referenced test scores, or (c) studying the dependability of the decisions they are making at certain cut points, then, the next chapter will better serve their purposes (Chapter 71, Score Dependability and Decision Consistency). So the first decision in selecting the form of reliability analysis is to decide whether to use this chapter or the next. Those choosing the next chapter may want to skip to it now.

For those readers who have decided on this chapter, the next step is to look at column one of Table 70.1 and decide on the form of the estimate, that is, whether they are interested in the proportion of reliability of their test or in an estimate of the amount of error in test score points. If the goal is to find out the proportion

Table 70.1 Selecting the appropriate reliability strategy

<i>Form of estimate</i>	<i>Reliability strategy</i>	<i>Specific statistic</i>	<i>Pros</i>	<i>Cons</i>
Proportion-of-reliability	Test-retest	Correlation coefficient for scores from test administered twice	Conceptually clear	Must administer same test twice to same examinees
	Equivalent-forms	Correlation for scores on two equivalent forms administered	Conceptually clear	Typically done by developing two equivalent tests and administering both to same examinees
	Internal-consistency	Split half $r_{xx'}$	One administration and one test; conceptually easy	Must score separate halves and total; Spearman-Brown needed for full-test reliability
Error-estimation	Standard error and confidence intervals	Rulon's split half $r_{xx'Rulon}$	One administration and one test; fewer steps than plain split half	Must score separate halves and total; assumes equal covariances
		Kuder-Richardson formula 21 (KR-21)	One administration and one test; relatively easy to calculate	Only for dichotomous items; may seriously underestimate if equal item difficulty assumption not met
		Kuder-Richardson formula 20 (KR-20)	One administration and one test; accurate	Only for dichotomous items; relatively difficult to calculate
		Cronbach's alpha (α)	Accurate and flexible (complex scoring possible)	Relatively difficult to calculate
		Inter-rater reliability is correlation between scores produced by two raters	Conceptually clear because similar to equivalent-forms reliability	Must use Spearman-Brown for two (or more) rater reliability
		Intra-rater reliability is correlation of scores produced by same rater twice	Conceptually clear because similar to test-retest reliability	Must use Spearman-Brown for two (or more) occasion reliability
		Alpha α for ratings	One administration and one test; accurate and flexible (complex scoring possible)	Relatively difficult to calculate
Error-estimation	Standard error and confidence intervals	Calculate SEM and use CIs at 68%, 95%, or 98% in decision making	Conceptually clearer than proportion of reliability	A step beyond reliability; subject to same cons as reliability estimate used

of reliability, then the reader must decide which strategy to use: test-retest, equivalent-forms, internal-consistency, or rater reliability. Then, for example, if readers choose the internal-consistency reliability strategy, the next step is to examine the specific statistics available and read through the pros and cons of each. From all of that, readers should be able to decide what the most appropriate statistic would be for their purposes. Referring back to the associated section of the chapter will provide the appropriate equation(s), show how to do the actual calculations, and supply additional references on the specific statistic so the reader can easily find further information if needed.

For example, let's say a group of teachers is interested in using a reliability statistic that is relatively easy to understand and calculate for a set of NRT placement test scores, and that they are interested in both the proportion-of-reliability and the error-estimation forms. After reading through the specific statistics column as well as the pros and cons, they decide to use the internal-consistency type that is easiest (i.e., requires only one administration of one test and is relatively easy to calculate); the table indicates that KR-21 would be appropriate but warns in the last column that the items must be dichotomously scored and be of about equal difficulty. These teachers also decide to use the SEM and CIs, and then refer back to the appropriate sections of the chapter and are able to calculate both KR-21 and the SEM, and use the SEM by interpreting it in terms of CIs for their placement test. It turns out that $KR-21 = .92$ and the $SEM = 4.18$. These results tell them that their scores are substantially reliable and, because they only need the 68% CI, they realize that they should gather additional information about any students within a range of plus or minus one SEM of 4.18 points of any cut point. Thus these teachers are able to make more reliable and professional decisions.

Alternatively, the table can be used to quickly learn about any of the specific reliability statistics by searching it out in column three and reading the material to the left and right of it in the same row. For instance, say the reader wants to remember what KR-20 is. Reading to the left, it is clearly a proportion-of-reliability statistic that estimates the internal consistency of a set of scores. Reading to the right, KR-20 can be used for a single test administered once, is accurate, is appropriate only for dichotomously scored items, and is relatively difficult to calculate.

Factors Affecting the Reliability of NRTs

For readers who would like to maximize the possibility of reliability in their test scores, it is worth considering factors that might affect reliability. Both Bachman (2004, pp. 190, 204–5) and Brown (2005, pp. 171–5, 222) discuss factors that affect the reliability of NRTs. Here, I will combine, reorganize, and liberally adapt from those observations. To begin with, in planning, developing, revising, implementing, and interpreting the test items, sources of error should be minimized in the environment, administration procedures, scoring procedures, test items, and examinees. In addition, the possibility of reliability will be maximized for any set of test scores by making sure the test is as long as is reasonable (without sacrificing the quality of the items), is well written and designed, and is as homogeneous in what it tests as makes sense in the situation. In addition, reliability will be

maximized if items are selected for the test that have been shown to discriminate (between the high- and low-achieving students), if the distribution of total scores is normal, and if the examinees to whom the items are administered range in ability as widely as makes sense in the particular testing situation.

Again, I remind readers that score reliability and validity are different concepts. Reliability is concerned with the consistency of scores on a test, while validity is focused on the degree to which the interpretations and score uses are appropriately related to the construct that the test designer purports to be measuring. In addition, reliability is a reasonable precondition for validity, that is, the scores on a test must logically be consistent before they can be shown to be consistently measuring what they are purported to measure.

Future Directions

I have shown in this chapter how research and practice in CT reliability for NRTs have developed and changed over time and how they stand today in language testing. Such developments will no doubt continue. In my view, the language-testing community would benefit from further developing some or all of the following topics:

1. test reliability for test scores made up of testlets (collections of items considered together as units or clusters, e.g., the items associated with a particular reading passage, those associated with a specific listening test lecture, etc.).
2. the importance of using the SEM and CI in interpreting and using reliability information. As Cronbach (in Cronbach & Shavelson, 2004, p. 413) put it: "I am convinced that the standard error of measurement . . . is the most important single piece of information to report regarding an instrument, and not a coefficient. The standard error, which is a report on the uncertainty associated with each score, is easily understood not only by professional test interpreters but also by educators and other persons unschooled in statistical theory, and also to lay persons to whom scores are reported."
3. the benefits of examining *conditional errors* in language testing. One of the great benefits often touted for item response theory (IRT) is that, unlike the CT SEM, which is the same at all score levels, IRT can supply estimates of measurement error for each score level. This state of affairs is true for the CT SEM because generally only *unconditional errors* (i.e., errors that are assumed to be the same for all examinees) have been considered, but if *conditional errors* (i.e., errors that vary depending on examinees' true scores) are considered, language testers will indeed be able to estimate errors at each score level within a CT framework (see Haertel, 2006, pp. 82–4, 98–9; Qualls-Payne, 1992). Clearly, research examining applications of errors conditioned on true scores would be useful in language testing.

Note

- 1 Note that there is some confusion in the labeling of these formulas in both Bachman (2004) and Brown (2005), which is not to say that either is wrong, but rather that the literature (especially when using secondary sources) is sometimes very confusing. For example, for the equation labeled $r_{xx'Rulon}$ in this chapter, Rulon (1939) is the earliest primary source I was able to locate, but he attributed it to Flanagan, and Guttman (1945) published an algebraically equivalent formula. So is it Rulon, or Flanagan, or Guttman? I chose Rulon because he published my earliest primary source. The bottom line is that the labels and equations used in this chapter have been checked against primary sources and are my current best shot at getting all of this right.

Score Dependability and Decision Consistency

James Dean Brown

University of Hawai'i at Mānoa, USA

The purpose of this chapter is to discuss and explain the options that test developers have for analyzing test score dependability and the consistency of their decisions.¹ Space precludes providing complete explanations for how to compute each and every statistic. However, relevant equations and example calculations will be provided for each statistic, as well as references to language testing and other resources that readers can turn to for further information. All *generalizability theory* (GT) equations will be written using Greek letters. This is the tradition for GT, but it will also help distinguish these statistics from the *classical theory* (CT) equations in the previous chapter, which were written in Roman letters.

In the second line of the previous paragraph, the word *consistency* was used. Terms like *accuracy*, *constancy*, *fidelity*, *precision*, *predictability*, *regularity*, *repeatability*, *stability*, *steadiness*, and so on could equally well have been used. However, from this point on, more precise and traditional terminology will be used, because it makes very important distinctions. In CT, score consistency is traditionally referred to as *reliability* (as was done in the previous chapter). In GT, the analogous concept is called *generalizability* when it refers to norm-referenced tests (NRTs, i.e., tests that focus on spreading examinees out along a continuum of scores for the purpose of making grouping decisions like language proficiency testing for admissions decisions, placement decisions, etc.); *decision dependability* when it is applied to decisions at particular cut points; and *dependability* when we are dealing with criterion-referenced tests (CRTs, i.e., tests that focus on testing how much of a domain of knowledge or set of abilities an examinee has learned or mastered). The rest of this chapter will examine those GT concepts in greater depth.

Generalizability in Norm-Referenced Testing

Cronbach, Rajaratnam, and Gleser (1963) presented GT as an alternative to CT reliability. GT views test consistency as the degree to which the tester can generalize from one observation to a *universe* of possible observations² (Cronbach, Gleser, Nanda, & Rajaratnam, 1972, p. 15). Since GT regards each observation as a sample from a universe of all possible observations, GT provides clearly defined estimation procedures for generalizing from a specific sample of observations to that universe. Analysis of variance procedures are used to identify, isolate, and estimate the relative size of whatever the *variance components*³ (VCs) are for the *facets*⁴ of interest in a particular testing situation. These VCs can be studied in their own right, in terms of their relative magnitude in a generalizability study (G study), and then they can serve as the basis for decision studies (D studies) in which the test designers further investigate how changes in the numbers of each of the facets are likely to affect the *generalizability coefficients* (which are analogous to NRT reliability coefficients) or the *dependability coefficients* (which are similar, but apply to CRT scores) for various possible combinations of numbers of those facets.

Proportion of NRT Generalizability in GT

As Shavelson, Webb, and Rowley pointed out, CT

test-retest reliability counts day-to-day variation in performance as error, but not variation due to item sampling. An internal-consistency coefficient counts variation due to item sampling as error, but not day-to-day variation. Alternative-forms reliability counts both sources as error. CT, then, sits precariously on shifting definitions of true- and error-scores. (Shavelson, Webb, & Rowley, 1989, p. 922)

The central problem is that CT reliability can only account for two sources of error and generally does so only for one at a time. Fortunately, GT can account for many different types of error and can do so for multiple sources simultaneously.

While CT reliability estimates indicate the proportion of true score variance in a set of scores by examining the ratio of the true score variance to observed score variance, which in turn is made up of true score and error variances, GT is based on the notions of *universe score*, *universe score variance*, and *error variance* (which are analogous to *true score*, *true score variance*, and *error variance*). With regard to universe scores, Cronbach and Shavelson (2004, p. 405) state: "In G Theory, it is referred to as the universe score because it is the person's average score over the entire universe of conditions." It follows that *universe score variance* is the variation in persons' scores "over the entire universe of conditions," and *error variance* is that proportion that remains when universe score variance is subtracted from the variance produced across "the entire universe of conditions." The crucial point here is that GT recognizes that error variance potentially comes from many identifiable sources, which can be examined simultaneously in a single GT framework and generalized to "the entire universe of conditions."

The general equation for calculating generalizability estimates for *relative decisions* (i.e., for NRTs that focus on differences among persons) is as follows:

$$E\rho^2(\delta) = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\delta)}$$

Thus the generalizability estimate for relative decisions, $E\rho^2(\delta)$,⁵ is the ratio of estimated persons variance ($\hat{\sigma}_p^2$) to the estimated persons variance plus the error variance for relative decisions, or $\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\delta)$.⁶ One of the primary benefits of using GT is that the tester can define error, in this case relative error, $\hat{\sigma}_e^2(\delta)$, in any way that makes sense in a particular testing situation.

For example, Brown and Bailey (1984) conducted at UCLA a study of the effectiveness of a rubric used on writing samples, gathered every semester from all newly entering international students at UCLA, for placement (NRT) purposes; it was also used to score the final examination (CRT) essays of all students who finished the highest level ESL (English as a second language) service course. The study used GT to study the consistency of scores for both purposes, by using 50 randomly selected compositions. Ten raters scored these essays on the basis of a five-category analytic rubric (consisting of organization, logical development of ideas, grammar, mechanics, and style). Each category was on a 1–20 scale for a total of 100 points. From a practical perspective, the researchers were concerned about the test design: How many raters were necessary? And how many categories would be most efficient?

As prescribed by GT, the researchers used analysis of variance procedures (ANOVA)—in this case focusing on three facets: persons (p) variance, because the students' scores were the central focus; raters (r) variance, because the appropriate number of raters was a design concern; and categories (c) variance, because the appropriate number of categories was another design concern.⁷ As in any three-way ANOVA, the design was for three main effects (the p, r, and c facets) and four possible interactions effects (the pr, pc, rc, and prc interactions). The interactions were of central interest because they would indicate inconsistencies between facets, which are considered sources of measurement error. For example, the relative magnitude or the persons-by-raters (pr) interaction indicates the degree to which raters were inconsistent across persons; similarly, the persons-by-categories (pc) interaction indicates the degree to which categories were scored inconsistently across persons. And so forth.

Since these researchers were interested in the first place in studying their writing test for NRT placement purposes, they used *relative error* (which only includes interactions with p, i.e., only the pr, pc, and prc,e interactions in this case)⁸ as follows:

$$\hat{\sigma}_e^2(\delta) = \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$$

Note that the various n values in the denominators are used to adjust for varying numbers of raters and categories. Substituting $\frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$ for the $\hat{\sigma}_e^2(\delta)$ in the general equation given above for $E\rho^2(\delta)$, the result is:

$$E\rho^2(\delta) = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\delta)} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}}$$

The variance components (VCs) found in Brown and Bailey (1984) for $\hat{\sigma}_p^2$, $\hat{\sigma}_{pc}^2$, $\hat{\sigma}_{pr}^2$, and $\hat{\sigma}_{prc,e}^2$ were reported to be 1.95, .70, 1.17, and 1.81, respectively.

Naturally, readers are probably wondering where VCs come from. As explained above, the VCs are derived from ANOVA procedures. A software program called GENOVA is designed specifically to use ANOVA to calculate VCs. Brown and Bailey used GENOVA on a mainframe computer for their 1984 study. However, today the GENOVA software programs and manuals for Windows or Mac are available free from the following URL: http://www.uiowa.edu/~casma/computer_programs.htm. Since GENOVA migrated from mainframe computers, it is not particularly user-friendly. However, GENOVA does calculate VCs for various sorts of designs, and so it is invaluable for language testers interested in GT.

If one substitutes the VC values that Brown and Bailey (1984) reported into the equation given above for $E\rho^2(\delta)$ and uses the original two raters ($n_r = 2$) and five categories ($n_c = 5$) reported by the authors, the generalizability (G) coefficient for relative error turns out to be about .68 as follows:

$$\begin{aligned} E\rho^2(\delta) &= \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}} = \frac{1.95}{1.95 + \frac{.70}{5} + \frac{1.17}{2} + \frac{1.81}{5(2)}} \\ &= \frac{1.95}{1.95 + .140 + .585 + .181} = \frac{1.95}{2.856} = .6827731 \approx .68 \end{aligned}$$

In what is called a decision study, the authors were able to calculate the G coefficients that would probably arise from different numbers of raters and categories by simply adjusting the values of n_r and n_c in the equation above. They could then examine these “what if” results (adapted here in Table 71.1) and decide how best to maximize the degree of generalizability when using this writing test for placement purposes, while taking into account the practical considerations of how many raters and categories were affordable and feasible.

For example, Table 71.1 shows that using two raters and five categories leads to a G coefficient of .68, just as calculated above. However, the table also indicates that using three raters with five categories would increase the generalizability to .76; four raters with five categories would increase the generalizability to .79; and four raters with the quicker three categories would still increase the generalizability to

Table 71.1 D-study generalizability coefficients for NRT relative decisions (adapted from Brown & Bailey, 1984)

# Raters	# Categories					
	1	2	3	4	5	10
1	.35	.45	.49	.52	.54	.58
2	.47	.58	.64	.66	.68	.70
3	.54	.65	.70	.73	.76	.79
4	.57	.69	.74	.77	.79	.83
5	.60	.72	.77	.80	.81	.85
10	.66	.78	.83	.85	.87	.90

.74; and so on. Thus, while considering the relative effects of numbers of raters and categories as well as other related issues, like resources and practicality, test designers can make decisions that will help them redesign the test and testing procedures in ways that should lead to whatever level of generalizability they feel is necessary.

Estimation of NRT Error in GT

In GT, the *standard error for relative decisions* (se_{rel}) is used in a manner analogous to that of the standard error of measurement (SEM) and confidence intervals (CIs) explained in the previous chapter. To review briefly, the se_{rel} for a particular NRT is an estimate of the range (or band) plus or minus one CI, within which examinees would likely score with 68% probability if the test were administered to them a second time. Following this logic further, two CIs plus or minus would mean the same thing, but with 95% probability, and three CIs plus or minus would mean the same thing but for 98% probability (see previous chapter for more help in interpreting CIs).

The GT equation for the standard error for relative decisions is:

$$se_{rel} = \sqrt{\hat{\sigma}_e^2(\delta)} = \hat{\sigma}_e(\delta)$$

Thus the se_{rel} is equivalent to the square root of the error variance for relative decisions. It is possible under GT to study the effects on the se_{rel} of differing numbers for the facets that have been included in the design. For example, in the Brown and Bailey (1984) study, the relative error was defined as follows (with persons interactions with raters, categories, and both in the error term, i.e., pr, pc, and prc,e interactions as error):

$$\hat{\sigma}_e^2(\delta) = \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$$

—since

$$\sqrt{\hat{\sigma}_e^2(\delta)} = \hat{\sigma}_e(\delta)$$

then

$$\hat{\sigma}_e(\delta) = \sqrt{\frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}}$$

Substituting the same values, into the equation used above from Brown and Bailey (1984), again with the original two raters ($n_r = 2$) and five categories ($n_c = 5$), the se_{rel} for relative error, the result turns out to be about .95, as follows:

$$\begin{aligned} se_{rel} &= \sqrt{\frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}} = \sqrt{\frac{.70}{5} + \frac{1.17}{2} + \frac{1.81}{5(2)}} \\ &= \sqrt{.140 + .585 + .181} = \sqrt{.906} = .95184 \approx .95 \end{aligned}$$

This is the se_{rel} over two raters and five categories. In Brown and Bailey (1984), two raters assigned to each examinee a score from 0 to 20 for each of five categories. Since the se_{rel} of .95 is the standard error over raters and categories, it is also for the 20-point scale. However, because the total scores for examinees were determined by adding up the five categories (worth 20 points each), the total scores are on a 100 point scale (5 categories \times 20 points = 100 points total). To put the se_{rel} of .95 on the 100 point scale, it is also necessary to multiply it by 5. So the se_{rel} for the total scores based on the 100 point scale would be 4.75 (5 \times .95 = 4.75). (Note that there is no need to adjust for the two raters because their scores were averaged, a process that led to no change in the magnitude or range of the scale.) In this case the se_{rel} is to be interpreted as the standard error of the expected observed scores across the universe of testing conditions (raters and categories). It is also possible to calculate different standard errors for relative error by varying the numbers of raters and categories and thereby studying the effects of these two facets on the se_{rel} .

For dichotomously scored tests, it is easier to use the following equation (adapted in Brown, 1990, from Brennan, 1984, p. 303) for the se_{rel} expressed here in CT notation:

$$se_{rel} = \sqrt{\frac{M_p(1-M_p)}{k-1}}$$

—where k is the number of items and M_p is the mean as a proportion. For example, if the proportion score mean (M_p) (i.e., the raw score mean divided by the number of items) turns out to be .47 on a test of 30 items (k), the se_{rel} would be:

$$se_{rel} = \sqrt{\frac{M_p(1-M_p)}{k-1}} = \sqrt{\frac{.47(1-.47)}{30-1}} = \sqrt{\frac{.2491}{29}} = \sqrt{.0085896} = .09268 \approx .0927$$

Since this se_{rel} is based entirely on proportion scores, the interpretation of CIs using this statistic is also in terms of proportions. For other examples of interpreting such CIs, see the discussion above and the explanation of standard errors of measurement (SEM) in the previous chapter. Note that this equation only applies to the test as it was administered. In this case, testers cannot study the effects of facets of error. However, this se_{rel} does let them think about error in terms of a CI for the proportion scores.

Signal-to-Noise Ratios for NRTs

Brennan (1984, p. 306) defines *signal-to-noise ratios* (S/N) as follows:

The signal is intended to characterize the magnitude of the desired discriminations. Noise characterizes the effect of extraneous variables in blurring these discriminations. If the signal is large compared to the noise, the intended discriminations are easily made. If the signal is weak compared to the noise, the intended discriminations may be completely lost.

He advocates using signal-to-noise ratios within the GT framework as one possible alternative way of interpreting NRT generalizability (i.e., for relative

decisions). Conceptually, the signal-to-noise ratio for relative decisions (S/N_{rel}) would be calculated as follows:

$$S/N_{rel} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_e^2(\delta)}$$

—where $\hat{\sigma}_p^2$ is the estimated VC for persons, and $\hat{\sigma}_e^2(\delta)$ is the estimated VC for relative error. For the Brown and Bailey (1984) example with the original two raters ($n_r = 2$) and five categories ($n_c = 5$), where $\hat{\sigma}_p^2 = 1.95$ and $\hat{\sigma}_e^2(\delta) = .906$, the S/N_{rel} would be calculated as follows:

$$S/N_{rel} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_e^2(\delta)} = \frac{1.95}{.906} = 2.15232 \approx 2.15$$

Alternatively, a short-cut for calculating S/N_{rel} (if $E\rho^2(\delta)$ is already in hand) would be:

$$S/N_{rel} = \frac{E\rho^2(\delta)}{1 - E\rho^2(\delta)}$$

Again, for the Brown and Bailey (1984) example, where $E\rho^2(\delta) = .6827731$,

$$S/N_{rel} = \frac{E\rho^2(\delta)}{1 - E\rho^2(\delta)} = \frac{.6827731}{1 - .6827731} = \frac{.6827731}{.3172269} = 2.15232 \approx 2.15$$

Clearly, if a set of scores produces an S/N_{rel} of 1.31, there is nearly as much noise as there is signal, and the scores are not very generalizable. However, if the S/N ratio is 2.15, 3.50, 5.67, or even 15.13, the generalizability is obviously better, much better, and much much better. In short, the higher the S/N ratio, the better.

Decision Dependability

Decision dependability is concerned with the degree to which a set of scores helps educators consistently make correct decisions about whether examinees are above or below a certain cut point. A *cut point* is a score at which a decision is being made. For example, a score of 60 might be the cut point on a test—a point at or above which students pass and below which they fail. Two general approaches are commonly used to determine the consistency of cut point decisions; they have the imposing-sounding names of threshold loss agreement approaches and squared error loss agreement approaches (after Berk, 1984, p. 235).

Threshold Loss Agreement Approaches

Within *threshold loss agreement* approaches two strategies are used: the agreement and the kappa coefficients. Both estimate the degree of dependability in mastery/

		Administration 2 groups		
		Mastery	Non-mastery	
Administration 1 groups	Mastery	A 45	B 20	$A + B = 65$
	Non-mastery	C 10	D 25	$C + D = 35$
		$A + C = 55$	$B + D = 45$	$N = A + B + C + D = 100$

Figure 71.1 Example: mastery/nonmastery groups for two test administrations

nonmastery classifications, where mastery means that an examinee knows or has the skill being tested, while nonmastery means that an examinee does not.

Agreement Coefficient The *agreement coefficient* (p_o) (Hambleton & Novick, 1973, p. 168) indicates the proportion of examinees who were consistently placed in the mastery and nonmastery groups on two successive administrations of a test. Once the test is administered twice and a cut point has been established, the examinees are categorized on the basis of their scores into the mastery and nonmastery groups on each test administration.

Figure 71.1 shows conceptually the basis for calculating p_o . The number of examinees in the mastery group on both administrations of the test is recorded in cell A; the number of examinees in the nonmastery group on both tests is recorded in cell D; the number of examinees assigned to the mastery group on the first administration and to the nonmastery group on the second is placed in cell B; and the number of examinees assigned to the nonmastery group on the first administration and to the mastery group on the second is put in cell C. In Figure 71.1, $A + B$ and $C + D$ are summed on the right side of the figure, and $A + C$ and $B + D$ are also summed below the figure. Finally, $A + B + C + D$ are summed in the bottom right hand corner.

The agreement estimate is calculated as follows:

$$p_o = \frac{A + D}{N}$$

—where p_o = agreement coefficient; A = number of examinees in cell A; D = number of examinees in cell D; and N = total number of examinees. For example, in Figure 71.1, where $A = 45$, $D = 25$, and $N = 100$, the agreement coefficient is:

$$p_o = \frac{A + D}{N} = \frac{45 + 25}{100} = \frac{70}{100} = .70$$

This means that the test consistently categorized the examinees into the mastery or nonmastery groups with about 70% agreement, and the decision dependability is therefore about 70%, which seems marginally consistent at best.

Kappa Coefficient Because p_o is based on a two-way classification (as shown in Figure 71.1) and even random assignment would put 25% in each cell, any agreement estimate has a lower bound value greater than zero by chance alone. This is called the p_{chance} level. Swaminathan, Hambleton, and Algina (1974) suggested using Cohen's (1960) *kappa coefficient* (κ) to correct for this problem by adjusting p_o to reflect only that proportion of the consistent classifications that is beyond what would occur by chance. The kappa coefficient adjustment is calculated as follows:

$$\kappa = \frac{(p_o - p_{chance})}{(1 - p_{chance})}$$

—where p_o is the kappa coefficient and p_{chance} is the proportion classification agreement that could occur by chance alone. The p_{chance} portion of the equation is calculated as follows:

$$p_{chance} = \frac{[(A+B)(A+C) + (C+D)(B+D)]}{N^2}$$

For the same data shown in Figure 71.1, p_{chance} would be calculated as follows:

$$\begin{aligned} p_{chance} &= \frac{[(A+B)(A+C) + (C+D)(B+D)]}{N^2} = \frac{[(65)(55) + (35)(45)]}{100^2} \\ &= \frac{[3575 + 1575]}{100^2} = \frac{5150}{10000} = .515 \end{aligned}$$

Using p_o from the agreement coefficient calculated for the data in Figure 71.1 and this p_{chance} to calculate κ , the result is:

$$\kappa = \frac{(p_o - p_{chance})}{(1 - p_{chance})} = \frac{(.70 - .515)}{(1 - .515)} = \frac{.185}{.485} = .3814 \approx .38$$

So κ turns out to be .38, which means that the test categorized the examinees into the mastery or nonmastery groups, consistently and beyond what would be expected by chance, with about 38% agreement; the decision dependability is therefore about 38%, which frankly is not very good. So, apparently, the agreement coefficient (.70 in the example) can be misleadingly high because it contains a good deal of chance, as indicated by the fact that the kappa coefficient was quite a bit lower. That is why the agreement coefficient of .70 was described circumspectly as being “marginally consistent at best.”

In short, the agreement coefficient indicates the total proportion of agreement, and kappa estimates that proportion of agreement which is beyond what would be expected by chance. Like the agreement estimate, kappa goes as high as 1.00 but, unlike the agreement estimate, which has a p_{chance} lower limit, kappa has a lower limit of .00—just like the reliability, generalizability, and dependability estimates discussed elsewhere in this chapter and in the previous one. Unfortu-

nately both strategies require administering the same test twice, which is cumbersome and imposes greatly on the examinees. Subkoviak worked out methods for estimating agreement and kappa from a single test administration (for more details, see Subkoviak, 1988; Brown, 2005, pp. 200–5). Conceptually, Subkoviak's agreement and kappa have the same interpretation as those explained above, though the method shown here is generally more accurate.

Squared Error Loss Agreement

The agreement and kappa coefficients indicate the degree to which classifications into clear-cut mastery or nonmastery categories are consistent, either overall or corrected for the probability of chance assignments to groups, respectively. However, these coefficients make no distinction with regard to how far each score is from the cut point. Since those distances from the cut point are related to the accuracy and consistency of cut point decisions, *squared error loss agreement approaches* were developed to take them into account. Two such approaches are commonly discussed: kappa squared and phi(lambda) estimates.

Kappa Squared *Kappa squared* (Livingston, 1972) can be estimated from a single test administration and takes into account where the cut point is in the distribution, as well as how far the scores are from the cut point. It is calculated as follows:

$$\kappa^2 = \frac{r_{xx'}S_x^2 + (M - C)^2}{S_x^2 + (M - C)^2}$$

—where κ^2 = kappa squared estimate; $r_{xx'}$ = reliability estimate (e.g., K-R 20, α , etc.); S_x^2 = standard deviation of the scores x ; M = mean of the scores; and C = cut score. κ^2 can range from .00 to 1.00, and it will change depending on the cut score (C). For example, calculating κ^2 for a test with $r_{xx'} = \text{K-R } 20 = .86$, $S_x = 11.45$, $M = 52.36$, and $C = 70$ would look like this:

$$\begin{aligned} \kappa^2 &= \frac{r_{xx'}S_x^2 + (M - C)^2}{S_x^2 + (M - C)^2} = \frac{.86(11.45^2) + (52.36 - 70)^2}{11.45^2 + (52.36 - 70)^2} = \frac{.86(131.1025) + 311.1696}{131.1025 + 311.1696} \\ &= \frac{112.7482 + 311.1696}{442.2721} = \frac{423.9178}{442.2721} = .9585 \approx .96 \end{aligned}$$

κ^2 indicates the consistency of decisions made on the basis of that cut point and is sensitive to both where the cut point is in the distribution and how far scores are arrayed away from it. In the example above, the decisions made at the cut point of 70 appear to be very dependable. Theoretically speaking, κ^2 and $\Phi(\lambda)$ (explained next) are different in that κ^2 carries the CT assumption of normal distribution and $\Phi(\lambda)$ does not. Consequently, contrary to Livingston's (1972) claims, κ^2 probably most often makes sense for use in NRT applications.

Phi(lambda) Dependability *Phi(lambda) dependability* (or $\Phi(\lambda)$) (Brennan & Kane, 1977) can also be estimated from a single test administration and, like κ^2 , it takes into account where the cut point is in the distribution and how far the scores are

from the cut point. In addition, since $\Phi(\lambda)$ is calculated within the GT framework, it can be designed to account for various sources of error. It is calculated as follows:

$$\Phi(\lambda) = \frac{\hat{\sigma}_p^2 + (\mu - \lambda)^2}{\hat{\sigma}_p^2 + (\mu - \lambda)^2 + \hat{\sigma}_e^2(\Delta)}$$

—where $\Phi(\lambda)$ = phi(lambda) dependability index; $\hat{\sigma}_p^2$ = estimated persons variance component; λ = lambda or the cut point; μ = mean; and $\hat{\sigma}_e^2(\Delta)$ = estimated upper case error for absolute decisions (see the explanations of $\hat{\sigma}_p^2$ and $\hat{\sigma}_e^2(\Delta)$ below). For CRT applications of the writing test analyzed in Brown and Bailey (1984), where $\hat{\sigma}_p^2 = 1.95$ and $\hat{\sigma}_e^2(\Delta) = 1.159$ for a lambda of $\lambda = 13$ over categories and $\mu = 14.22$ over categories, $\Phi(\lambda)$ would be calculated as follows (note that, in both cases, the 13 and 14.22 are on the 20-point scale, which is used for each of the five category scores; to adjust them for the total 100-point scale, multiply times five, e.g., 14.22 on the 20-point scale = 71.10 on the 100-point scale because $5 \times 14.22 = 71.10$):

$$\begin{aligned} \Phi(\lambda) &= \frac{\hat{\sigma}_p^2 + (\mu - \lambda)^2}{\hat{\sigma}_p^2 + (\mu - \lambda)^2 + \hat{\sigma}_e^2(\Delta)} = \frac{1.95 + (14.22 - 13)^2}{1.95 + (14.22 - 13)^2 + 1.159} = \frac{1.95 + (1.22)^2}{1.95 + (1.22)^2 + 1.159} \\ &= \frac{1.95 + 1.4884}{1.95 + 1.4884 + 1.159} = \frac{3.4384}{4.5974} = .7479 \approx .75 \end{aligned}$$

On the basis of Brennan (1984), Brown (1990) offered the following equation for calculating $\Phi(\lambda)$ from raw score test statistics on a dichotomously scored test:

$$\Phi(\lambda) = 1 - \left[\frac{1}{k-1} \left(\frac{M_p(1-M_p) - S_p^2}{(M_p - \lambda)^2 + S_p^2} \right) \right]$$

—where $\Phi(\lambda)$ is the phi(lambda) dependability index; λ is lambda or the cut point as a proportion; k is the number of items; M_p is the proportion score mean; and S_p is the proportion score standard deviation. For example, for a test where $\lambda = .70$, $k = 50$, $M_p = .62$, and $S_p^2 = .0289$, $\Phi(\lambda)$ would be calculated as follows:

$$\begin{aligned} \Phi(\lambda) &= 1 - \left[\frac{1}{k-1} \left(\frac{M_p(1-M_p) - S_p^2}{(M_p - \lambda)^2 + S_p^2} \right) \right] = 1 - \left[\frac{1}{50-1} \left(\frac{.62(1-.62) - .0289}{(.62-.70)^2 + .0289} \right) \right] \\ &= 1 - \left[\frac{1}{49} \left(\frac{.62(.38) - .0289}{.0064 + .0289} \right) \right] = 1 - \left[.004808 \left(\frac{.2356 - .0289}{.0064 + .0289} \right) \right] \\ &= 1 - \left[.004808 \left(\frac{.2067}{.0353} \right) \right] \\ &= 1 - [.004808(5.8555)] = 1 - .0282 = .9718 \approx .97 \end{aligned}$$

For more information on calculating this version of $\Phi(\lambda)$, see Bachman (2004, p. 203) or Brown (1990; 2005, pp. 206–7).

Testers can certainly calculate $\Phi(\lambda)$ for a particular cut point—say, 70 percent, or $\Phi(.70)$. If that value turns out to be .97, as in the example above, they should feel fairly confident that their decision dependability was very high at that cut point. If, however, the dependability turns out to be low or mediocre, they might

Table 71.2 $\Phi(\lambda)$ dependability indices and signal/noise ratios at various cut points for scores on a 20-point rubric-based writing scale (adapted from table 6 in Brown, 2007)

<i>Cut point</i>	<i>Decisions</i>	$\Phi(\lambda)$	<i>Signal/Noise</i>
2		0.98	44.55
4		0.97	28.00
6	ENG22	0.94	15.48
8		0.87	6.97
9	ENG101	0.81	4.22
10		0.71	2.48
Mean = 11.23		0.63	1.72
12		0.67	2.01
14	ENG100	0.85	5.57
16		0.93	13.13
18		0.96	24.72
20		0.98	40.33

want to explore the dependability at different cut points, as shown in Table 71.2 from Brown (2007), so they can then rationally change their cut point.

Table 71.2 shows $\Phi(\lambda)$ estimates for various possible cut scores on a 20-point rubric-based writing scale (two raters each used five-point scales to rate two essays from each examinee). The mean for these scores was 11.23. Clearly, a cut point at that score for the placement decisions involved in the study would be .63 (i.e., the lowest of the $\Phi(\lambda)$ calculated in the example), which indicates that the degree of decision consistency (while accounting for the distances from the cut score of the examinees' scores) is 63% (see Haertel, 2006, pp. 99–100). The decision dependability will always be lowest at the means (Brennan, 1984), so the mean is clearly a cut point to avoid. Luckily the real cut points for placement into English 22 (ENG22), English 101 (ENG101), and English 100 (ENG100) were 6, 9, and 14, respectively—nowhere near the mean. Consequently the $\Phi(\lambda)$ decision dependability for ENG22 was satisfactory at .94, and the same statistics for ENG101 and ENG100 were moderately high at .81 and .85, respectively.

Signal-to-Noise Ratios for $\Phi(\lambda)$ The S/N_{rel} ratio for relative decisions was defined above. The interpretation when the S/N is applied to $\Phi(\lambda)$ decision dependability is analogous. However, the calculations are somewhat different. The easiest way to calculate $S/N(\lambda)$ (when $\Phi(\lambda)$ is at hand) is as follows:

$$S/N(\lambda) = \frac{\Phi(\lambda)}{1 - \Phi(\lambda)}$$

For example, for the first $\Phi(\lambda)$ calculated above, of .7479:

$$S/N(\lambda) = \frac{\Phi(\lambda)}{1 - \Phi(\lambda)} = \frac{.7479}{1 - .7479} = \frac{.7479}{.2521} = 2.9666 \approx 2.97$$

As a second example, consider the $\Phi(\lambda)$ calculated just above with a nearly perfect dependability of .9718:

$$S/N(\lambda) = \frac{\Phi(\lambda)}{1 - \Phi(\lambda)} = \frac{.9718}{1 - .9718} = \frac{.9718}{.0282} = 34.4609 \approx 34.46$$

Clearly, as dependability increases in magnitude, so does the $S/N(\lambda)$. Brennan (1984, p. 308) advocates using signal-to-noise ratios as one possible alternative for interpreting $\Phi(\lambda)$ decision consistency. Table 71.2 shows the signal-to-noise ratios derived from the $\Phi(\lambda)$ estimates in the same table. Clearly, as $\Phi(\lambda)$ grows in magnitude, so does the S/N ratio. In Table 71.2, the difference in interpretation for, say, a cut point of 6 (where ENG22 decisions are made) is that the .94 indicates that decision consistency (while accounting for the distances from the cut score of the examinees scores) is 94% (see Haertel, 2006, pp. 99–100), whereas the S/N ratio of 15.48 means that the signal is more than 15 times stronger than the noise.

Dependability in Criterion-Referenced Testing

The NRTs discussed above are designed to measure language *constructs* (which are typically things going on in the examinees' brains) like English language proficiency, academic English ability, and so on, in terms of differences among the individuals in that particular construct. In contrast, CRTs are designed to measure language *domains* (i.e., clearly defined sets of language objectives or expected learning outcomes involving language knowledge, skills, tasks, etc.) in terms of the amounts of domain that each examinee has mastered. In simple terms, NRTs focus on variations among examinees in a construct, while CRTs center on the amount of domain that each examinee has mastered. This single overriding difference resonates throughout any discussion of consistency in language assessment, and so it does here.

As far back as Popham and Husek (1969), questions arose about the suitability of using CT correlational methods to estimate CRT consistency, because correlation coefficients assume normal distribution and are very sensitive to the magnitude of the standard deviations involved. Under ideal conditions CRT scores can reasonably be expected to be positively skewed in a diagnostic pretest administration and negatively skewed in an achievement post-test. Certainly violations of an assumption of normal distribution for CRT scores are common and indeed may be a good sign (i.e., negative skewing may mean that a lot of learning has occurred). However, such violations make the correlation coefficient in test-retest or parallel forms reliabilities less than useful. Similarly, the KR-20, KR-21, and α reliability estimates discussed in the previous chapter are sensitive to variations in skewing and in the magnitude of the standard deviation for a set of scores. In short, all of the CT reliability indicators discussed in the previous chapter are fine for NRTs but may be quite inappropriate for CRTs, because CRTs are not developed for the purpose of producing variance in scores or normal distributions.

Fortunately, GT can be used to estimate the dependability of both NRT *and* CRT scores. As described in the two previous main sections of this chapter, GT can

account for differences in the dependability of NRTs, which are used to make what are called *relative decisions* (see definition on p. 1183), but GT can also account for differences in the dependability of *criterion-referenced tests*, which are used to make *absolute decisions* (i.e., decisions that focus only on the amount of the domain that each examinee knows). Indeed, GT is particularly suitable for estimating CRT dependability—in part because, unlike the CT model that makes strong assumptions, including that of normal distribution, the GT model is weak in that it does not make such assumptions of normality (see Brennan, 2000, p. 7).

In addition, while CT reliability typically only accounts for one source of error at a time—that is, only for error due to differences in examinees or to differences in item difficulties—GT can simultaneously account for both, as well as for any other facets of interest. In GT used for CRT purposes, a “well defined universe of item content” should be “specified in advance” and “selected by random sampling or stratified random sampling from the universe of content” or “universe of admissible observations” (Brennan, 2000, p. 6). As Brennan added: “Strictly speaking, an examinee’s universe score is the examinee’s expected score *over all replications of the measurement procedure*” (p. 6). Thus GT provides a framework for CRT analysis that not only allows for the analysis of item content in the defined domain, but also allows for a simultaneous analysis of item types (or any other important testing facet) in the form of an analysis of the relative importance of the universe of admissible observations to overall test variance.

This section will continue with discussions of three common statistics for examining CRT dependability: the phi dependability estimate, standard error for absolute decisions, and signal-to-noise ratios.

Phi Dependability

The *phi dependability* estimate (also known as Φ , or the dependability coefficient) can be used to estimate the overall dependability, or proportion of universe score variance, of a set of CRT scores. It is interpreted on the familiar .00 to 1.00 scale. Such interpretations assume that all items are taken from a well-defined domain and make no reference to any particular cut score.

Phi dependability estimates can be calculated using the general GT equation that follows:

$$\Phi(\Delta) = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\Delta)}$$

—where $\Phi(\Delta)$ is the phi dependability estimate for absolute error (Δ), $\hat{\sigma}_p^2$ is the estimated persons variance component, and $\hat{\sigma}_e^2(\Delta)$ is the estimated error variance for absolute decisions. Then the dependability estimate is the ratio of estimated persons variance ($\hat{\sigma}_p^2$) to the estimated persons variance plus absolute error variance ($\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\Delta)$).

In the Brown and Bailey (1984) study discussed above for GT applications to NRTs, recall that the facets were persons (p), raters (r), and categories (c), and four possible interactions were also considered: pr, pc, rc, and prc.⁹ The authors were interested in the NRT generalizability of their writing test scores for relative

placement decisions. However, because the test was also used as part of the final achievement examination in the highest level ESL course at UCLA, they also wanted to study the CRT dependability of the scores for absolute decisions.

Since GT posits that all facets (except persons) and interactions contribute to error in CRT absolute decisions, they are all used as follows in the equation for absolute error (note again: the various n values in the denominators can be used to adjust for varying numbers of raters and categories):

$$\hat{\sigma}_e^2(\Delta) = \frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$$

In short, while the error for NRT relative decisions discussed above for Brown and Bailey (1984) included only those VCs for interaction facets involving persons, the error here for criterion-referenced absolute decisions includes the VCs for all facets (except persons) and interactions.

If we place $\frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$ in the general equation in lieu of $\hat{\sigma}_e^2(\Delta)$, the G coefficient for absolute decisions is:

$$\Phi(\Delta) = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_e^2(\Delta)} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}}$$

Recall that the VCs in Brown and Bailey (1984) for $\hat{\sigma}_p^2$, $\hat{\sigma}_r^2$, $\hat{\sigma}_c^2$, $\hat{\sigma}_{pr}^2$, $\hat{\sigma}_{pc}^2$, $\hat{\sigma}_{rc}^2$, and $\hat{\sigma}_{prc,e}^2$ were 1.95, .16, .80, 1.17, .70, .13, and 1.81, respectively. If we substitute these values into the equation and use the original two raters ($n_r = 2$) and five categories ($n_c = 5$) reported by the authors, the generalizability coefficient for relative error turns out to be .6272113, or about .63, as follows:

$$\begin{aligned} \Phi(\Delta) &= \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}} \\ &= \frac{1.95}{1.95 + \frac{.16}{2} + \frac{.80}{5} + \frac{1.17}{2} + \frac{.70}{5} + \frac{.13}{2(5)} + \frac{1.81}{2(5)}} \\ &= \frac{1.95}{1.95 + .08 + .16 + .585 + .14 + .013 + .181} \\ &= \frac{1.95}{1.95 + 1.159} = \frac{1.95}{3.109} = .6272113 \approx .63 \end{aligned}$$

This $\Phi(\Delta)$ of .63 indicates that the dependability of the scores based on two raters and five categories is not very high. Indeed, the scores appear to be about two thirds dependable and one third error.

However, by changing the n_r and n_c in the above equation in what is called a decision study, dependability coefficients can be estimated for other possible combinations of numbers of raters and categories, as shown in Table 71.3. The test designers can then use that "what if" information in conjunction with practical

Table 71.3 D-study dependability coefficients for CRT absolute decisions (adapted from Brown & Bailey, 1984)

# Raters	# Categories					
	1	2	3	4	5	10
1	.30	.40	.45	.48	.50	.54
2	.39	.51	.57	.61	.63	.66
3	.43	.57	.63	.67	.70	.75
4	.46	.60	.66	.70	.73	.79
5	.48	.62	.69	.73	.75	.81
10	.52	.67	.74	.78	.81	.86

considerations in the testing situation to redesign the testing procedures so they are likely to produce higher dependability. For example, Table 71.3 shows that using three raters with five categories (instead of two and five, respectively, as in the original design) would increase the dependability to .70; or four raters and five categories would increase the dependability to .73, while increasing the number of raters to four and making the process quicker by decreasing the number of categories to three would still increase dependability to .66—and so on. Thus, while considering the relative effects of numbers of raters and categories along with other factors like resources and practicality, test designers can make decisions about redesigning the testing procedures that should lead to whatever level of dependability they need to achieve.

Another way to calculate Φ when the scores are based on dichotomously scored items (right or wrong) was derived in Brown (1990) from information presented by Brennan (1984, 2001):

$$\Phi(\Delta) = \frac{\frac{nS_p^2}{n-1}[K-R20]}{\frac{nS_p^2}{n-1}[K-R20] + \frac{M_p(1-M_p) - S_p^2}{k-1}}$$

—where n = number of examinees; k = number of items; M_p = proportion score mean; S_p = proportion score standard deviation; and KR-20 = Kuder-Richardson formula 20 (see previous chapter). For example, for a CRT with $n = 50$, $k = 30$; $M_p = .47$, $S_p = .18$, and KR-20 = .87.

$$\begin{aligned} \Phi(\Delta) &= \frac{\frac{nS_p^2}{n-1}[K-R20]}{\frac{nS_p^2}{n-1}[K-R20] + \frac{M_p(1-M_p) - S_p^2}{k-1}} = \frac{\frac{50(.18^2)}{50-1} [.87]}{\frac{50(.18^2)}{50-1} [.87] + \frac{.47(1-.47) - .18^2}{30-1}} \\ &= \frac{.0330612 [.87]}{.0330612 [.87] + \frac{.2491 - .0324}{29}} = \frac{.0287632}{.0287632 + .0074724} \\ &= \frac{.0287632}{.0363356} = .7915983 \approx .79 \end{aligned}$$

For further explanations of how to calculate this version of Φ , see Bachman (2004, pp. 194–5) or Brown (1990; 2005, pp. 207–9).

Standard Error for Absolute Decisions

The *standard error for absolute decisions* (se_{abs}) is used in a manner that is analogous, for CRTs, to that of the SEM and se_{rel} for NRTs. The se_{abs} for a particular CRT is an estimate of the range (or band) around a particular score (plus or minus one CI) in which examinees would likely score with 68% probability if the test was administered to them a second time. Following this logic further, two CIs plus or minus would mean the same thing, but with 95% probability, and three CIs plus or minus would mean the same thing, but with 98% probability.

The GT equation for the standard error for absolute decisions is:

$$se_{abs} = \sqrt{\hat{\sigma}_e^2(\Delta)}$$

Thus the se_{abs} is equivalent to the square root of the estimated VC for absolute error. GT also allows studying the effects on the se_{abs} of differing numbers for the facets that have been included in the design. For example, in the CRT part of the Brown and Bailey (1984) study, the absolute error was defined as follows:

$$\hat{\sigma}_e^2(\Delta) = \frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}$$

Since:

$$se_{abs} = \sqrt{\hat{\sigma}_e^2(\Delta)} = \sqrt{\frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}}$$

Again, using the variance components from Brown and Bailey (1984) ($\hat{\sigma}_r^2$, $\hat{\sigma}_c^2$, $\hat{\sigma}_{pr}^2$, $\hat{\sigma}_{pc}^2$, $\hat{\sigma}_{rc}^2$, and $\hat{\sigma}_{prc,e}^2$, which were 1.95, .16, .80, 1.17, .70, .13, and 1.81, respectively) and substituting these values into the equation with the original two raters ($n_r = 2$) and five categories ($n_c = 5$) reported by the authors, one calculates the se_{abs} as follows:

$$\begin{aligned} se_{abs} &= \sqrt{\hat{\sigma}_e^2(\Delta)} = \sqrt{\frac{\hat{\sigma}_r^2}{n_r} + \frac{\hat{\sigma}_c^2}{n_c} + \frac{\hat{\sigma}_{pr}^2}{n_r} + \frac{\hat{\sigma}_{pc}^2}{n_c} + \frac{\hat{\sigma}_{rc}^2}{n_r n_c} + \frac{\hat{\sigma}_{prc,e}^2}{n_r n_c}} \\ &= \sqrt{\frac{.16}{2} + \frac{.80}{5} + \frac{1.17}{2} + \frac{.70}{5} + \frac{.13}{2(5)} + \frac{1.81}{2(5)}} \\ &= \sqrt{.08 + .16 + .585 + .14 + .013 + .181} = \sqrt{1.159} = 1.07656 \approx 1.08 \end{aligned}$$

The se_{abs} is interpreted as the standard error of the expected observed scores over the universe of testing conditions (in this example, raters and categories). This is the se_{abs} over two raters and five categories. However, in Brown and Bailey (1984), two raters assigned to each examinee a score from 0 to 20 for each of the five categories. Since the se_{abs} of 1.08 is the standard error over raters and

categories, it too is for the 20-point scale. However, because the total scores for examinees were determined by adding up the five categories (worth 20 points each), the total scores are on a 100-point scale (5 categories \times 20 points = 100 points total). To put the se_{abs} of 1.08 on the 100-point scale, it is also necessary to multiply it by 5. So the se_{abs} for the total scores would be 5.40 (5 \times 1.08 = 5.40). (Note that there is no need to adjust for the two raters because their scores were averaged (rather than added), a process that led to no change in the range or magnitude of the scale.)

For a dichotomously scored test, a somewhat easier equation for the se_{abs} (adapted from Brennan, 1984) is:

$$se_{abs} = \sqrt{\frac{M_p(1 - M_p) - S_p^2}{k - 1}}$$

—where k is the number of items; M_p is the mean as a proportion; and S_p is the standard deviation as a proportion. For example, if a test has 30 items (k), the proportion score mean (M_p) (i.e., the raw score mean divided by the number of items) turns out to be .47, and the proportion score standard deviation (S_p) (i.e., the raw score standard deviation divided by the number of items) is .18, the se_{abs} would be calculated as follows:

$$\begin{aligned} se_{abs} &= \sqrt{\frac{M_p(1 - M_p) - S_p^2}{k - 1}} = \sqrt{\frac{.47(1 - .47) - .18^2}{30 - 1}} = \sqrt{\frac{.2491 - .0324}{29}} \\ &= \sqrt{.0074724} = .086443 \approx .0864 \end{aligned}$$

Since this se_{abs} is based entirely on proportion scores, the interpretation is in terms of proportions as well. Thus, converting the proportion $se_{abs} = .0864$ to a percentage where $se_{abs} = 8.64\%$, we can interpret the result as meaning that an examinee's score at the cut point of 60% would be likely to fall within a band of \pm one se_{abs} of 8.64% (or between 51.36% and 68.64%), with 68% confidence. For other examples of interpreting such CIs, see the discussion of the se_{rel} above and the discussion of standard error of measurement (SEM) in the previous chapter.

Calculating the se_{abs} lets testers think about error in terms of a confidence interval for the proportion scores. Note, however, that Brennan (2000, p. 8) points out that, within GT, "such normality-based estimates are highly suspect, although they may be somewhat useful as rough approximations."

Signal-to-Noise Ratios for CRTs The S/N ratio for absolute decisions is interpreted in a manner similar to the way it was for relative decisions and for $\Phi(\lambda)$ decision consistency. However, the calculations are somewhat different. Conceptually the equation for the S/N_{abs} is as follows:

$$S/N_{abs} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_e^2(\Delta)}$$

For the Brown and Bailey (1984) example calculated above for the Φ coefficient, $\hat{\sigma}_p^2 = 1.95$ and $\hat{\sigma}_e^2(\Delta) = 1.159$. Thus:

$$S/N_{abs} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_c^2(\Delta)} = \frac{1.95}{1.159} = 1.68248 \approx 1.68$$

The easiest way to calculate S/N_{abs} (when Φ is at hand) is as follows:

$$S/N_{abs} = \frac{\Phi}{1 - \Phi}$$

For the Brown and Bailey (1984) Φ coefficient calculated above, where $\Phi(\Delta) = .6272113$:

$$S/N_{abs} = \frac{\Phi(\Delta)}{1 - \Phi(\Delta)} = \frac{.6272113}{1 - .6272113} = \frac{.6272113}{.3727887} = 1.68248 \approx 1.68$$

The interpretation of this S/N_{abs} is the same as it was for the S/N_{rel} and $S/N(\lambda)$ discussed above. That is, the S/N ratio of 1.68 means that the signal is about 1.68 times stronger than the noise, which frankly indicates that the signal is not very clear and that the noise may interfere with it.

Conclusions

Choosing a Generalizability/Dependability Strategy

Table 71.4 summarizes the material in this chapter with an eye to helping readers determine which NRT generalizability, decision dependability, or CRT dependability statistics they might want to use in their own testing situation. That said, it is important to first recognize that this chapter and Table 71.4 only cover statistics for analyzing NRTs and CRTs within the GT framework. For readers who only need to analyze the reliability of NRTs from a CT perspective, the previous chapter, especially the summary provided in Table 70.1, should be adequate for their needs.

In contrast, the discussion in this chapter and the summary in Table 71.4 will better serve the purposes of readers who are interested in test design and score interpretation issues related to complex sources of measurement error, which cannot be handled in CT. For example, language testers often need to design and use speaking, writing, task-based, and other sorts of assessments that involve multiple raters, rubric categories, task types, and so on. Such potential sources of measurement error can clearly be studied and accounted for in GT, but not in CT. Language testers are also often interested in designing reading or listening tests that have interdependent items grouped with particular listening or reading passages. Such items are difficult to handle in CT, but can be dealt with satisfactorily in GT. Language testers often find themselves needing (a) to analyze NRT scores from a sophisticated point of view, where sources of measurement error can be investigated and accounted for; (b) to study the dependability of the decisions made at certain cut points; or (c) to investigate the dependability of criterion-referenced test scores.

For readers who choose this chapter, the next step is to look at Table 71.4 and select the overall purpose from column 1. Are they interested in NRT

dependability, decision dependability, or CRT dependability? Next, column 2 can be used to decide on the form of the estimate, that is, whether the reader is interested in finding a proportion of dependability, an error estimation, or a signal-to-noise ratio. Then and only then are readers ready to decide which specific statistic (and method) they may want to use (in column 3). After reading about the pros (column 4) and cons (column 5), readers should be able to decide what the best statistic might be for their testing purposes. Then, referring back to the part of the chapter that discusses that particular statistic will supply the appropriate equation(s), demonstrate how to do the actual calculations, and supply additional references so the reader can find further information on the specific statistic.

For example, consider a group of teachers interested in using a CRT dependability statistic for a set of CRT achievement test scores who want to focus only on the proportion of dependability. Looking only at those specific statistics related to CRT dependability (see column 1), they read through the pros and cons and decide to use the Brown version of the phi for absolute error [$\Phi(\Delta)$] because their multiple choice test is scored right/wrong (i.e., dichotomously). They use the information provided in this chapter and the references given in the section on absolute error [$\Phi(\Delta)$] type for dichotomously scored items to calculate their dependability index, which turns out to be .91. The teachers are so happy with that result that they go on to calculate the associated standard error and signal-to-noise ratio.

Table 71.4 can also be used to quickly learn about any specific statistic by searching it out in the third column and reading the material to the left and right of it in the same row. For instance, say the reader wants to be reminded of what the GT $\Phi(\lambda)$ is. Reading to the left, $\Phi(\lambda)$ is clearly used for purposes of estimating squared error loss (including distances of scores from the cut point) decision consistency; $\Phi(\lambda)$ is thus an estimate of decision consistency that assumes GT randomly parallel tests. In its favor, this statistic accounts for the location of the cut point in the distribution of scores and the distances of the scores from the cut point. It also allows the analyst to define the error facets. However, it is relatively difficult to calculate and conceptually challenging.

Factors Affecting Generalizability and Dependability

The previous chapter included a section about factors affecting the reliability of NRTs. For readers who would like to maximize the decision or CRT dependability estimates covered in this chapter, it is worth considering the factors that might affect them. Bachman (2004, pp. 190, 204–5) and Brown (2005, pp. 196, 215–16) discuss factors that affect the consistency of both NRTs and CRTs. Here those observations will be combined, reorganized, and liberally adapted, but the focus will be on decision and CRT dependability estimates. First, the possibility of dependability will generally be maximized for any test by insuring that it is as long as is reasonable, well written, and as homogeneous in what it tests as the particular testing situation demands. Decision dependability will generally be maximized if the cut point is as far from the mean as makes sense in the given situation and if the items selected for the test produced a high *B*-index (an item statistic that indicates the degree to which each item is contributing to the decision dependability; see Brown, 2005, pp. 82–3). For CRTs, dependability will

Table 71.4 Selecting the appropriate score or decision consistency strategy in GT

<i>Overall purpose</i>	<i>Form of estimate</i>	<i>Specific statistic (& method)</i>	<i>Pros</i>	<i>Cons</i>
NRT dependability	Proportion of dependability Error estimation	G coefficient for relative error $E\rho^2(\delta)$ Calculate se_{rel} and use CIs at 68%, 95%, or 98% in decision making GT se_{rel} Brennan se_{rel}	Analyst defines relative error facets Analyst defines relative error facets Relatively easy to calculate	Difficult to calculate & conceptually challenging Difficult to calculate & conceptually challenging; only a rough estimate Analyst cannot define error facets; test must be dichotomously scored; only applies to the persons and items involved in this testing session

(Continued)

Table 71.4 (Continued)

Overall purpose	Form of estimate	Specific statistic (& method)	Pros	Cons
Squared error loss decision consistency (including distances of scores from cut-point)	Decision consistency	Kappa squared κ^2 (Assumes CT classically parallel tests)	Accounts for location of the cut point in the distribution and distances of scores	Relatively difficult to calculate and conceptually challenging; assumes normal distribution
		Phi(λ)	Accounts for location of the cut point in the distribution and distances of scores; analyst defines error facets	Relatively difficult to calculate and conceptually challenging
		GT $\Phi(\lambda)$ (assumes GT randomly parallel tests)	Accounts for location of the cut point in the distribution and distances of scores; relatively easy to calculate	Only for dichotomously scored items
		Brennan $\Phi(\lambda)$	Conceptually relatively easy to understand	Currently not commonly reported
CRT dependability	Signal-to-noise ratio	Signal-to-noise ratio for $(\lambda) S/N(\lambda)$	Analyst defines absolute error facets	Difficult to calculate & conceptually challenging
	Proportion of dependability	Phi for absolute error $\Phi(\Delta)$	Relatively easy to calculate	Only for dichotomously scored items; cannot define absolute error facets
	Error estimation	Calculate sE_{abs} and use CIs at 68%, 95%, or 98% in decision making	Analyst can define relative error facets	Difficult to calculate & conceptually challenging; only a rough estimate
	Signal-to-noise ratio	Signal-to-noise ratio for absolute error S/N_{abs}	Conceptually relatively easy to understand	Analyst cannot define error facets; test must be dichotomously scored
				Currently not commonly reported

be maximized if the items are clearly linked to the objectives or learning outcomes of the course or program involved and those items produce high difference indexes (a difference index is an item statistic that indicates how much each item is related to the material and skills being taught/learned in a particular course or program; see Brown, 2005, pp. 80–2).

Future Directions

This chapter has shown how GT research and practice with regard to NRT generalizability, decision dependability, and CRT dependability are related and where they stand today in language testing. Such developments will no doubt continue. In my view, language testing would further benefit from examining some or all of the following topics:

- 1 GT score generalizability and dependability, as well as decision dependability for tests organized around testlets (e.g., Lee & Frisbie, 1999).
- 2 The importance of using SE_{rel} and SE_{abs} and their associated CIs in interpreting and using dependability information. As Cronbach (in Cronbach & Shavelson, 2004, p. 394) put it: “Coefficients are a crude device that does not bring to the surface many subtleties implied by variance components. In particular, the interpretations being made in current assessments are best evaluated through use of a standard error of measurement . . .”
- 3 The benefits of examining conditional errors in a GT framework for language testing. SE_{rel} and SE_{abs} statistics are assumed to be the same at all score levels because only unconditional errors are considered. However, within a GT framework, errors conditioned on examinees’ true scores can be taken into account, thereby enabling language testers to estimate errors at each score level (see Haertel, 2006, pp. 98–9).
- 4 The dependability of classification decisions that take into account examinees’ true scores (Haertel, 2006, p. 100) and/or the dependability of classification decisions based on multiple measures (see for example Douglas 2010; Lee, Brennan, & Wan, 2009).
- 5 The benefits of software advances in GT. In the early days, GT studies relied on GENOVA software on mainframe computers, which could only handle balanced designs for single sets of scores. Software advances have made it possible to analyze multivariate designs (i.e., designs that include more than one set of scores, e.g., Lee, 2006) with mGENOVA and unbalanced designs with urGENOVA. (For more on these GENOVA software programs and manuals, see: http://www.uiowa.edu/~casma/computer_programs.htm)
- 6 The benefits of pairing GT with multifaceted Rasch using the GENOVA and FACETS computer programs (e.g., Brown & Ahn, 2011). This dual strategy allows testers to use scores corrected for the effects of error to examine the levels of given sources of error, so that error variance can be minimized and generalizability/dependability maximized in future designs of a test.

Theory Reliability; Chapter 72, The Use of Generalizability Theory in Language Assessment

Notes

- 1 Note that a good deal of jargon is used in the first two paragraphs of this chapter. All of these terms were defined in the previous chapter or will be defined later in this chapter.
- 2 One way to look at the *universe* of possible observations is to think of it as the collection of all the observations or items that the test designer would consider to be suitable alternatives for the observations or items on the existing test.
- 3 Note that a *variance component* is defined as the variance calculated for a particular facet in a G study.
- 4 *Facets* are defined as characteristics of measurement in a particular situation that are viewed as potential sources of measurement error; for example, raters, rubric categories, writing prompts could all be viewed as potential sources of measurement error in a particular testing situation and thus be identified as facets for a G study.
- 5 Note that $E\rho^2(\delta)$ is traditionally used to symbolize the G coefficient for NRT relative decisions, while Φ is used for the dependability coefficient for CRT absolute decisions.
- 6 All of the variance components discussed in this chapter can be and were calculated in the GENOVA statistical programs discussed later in the chapter.
- 7 Technical note: These facets were treated as *fixed effects* because the researchers were only interested in the effects particular to the institutional setting. Had they been interested in generalizing the results to other testing situations, they would have treated the facets as *random effects*.
- 8 Note that the highest order (most complex) interaction always contains undifferentiated error in GT. Thus the estimated variance component for the prc interaction is appropriately subscripted prc,e.
- 9 Note that such a study could include other facets like rating occasions (if the raters did their scoring two or more times), rater type (native vs. non-native), etc. The facets need only be identifiable and of interest to the testers involved.

The Use of Generalizability Theory in Language Assessment

George A. Marcoulides
University of California, Riverside, USA

Marsha Ing
University of California, Riverside, USA

Introduction

Language assessments are frequently used for high stakes decisions about student selection, placement diagnosis, progress, and grading (Bachman, 1990). For example, the Test of English as a Foreign Language (TOEFL) measures English language ability and is commonly used in helping with decisions for student admission to higher education institutions. Student responses to language assessments are also regularly used in K-12 educational settings to identify the level of language ability and place students into particular classrooms or provide types of instructional opportunities.

There are numerous measurement issues involved in the development and interpretation of language assessments, including the administration of the same assessment on multiple days, the administration of different forms to the same individuals, and individuals being asked to perform language-related tasks that are evaluated by different raters. Generalizability theory (G-theory) is a widely used approach to address these measurement issues (e.g., Bachman, Lynch, & Mason, 1995). G-theory examines the sources of measurement error or factors that might influence performance and determines the relative impact of these different potential sources of error. In an illustrative study on the relative impact of linguistic diversity on academic achievement, Solano-Flores and Li (2006) describe how G-theory can be used in the testing of linguistic minorities. These authors hypothesized that different codes or dialects reflect variation between Haitian Creole English language learners in terms of migration history and instructional opportunities with learning language. Their findings have major implications for decisions around which language students should be tested in order to produce dependable measures of their academic achievement.

This chapter provides an overview of previous views and conceptions of G-theory offered to date in the extant literature. The overview provides information on how G-theory can be used to design, assess, and improve the dependability of measurement procedures. The chapter then discusses a few of the limitations of G-theory and describes how other related psychometric theories and modeling approaches can be integrated to address some of these limitations. Finally, it previews current research in this particular area, provides thoughts on challenges faced, and addresses future directions of G-theory in the area of language assessment.

Previous Views and Conceptions

A Sampling Approach

Early conceptions of reliability did not specifically differentiate between sources of measurement error (for further details on reliability, see Chapter 70, Classical Theory Reliability). All potential error sources were combined and thus indistinguishable. This conceptualization provided limited information in terms of how to minimize systematic error for future administrations of any measure. These early conceptions are referred to as classical test theory (see Chapter 69, Classical Test Theory), where a respondent's observed score (X_{pi}) was conceptualized as the linear combination of their true ability (T_p) and unsystematic, random error (E_{pi}).

$$X_{pi} = T_p + E_{pi} \quad (1)$$

The reliability of a particular measure was the ratio of true score variance to observed score variance. If there was greater variance attributed to true scores compared to observed scores, there was a higher reliability coefficient. A low reliability coefficient indicated that the observed score did not accurately reflect a respondent's true score. Unfortunately, researchers were not able to uncover possible reasons for the low reliability because these early conceptions did not differentiate between different sources of error. For example, if a respondent was given the same test on a different day, they might obtain different scores. They might obtain a high score on one day and a low score on another day. Under such circumstances, it is unclear which score is more representative of true ability. In this scenario, reliability might be low but the researcher would not have information on how to improve the dependability of the behavioral measure for future administrations.

G-theory is a psychometric approach to assessing the dependability of behavioral measurement that takes into consideration different sources of error (Shavelson & Webb, 1991; Brennan, 2001). G-theory considers each measure as a sample from a universe of all possible measures (Cronbach, Gleser, Nanda, & Rajaratnam, 1972). The universe of all possible measures is defined by the researcher and includes all possible combinations of aspects that influence performance on the measure. Thus, a universe is defined in terms of those aspects of the observations that determine the conditions under which an acceptable measure or score can be

obtained. These different aspects are potential sources of error and are referred to as facets. One example of a facet is the items included in the measure or test. These are only a sample from a pool of possible items that measure the particular construct of interest. The intention is that the sample of items represents the defined universe of items. G-theory helps clarify the extent to which a measure represents or allows one to generalize from this particular set of items across all possible combinations of items for a given universe. Although in most instances some attribute of persons will usually be the object of measurement, it is possible to consider other facets as the object of measurement. In such cases the person facet is treated as an error component and has been termed the *principle of symmetry* (Cardinet, Tourneur, & Allal, 1976).

Designing a Measure

Numerous approaches within G-theory can be used to examine the design of behavioral measurements. Each approach is identified using the number of facets in the design. This section describes one- and two-faceted crossed designs and then discusses possible variations within each design.

One-Facet Design In a one-facet design, there is only one potential source of error included in the measurement procedure. This is fundamentally the same model as the one considered in classical test theory (see Chapter 69, Classical Test Theory, for further details). One common example is to administer a multiple choice test consisting of a random sample of items (n_i) from a universe of items to a random sample of persons (n_p). All the respondents in the selected sample receive the same items. This is referred to as a person-crossed-with-items ($p \times i$) design because items are the only potential source of error included in the measurement procedure. The observed score of person (p) on item (i) is denoted as X_{pi} and can be decomposed into the sum of the grand mean (μ), the person effect ($\mu_p - \mu$), the item effect ($\mu_i - \mu$), and residual effect ($X_{pi} - \mu_p - \mu_i + \mu$), where μ_p is the person's universe score and μ_i is the person population mean for item i . The residual is the effect attributable to the interaction of person p with item i confounded with experimental error, which is denoted as pi,e .

The variance components of these effects in the model are as follows:

$$\sigma^2(X_{pi}) = \sigma_p^2 + \sigma_i^2 + \sigma_{pi,e}^2 \quad (2)$$

where σ_p^2 is the variance due to persons, σ_i^2 is the variance due to items, and $\sigma_{pi,e}^2$ is the residual variance. The relative magnitude of the different variance components provides information about the potential source of error influencing a measurement and determines the dependability of the measure.

The variance components are commonly calculated using mean squares from an analysis of variance (ANOVA), equating these to their expected values and solving a set of linear equations (see also Chapter 70, Classical Theory Reliability). Table 72.1 provides the expected means squares and variance components for a one-facet crossed design. Results for a hypothetical one-facet study where 20 respondents were administered the same five items are provided in Table 72.2.

Table 72.1 Expected mean squares for a random-effects persons by items ($p \times i$) design

Source of variation	MS	Expected MS	Estimated variance component
Persons (p)	MS_p	$\sigma_{pi,e}^2 + n_i\sigma_p^2$	$\sigma_p^2 = (MS_p - MS_{res})/n_i$
Items (i)	MS_i	$\sigma_{pi,e}^2 + n_p\sigma_i^2$	$\sigma_i^2 = (MS_i - MS_{res})/n_p$
Residual (pi,e)	MS_{res}	$\sigma_{pi,e}^2$	$\sigma_{pi,e}^2 = MS_{res}$

Table 72.2 ANOVA estimates of variance components for example one-facet crossed design

Source of variation	SS	df	MS	Estimated variance component	Percentage of total variance
Persons (p)	106.00	19	5.58	1.01	64.74
Items (i)	3.10	4	0.78	0.01	0.01
Residual (pi,e)	40.90	76	0.54	0.54	34.62

The relative contribution of the sources of variation in this model can be interpreted based on the percentage of total variance attributable to each. In this example, most of the variation is due to persons, and less than 1% is due to items. Almost 35% of the variation is unexplained or due to residual effects. Other estimation procedures can provide variance components. Elsewhere, Shavelson and Webb (1981, 1991) described such methods, including Bayesian, minimum variance, restricted maximum likelihood, and covariance structure methods. These methods frequently provide more accurate estimates than ANOVA in cases involving small samples, dichotomous data, unbalanced designs, or missing data (Maroulides, 1996). Because ANOVA is straightforward, it is the most commonly used estimation method in G-theory. As these components are the basis for indexing the relative contribution of sources of error and determining dependability of measurement, their estimation is referred to as the “Achilles heel of G theory” (Shavelson & Webb, 1981).

Two-Facet Design In a two-facet design, there are two potential sources of measurement error. For example, the same items could be administered to the same group of respondents but on multiple occasions. In this situation, one is interested in the degree to which there are differences in how respondents perform on these items on the different administrations. This is referred to as person-crossed-with-items-and-occasions ($p \times i \times o$) design because items and occasions are the potential sources of error included in the measurement procedure. The observed score of person (p) on item (i) on occasion (o) is denoted as X_{pior} and is the sum of the grand mean, the person, item, and occasion effects, their corresponding two-way interactions, and the residual effect. The residual effect is attributable to the three-way interaction of person p with item i and occasion o confounded with experimental error.

Table 72.3 ANOVA estimates of variance components for example two-facet crossed design

Source of variation	SS	df	MS	Estimated variance component	Percentage of total variance
Persons (<i>p</i>)	179.13	19	9.43	0.39	18.14
Items (<i>i</i>)	14.21	4	3.55	0.02	0.93
Occasions (<i>o</i>)	43.74	2	21.87	0.18	8.37
<i>p</i> × <i>i</i>	116.45	76	1.53	0.21	9.77
<i>p</i> × <i>o</i>	114.26	38	3.01	0.42	19.53
<i>i</i> × <i>o</i>	12.43	8	1.55	0.03	1.40
Residual (<i>pio,e</i>)	136.91	152	0.90	0.90	41.86

The variance components of these effects in this model are as follows:

$$\sigma^2(X_{pio}) = \sigma_p^2 + \sigma_i^2 + \sigma_o^2 + \sigma_{pi}^2 + \sigma_{po}^2 + \sigma_{io}^2 + \sigma_{pio,e}^2 \quad (3)$$

where σ_p^2 is the variance due to persons, σ_i^2 is the variance due to items, σ_o^2 is the variance due to occasions, σ_{pi}^2 is the variance due to the interaction between person and items, σ_{po}^2 is the variance due to the interaction between person and occasions, σ_{io}^2 is the variance due to the interaction between items and occasions, and $\sigma_{pio,e}^2$ is the residual variance.

Results for a hypothetical two-facet crossed study where 20 respondents were administered the same five items on three occasions are provided in Table 72.3. The person effect (the object of measurement) should be the largest effect, since individuals are expected to perform differently. In this example the person effect is not the largest, but rather the third largest effect. The largest percentage of the total variance is due to the residual effect, which the varying relative standing of persons across items and occasions and/or other sources of error does not systematically incorporate into the measurement design. The next largest is the person × occasion interaction followed by the person effect, which implies that persons are not scoring similarly across occasions. Interpreting these variance components is important because they provide information about the different facets that contribute to the overall dependability of the observational measure. This hypothetical two-facet design provides information about how much of the variation is explained by the five different items included in the study. The relatively low variance component pertaining to items suggests that items do not play a large role in the variation.

The designs described above are considered fully crossed because the object of measurement is exposed to all conditions. In other words, all respondents answered the same items on all three occasions. It is also possible to estimate components from variations to these designs, for example if respondents are provided with only some of the items on one occasion and another set of items on another occasion. In the case where respondents do not answer all of the items on all three occasions, items are nested within persons, thus confounding the effects of items. Despite this added complexity, G-theory accommodates nested designs by

providing information about which components contribute to the variation in the observed scores.

Another design variation is treating the facets as fixed and not random. G-theory is based on a sampling framework, so facets are typically treated as being randomly selected from the universe. For example, teachers are randomly sampled from across the nation to participate in the study. Findings could thus be generalized to all teachers in the nation. A fixed facet is when specific levels of the facet are purposefully selected. For example, if teachers from a particular grade level within the same school are selected to participate in the study, the researcher is not interested in generalizing beyond the particular sample of teachers selected (for more variations, see Brennan, 2001).

Assessing Dependability

G-theory assesses the dependability of measurement procedures by distinguishing between two types of error variances: relative error and absolute error. Relative error variance is appropriate when the object of measurement is rank-ordered and interpretations of individual differences are needed. The measurement error for relative decisions includes all sources of variation pertaining to the object of measurement. Absolute error variance is appropriate when decisions involve whether an examinee can perform at a pre-specified level where information about the rank ordering of persons and any differences in average scores are considered measurement errors. For absolute decisions, the differences between the observed and universe scores are the focus, and not necessarily the relative ranking of individual units. To calculate error for relative decisions in the one-facet crossed design, the following equation is used:

$$\sigma_{\delta}^2 = (X_{pi} - \bar{X}_i) - (\bar{X}_p - \bar{X}) \quad (4)$$

where \bar{X}_i indicates the average over the levels of facet i under which p is observed. The square root of this index is the δ -type (relative) standard error of measurement. Using σ_{δ} , a confidence interval that contains the universe score (with some degree of certainty) can also be determined, and a confidence interval for a person with a score (X) is obtained using $X \pm Z_{\alpha/2}\sigma_{\delta}$. G-theory makes no distributional assumption about observed scores or the scores effects, but a normal distribution is assumed to attach a probability statement to the confidence interval.

For absolute decisions, the following equation is used for one-facet crossed designs:

$$\sigma_{\Delta}^2 = X_{pi} - \bar{X}_p \quad (5)$$

The square root of this index can also be used to determine a confidence using $X \pm Z_{\alpha/2}\sigma_{\Delta}$.

The difference between the above equations is that for absolute decisions the equation reflects both information about the rank ordering of the object of measurement and any differences in average scores, whereas the equation for relative decisions does not include this information. Generalizability coefficients for deci-

Table 72.4 Relative and absolute coefficients for example one- and two-facet designs

	Relative		Absolute	
	Error variance	Coefficient	Error variance	Coefficient
One-facet crossed	0.11	0.90	0.11	0.90
Two-facet crossed	0.25	0.61	0.31	0.56

sions are computed based on these error terms for relative decisions (σ_{δ}^2) and absolute decisions (σ_{Δ}^2):

$$\sigma_{\delta}^2 = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_{\delta}^2} \tag{6}$$

$$\sigma_{\Delta}^2 = \phi = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_{\Delta}^2} \tag{7}$$

These coefficients range from 0 to 1.0, with higher values reflecting more dependable procedures. Table 72.4 presents the relative and absolute coefficients for the one- and two-facet designs presented earlier. These are found to be 0.90 for the one-facet design, but at or below 0.60 for the two-facet design.

When a researcher places emphasis on dependability in relation to a cutoff score (e.g., a domain-referenced test with a fixed cutoff score), a modified generalizability index for absolute decisions must be computed (Brennan & Kane, 1977). The index is denoted by $\Phi(\lambda)$ and represents domain-referenced interpretations involving the selected fixed cutoff score. The value of (λ) is determined by:

$$\Phi(\lambda) = \frac{\sigma_p^2 + (-\lambda)^2}{\sigma_p^2 + (-\lambda)^2 + \sigma_{\Delta}^2} \tag{8}$$

For computational ease, an unbiased estimator of $(\mu - \lambda)^2$ is determined by using $(\bar{X} - \lambda)^2 - \sigma_{\bar{X}}^2$ where $\sigma_{\bar{X}}^2 = \frac{\sigma_p^2}{n_p} + \frac{\sigma_i^2}{n_i} + \frac{\sigma_{pi,e}^2}{n_p n_i}$, represents the mean error variance and is the error involved in using the mean (\bar{X}) over the sample of persons and items as an estimate of the overall mean (μ) in the population of persons and the universe of items; the smaller the mean error variance the more stable the population estimate (Marcoulides, 1993).

Improving Dependability

G-theory refers to the initial measurement study as a G study. Results from a G study are then used in a “what if” decision study (D study) to improve dependability. The initial study might show that some sources of error are small, and one may elect a procedure that reduces the number of levels of that facet (e.g., the number of items or occasions) or even ignore it. The initial study might show that some sources of error are large, and one may elect to increase the levels of that facet to maximize generalizability. A D study helps address the question

“what should be done differently if you are going to rely on this measurement procedure for making future decisions or drawing conclusions?” For example, a D study provides information on whether adding items would improve dependability. For a one-facet crossed design, the estimated error variance and corresponding generalizability coefficient for relative errors is modified using the following equation:

$$\rho_{\delta}^2 = \frac{\sigma_{pi,e}^2}{n'_i} \tag{9}$$

All variance components in the entire design except the universe score variance contribute to error for absolute decisions. To calculate and modify the estimated absolute error variance and corresponding generalizability coefficient for a one-facet design, the following equation is used:

$$\rho_{\Delta}^2 = \frac{\sigma_i^2}{n'_i} + \frac{\sigma_{pi,e}^2}{n'_i} \tag{10}$$

In both of the above equations, the n'_i refers to the number of items modified to determine how the relative and absolute error variances change. For the one-facet example, Figure 72.1 provides a graphic description of how the relative and absolute error variances change as the number of items change. In this example case, the two lines appear almost on top of each other. A D study for a two-facet design can also be calculated in a similar manner.

A D study provides information about tradeoffs to future administrations of the measure. In addition to providing values for realistic and optimum number of measurement conditions under various constraints (e.g., budgetary, time, etc.), D studies can also provide an understanding of how a scenario can be extended to more complex designs, including those in which some sources of unwanted variation in the observations may be considered to be random, fixed, or nested.

Figure 72.1 D study for a one-facet example

Multivariate Extensions

Language assessments often involve multiple scores in order to describe an individual's aptitude or skills. For example, a language examination can contain subtests to measure different dimensions of knowledge and skills (e.g., memory, verbal and abstract reasoning). The most commonly used procedure to examine measurements with multiple scores is to assess their dependability separately using a univariate analysis (Marcoulides, 1994). In contrast, a multivariate analysis of such measurements can provide information about facets that also contribute to covariance among the multiple scores that cannot be obtained in a univariate analysis. This information is essential for designing optimal decision studies that maximize the dependability of measurement procedures.

If the two-facet design described earlier was used to examine scores obtained from several language dimensions, one way to look at the dependability is by using a univariate approach. However, by conducting a univariate analysis of the data, no information is available about any sources of covariation (correlation) that might exist among the different dimensions. Such information may be important for correctly determining the magnitude of error influencing the measurement. One way to ensure that all sources of variation and covariation are considered is by conducting a multivariate G study and comparing the results with those obtained from univariate results. If there are no differences, one can proceed with the information obtained from the univariate analysis.

In order to extend the notion of multifaceted error variance from the univariate case to the multivariate, one must treat the scores obtained from the different dimensions as a vector of outcome scores (e.g., with scores from two dimensions,

the vector would be $\begin{bmatrix} X1 \\ X2 \end{bmatrix}$, and is commonly denoted using the Greek letter v).

The total variance of the observed score $\sigma_v^2 X_{pi}$ (analogous in the univariate case to $\sigma^2 X_{pi}$ for each separate score) is:

$$\sigma_v^2 X_{pi} = \sigma_{vp}^2 + \sigma_{vi}^2 + \sigma_{vpi,e}^2 \tag{11}$$

A univariate analysis focuses on estimating variance components, whereas the focus of multivariate analyses is on variance *and* covariance components. As such, a matrix of variances and covariances among observed scores is decomposed into matrices of components of variance and covariance. And, just as ANOVA can be used to obtain estimates of variance components, multivariate analysis of variance (MANOVA) provides estimates of variance and covariance components.

A multivariate generalizability coefficient for the above study can also be computed using (Woodward & Joe, 1973):

$$\rho^2 = \frac{a' \sum_p a}{a' \sum_p a + \frac{a' \sum_{pi,e} a}{n_i}} \tag{12}$$

where a is a weighting of variables used in the multivariate design (i.e., a weight vector for the dimensions considered). Determining the weights to use is not without controversy and assorted approaches have been proposed in the literature (see Marcoulides, 1994). These approaches are based on either empirical or theoretical criteria and include: (a) weightings based on expert ratings, (b) weightings based on models examined through confirmatory factor analysis, (c) equal or unit weights, (d) weightings proportional to observed reliabilities, (e) weightings proportional to an average correlation with another subcriterion and (f) weightings based on eigenvalue decomposition criteria. Criticisms of these approaches are based on three criteria (relevance, multidimensionality, and measurability). Marcoulides (1994) examined the effects of different weighting schemes on selecting the optimal number of observations in multivariate-multifaceted designs and indicated that, in practice, selecting weights should be guided more by underlying theory than by empirical criteria.

Software

There are a number of specialized programs that can be used to conduct generalizability analyses. For example, Brennan (2001) developed a suite of software programs to conduct different types of analyses: GENOVA (for complete, balanced designs), urGENOVA (for unbalanced random effects), and mGENOVA (for multivariate analyses); and Cardinet, Johnson, and Pini (2009) developed EduG. These programs provide results for both G and D studies. Analyses can also be conducted through general statistical software programs such as SAS (SAS Institute, Inc., 1994) or even structural equation-modeling programs like AMOS, LISREL, EQS, Mplus, and so on (Marcoulides, 1996). Calculations for the D studies are sometimes available through these statistical programs but can of course always be obtained by hand.

Appendix A contains an example GENOVA program setup for the above one-facet design using raw data as input. A variety of D study designs can also be specified for estimation in GENOVA. For example, lines 21–7 specify some D studies with different numbers of item choices (e.g., 1, 5, 10, 15, and 20). Appendix B contains an example SAS-PROC ANOVA and PROC VARCOMP setup for the two-facet crossed design, but the user must compute the relative and absolute error variances and generalizability coefficients separately.

Current Views and Conceptualizations

Different Assessment Contexts

Several chapters in this companion focus on different assessment contexts. In this section, we provide examples of how G-theory was applied to three such contexts: school exit examinations (see Chapter 18, English Language Proficiency Assessments as an Exit Criterion for English Learners); university admissions examinations (see Chapter 19, Tests of English for Academic Purposes in University Admissions); and government and military assessments (see Chapter 20, Government and Military Assessment).

One purpose of school exit examinations is to ensure students who leave a program meet some minimum standards in particular areas. High school exit examinations, for example, are designed to ensure that graduating students meet minimum standards in terms of knowledge and skills in content areas. In California, students must pass a mathematics and English/language arts assessment before receiving a high school diploma. Assessment is based on the California state content standards through grade 10. There are two item response formats for the English/language arts portion: a fixed response format and an extended response. During the pilot phase of the English/language arts portion, students responded to two extended response questions (Wise et al., 2000). Two trained raters assigned a score of 1 (no mastery) to 4 (mastery) for each question for approximately 3,000 student responses. To examine the psychometric properties of the English/language arts portion, generalizability analyses were conducted "as a final indication of the impact of discrepancies across scorers" (Wise et al., 2000, p. 10). Prior to conducting the analyses, rater agreement was considered by the level of score overlap between the two raters. There was an 83% exact agreement between the two raters. The raters differed by one score point on 16% of the student responses and differed by two score points on 1% of the student responses. There were slight differences in rater agreement depending on the question type (reading compared to writing prompt). Conducting generalizability analyses enabled the authors to simultaneously analyze specific sources of variation due to students, raters, and the type of question. In these analyses, students were treated as the object of measurement and thereby assumed to be randomly sampled from a population of interest. The results indicated that most observed variation was in fact due to students, whereas less than 1% of the variation was due to raters. Despite the low rater variation and small increase in the generalizability coefficient when adding supplementary raters, the authors still recommended that multiple raters be used due to the high stakes nature of the individual student scores.

One concern of university admissions committees is to develop procedures for identifying a student's readiness to succeed at their institution. In the case of medical schools, admission is often based on various criteria such as performance on an interview, academic achievement, and recommendation letters. G-theory was applied to research on the use of interviews in medical school admission decisions. In one such study, Kreiter, Yin, Solow, and Brennan (2004) examined the generalizability of structured interview scores. Two raters presented four structured interview questions to 92 medical school applicants. These applicants were not admitted in the first year, reapplied in the second year, and were interviewed in the first and second year. Each rater assigned a score of 1 (problematic candidate) to 5 (a truly outstanding candidate) for each question. The authors analyzed the estimated variance components of each applicant, the structured interview questions, and the raters (with raters nested within persons, $r:p$) across both occasions. The variance component for applicants was relatively high (27% for occasion 1 and 17% for occasion 2), which suggested some differences between applicants in terms of their universe scores. However, most of the variation was unexplained (35% for occasion 1 and 49% for occasion 2). Findings from the D studies provided additional evidence that increasing the number of questions, occasions, or raters was not likely to generate a more dependable assessment

method. These results raised concerns and provided insight into the issues that must be considered when using structured interview questions for medical school admissions decisions.

A variety of situations within government and military contexts may also require assessment. For example, Webb, Shavelson, Kim, and Chen (1989) studied the dependability of scores of job performance of navy machinist-mates carrying out tasks in a ship's engine room, and Webb and Shavelson (1981) examined the dependability of general education development (GED) ratings of jobs in the USA. Other examples include a study by Shavelson, Mayberry, Li, and Webb (1990) in which they investigated Marine Corps rifleman performance on different infantry tasks. A total of 150 riflemen were observed by two raters on 35 tasks (such as treating a victim for shock, measuring distance on a map, and establishing a helicopter landing zone) across two locations. Each task was dichotomously scored (1 = right, 0 = wrong) by each rater. Findings from generalizability analyses indicated that trained raters produced reliable scores for evaluating military performance. Findings also indicated that the tasks selected to evaluate performance are very important, therefore selecting few tasks can be problematic. Although increasing the number of tasks improves dependability, the authors also highlighted the tradeoffs between the costs of increasing the number of tasks and reliability concerns. This issue of modifying different facets of measurement is just another way that G-theory can help researchers design studies with practical considerations (Marcoulides, 1993).

Current Research and Extensions

Links to Structural Equation Modeling

Structural equation modeling (SEM) can also be used to estimate reliability and generalizability coefficients (see Raykov & Marcoulides, 2006, 2011, and references therein). This approach is based upon the relationship between covariance structure analysis and the random effects ANOVA. The approach may also help address issues of missing data and provide a more flexible modeling and estimation approach than ones traditionally used.

The SEM approach uses as a basis the factor analysis model $X = \Lambda\eta + \varepsilon$, where Λ is the matrix of factor loadings while X , η , and ε are the vectors of observed variables, common factors, and unique factors respectively. The covariance matrix of the observed variables (Σ_{xx}) is given by $\Sigma_{xx} = \Lambda\Phi\Lambda' + \Theta$, where Φ is the covariance matrix of latent variables and Θ is the covariance matrix of the unique factors. For example, in the context of the two-faceted design illustrated previously, a confirmatory factor analysis model can be used to estimate all the variance components that involve persons (i.e., σ_p^2 , σ_{pi}^2 , σ_{po}^2 , and $\sigma_{pio,e}^2$)—for details see Raykov and Marcoulides (2011).

Links to Item Response Theory

Item response theory (IRT) has also been linked to G-theory (see for example Briggs & Wilson, 2007). G-theory looks across an individual's performance on

different items so there is limited information regarding specific conditions of particular items that are generated (Marcoulides, 1993). An IRT approach helps address the issue of providing information about examinee responses at an item level rather than an aggregated level. Although estimating a person's ability level is considered by many researchers to be fundamentally different in the two theories (Embretson & Hershberger, 1999), Marcoulides (1999, 2000) has argued that the theories can be conceptualized as merely alternative representations of similar information. Marcoulides (1999) also introduced an extension to the G-theory model (called the MD model—see Marcoulides & Drezner, 1993) that can be used to estimate latent traits such as examinee ability estimates, rater severity, and item difficulties, to name a few. The above extension to G-theory can be considered a special type of IRT model capable of estimating all latent traits of interest. Somewhat similar to IRT, where detecting a person's trait level is considered to be analogous to the clinical inference process, the MD model infers trait levels on the basis of the presented behaviors and places each individual on a trait continuum.

Other conceptualizations have also been proposed. For example, Briggs and Wilson (2007) proposed a model that estimates both traditional IRT parameters and IRT equivalents to variance components used in G-theory. Others simply use the two approaches sequentially, by first carrying out a generalizability analysis to estimate the sources of variation and then applying IRT techniques to diagnose unusual persons and/or facets, or vice versa in order to obtain insight into what changes should be made to the measurement procedure (Bachman et al., 1995).

The Marcoulides and Drezner (MD) model assumes that observed points (i.e., examinees, items, etc.) are located in an n -dimensional space and weights (w_{ij}) indicating the relation between any pair of points in this space can be calculated. For example, these weights may constitute a measure of the similarity of any pair of examinees in terms of ability level, any raters in terms of severity estimates, or items in terms of item difficulty (Marcoulides & Drezner, 1993). The MD model can also be extended to include any other latent traits of interest depending on the facets in the measurement study. Marcoulides and Drezner (1997) referred to the ability measure for each examinee (S_e) as the Examinee Index (similar to the ability estimate used in IRT models, generally represented as θ), and the severity estimate for each rater (S_j) as the Rater Index. Because the MD model independently calibrates the examinees, raters, and so on so that all observations are positioned on the same scale, the scales range from +1 to -1. Thus, negative values of the Examinee Index indicate relatively less able examinees and positive values relatively more able examinees. Similarly, a negative Rater Index reflects lenient raters and positive values severe raters.

Mathematically the MD model posits that in any measurement design with a distribution of random observations $X = (x_{ijk...n})(i = 1, \dots, m; j = 1, \dots, p; k = 1, \dots, q, \dots, n = 1, \dots, r)$ (e.g., representing m people taking a test with p items), n points (e.g., an examinee's score) are located in a dimensional space and weights (w_{ij}) between points must be determined for $i, j = 1, \dots, n$. The weights express the importance of the proximity between points in space—the similarity in examinee

ability level estimates or item difficulty—with the points found by minimizing a Euclidean distance function (for complete details, see Marcoulides & Drezner, 1993, 1997). The approach is also used to provide coordinates of a diagnostic scatterplot (either one-dimensional or two-dimensional) for examining observations and conditions within a facet in any measurement. Examination of the diagnostic plot can assist with detecting unusual examinee performances, and/or items, ratings, and so forth. Example illustrations that highlight the diagnostic capabilities and exemplify the discrepancies between the MD and IRT approaches are provided by Marcoulides and Kyriakides (2010). These examples also make clear the diagnostic capabilities of the MD method alongside the traditional G-theory approach and exemplify the wealth of information about the psychometric properties of measurement procedures available.

A Final Note on Limitations

There are some noteworthy limitations to G-theory. One limitation is that observations are dependent on the sample selected. If there is something particularly unique about the sample characteristics, it can raise questions about how well the sample actually represents the universe of observations. Who is sampled and how this sample both practically and theoretically relates to the universe to which the findings are to be generalized must be made explicit. Other more technical concerns include how to deal with missing data and how to model examinee responses at an item level (since G-theory focuses on performance across all items). Current research in SEM and IRT seems ideally situated to help address some of these limitations, so there is much optimism for the future of G-theory.

Exploratory Factor Analysis and Structural Equation Modeling

Gary J. Ockey
Educational Testing Service, USA

Introduction

Exploratory factor analysis (EFA) and structural equation modeling (SEM) are techniques commonly used in the field of language assessment. Both are multivariate statistical techniques, which have their basis in correlational analysis. EFA is a data-driven approach which is generally used as an investigative technique to identify relationships among variables. This usually means determining the smallest number of factors that can reasonably account for the correlations among the scores on items of an assessment instrument. For instance, EFA might help a researcher to determine that a 30-item multiple choice test aimed at assessing reading comprehension measures two somewhat distinct abilities. After content analysis of the items which assess these different abilities, it might be determined that these two abilities are grammatical knowledge and lexical knowledge.

SEM is an a priori theory approach which is most often used to determine the extent to which an already established theory, generally based on previous research, about relationships among variables is supported by observed data. The aim of an analysis is to test a hypothesized set of relationships among scores on items. For instance, if a researcher believed that reading comprehension was composed of the two subabilities of grammatical knowledge and lexical knowledge, an SEM analysis could be used to test this hypothesis.

Understanding EFA requires a basic knowledge of correlational statistics, and SEM requires an understanding of correlational statistics as well as multiple regression analysis. Readers who are not familiar with correlation and regression are encouraged to explore these topics before embarking on this chapter. Good sources in the field of language testing are *Statistical Analyses for Language Assess-*

ment (Bachman, 2005) and the accompanying workbook, *Statistical Analysis for Language Assessment Workbook* (Bachman & Kunnan, 2005).

The following definitions are helpful for understanding some of the concepts introduced in this chapter. Observed variables, or measured variables, are the actual scores on a particular test item, such as the raw scores on a multiple choice listening test. *Latent variables*, or *factors*, are unobservable *constructs*, *traits*, or *abilities*, like second language speaking ability. The term *factor* is most often used when the concept is defined mathematically (Royce, 1963), but all five of these terms refer to the same concept and are used synonymously throughout this chapter. A model is a set of mathematical relationships among variables. In SEM, a researcher tests a mathematical model believed to best explain the relationships among the variables of interest.

The chapter is divided into two major sections, the first introducing EFA and the second SEM. Theoretical explanations are accompanied by a practical example from real data.

Exploratory Factor Analysis

EFA is most often used to determine how many factors or constructs underlie a set of test scores and to what extent these factors are related to each other. For language assessment researchers, EFA is generally used to help identify theoretical constructs, which are measured by an assessment instrument, such as the ability to comprehend a written passage, or subconstructs, such as the ability to comprehend details or global ideas in a written passage.

EFA analyzes the pattern of correlations among many observed variables in order to determine which of them measure the same or similar constructs. The process converts a set of correlated observed variables into a set of uncorrelated unobservable factors. The factors are interpreted by using the factor loadings, the correlations between the observed variables, and the unobservable factors. Observed variables are said to *load on* a factor when they correlate highly with it. After factors have been identified, a content analysis of the set of items which load on each factor can be conducted to determine the ability which is measured by the set of items.

An EFA generally follows five steps. First, the data are screened and prepared for analysis; second, factors are extracted; third, the number of factors to retain for the solution is determined; fourth, a rotation method is selected and employed; and fifth, the solution is interpreted. To demonstrate this five-step process, data from a study which aimed to identify the factors measured by an academic abilities self-assessment questionnaire are used. The researchers were particularly interested in determining the ways and extent to which language ability might be manifested as a construct measured by the instrument. Three hundred test takers completed the assessment. The test takers responded to 20 five-point Likert scale items, 5 indicating “strongly agree” and 1 indicating “strongly disagree.” The item correlations are presented in Table 73.1.

As can be seen, all correlations are positive, and the magnitudes of the correlations are diverse, ranging from a high of 0.86 to a low of .09. From looking at the

Table 73.1 Data matrix for example data set of self-assessed academic abilities

matrix of correlations, it is clear that these variables measure related concepts, but with so many correlations, it is difficult to determine much more about the relationships among the items. EFA can be used to make large correlation matrices, such as this one, more interpretable.

Data Screening

Prior to analysis, data should be screened. Factor analysis relies on the following assumptions: independence, linearity of relationships among all pairs of variables, the absence of multicollinearity and singularity, and, depending on the objectives of the analysis, possibly multivariate normality. Outliers can also lead to a flawed analysis. The assumption of independence holds that scores of the individuals in the experiment are independent. A violation of this assumption would be test takers working together or cheating from each other. Researchers should ensure that this assumption is met during data collection. Linearity assumes that the observed variables are associated in a straight-line relationship, which can be assessed by inspecting bivariate scatterplots. Data transformations (Keppel & Wickens, 2004) can be used as a remedy for lack of linear relationships between pairs of variables. The assumption of absence of singularity and multicollinearity is that the variables are not too highly correlated. This assumption may be violated if the variables correlate at .90 or above. When correlations among variables are higher than .90, measures of tolerance (or variance inflation factor) (Keppel & Wickens, 2004) should be checked. When multicollinearity is present, one or more of the highly correlated variables should be excluded from the analysis. Satisfying the assumption of multivariate normality is only necessary when statistical inference is used to determine the number of factors, which is not commonly done in language assessment research. This assumption is discussed in the SEM section.

A sufficient sample size is important when conducting an EFA. When assumptions are clearly met, and there are no outliers, fewer cases will be needed for accurate estimates than for less well-behaved data sets. According to Kline (1994), a sample size of 100 is quite reliable, but 50 may be tolerable if the researcher is willing to accept that the results may not be very accurate. Comrey and Lee (1992) are more conservative in suggesting that 300 cases results in a sound analysis.

It is crucial that procedures for collecting and screening data are reported. Procedures for determining the extent to which assumptions are tenable should be described, and if, for example, outliers are excluded or data transformations are conducted, a description of these data manipulations accompanied by a rationale for the changes should be reported. Particular attention should be paid to outliers since they can have a considerable effect on an EFA. All variables in the self-assessment of academic ability data set satisfied the assumptions, and no outliers were detected.

Factor Extraction

Various procedures for factor extraction are available, including principal components (PCA), principal factors, maximum likelihood (ML), and weighted or unweighted least squares factoring. Extraction techniques identify a set of

orthogonal factors from the correlation matrix (Tabachnick & Fidell, 2006). Because of somewhat differing mathematical procedures, PCA is distinguished from factor analysis. PCA is described here, however, because it is likely the most commonly encountered factor extraction technique in the language assessment literature—it is the default setting in many computer packages. In PCA, the total variance among the observed variables is partitioned so that a linear combination of them that accounts for the most possible variance is identified. The value placed on this linear combination is referred to as the first eigenvalue. The process continues so that a second linear combination, one that is uncorrelated with the first, is found that accounts for the most possible variance that remains, the second eigenvalue. This process continues until all of the variance has been accounted for (Stevens, 2002). ML factor extraction is also quite commonly used by language assessment researchers. In this approach, factor loadings are calculated by maximizing the probability of sampling the correlation matrix from a population (Tabachnick & Fidell, 2006).

A PCA, using the EQS 6.1 program (Bentler, 1995–2008), was used to extract the eigenvalues from the self-assessment of academic ability data. The magnitudes of the eigenvalues were as follows: 9.27, 2.77, 1.59, 1.09, 0.68, 0.58, 0.51, 0.44, 0.42, 0.38, 0.36, 0.33, 0.28, 0.27, 0.23, 0.22, 0.20, 0.16, 0.12, and 0.10. It is quite clear that most of the variance in scores can be quite accurately represented with fewer than 20 items since a number of the eigenvalues are very small—close to zero. However, determining how many factors are needed to reasonably and parsimoniously represent the way the items cluster together is often not clear.

Determining the Number of Factors in a Solution

Multiple methods for determining the number of factors in a solution are available, and it is recommended that a combination of them be used to find the appropriate number. The default in most computer programs is set to the Kaiser rule, which is to retain factors that are greater than one. The logic is that a factor should account for at least as much unique variance as an item. Unfortunately, this easy-to-follow rule has been shown to be a poor indicator of the number of factors, especially when there are a lot of items, as is the case with many language tests. Using Kaiser's rule will overestimate the number of factors when there are a large number of items (Cattell, 1978). It should be noted that the Kaiser rule only applies to an eigenvalue decomposition of the unreduced correlation matrix, not the reduced correlation matrix. For the reduced correlation matrix, in which squared multiple correlations are placed on the diagonal instead of ones, eigenvalues greater than zero are considered substantial. Parallel analysis (Zwick & Velicer, 1986) is a sample-based technique designed to minimize the overestimation limitation of the Kaiser rule. The approach has not caught on in the language-testing field but is recommended over simply using the Kaiser rule.

Another indicator of the number of factors for a set of scores is a scree plot, a visual representation of the size of the eigenvalues. Scree plots help the researcher to determine at what point the decrease in variance accounted for by factors is no longer justified. When the decrease in size from one eigenvalue to the next smallest becomes insubstantial relative to the decrease in size from the next largest, it

Figure 73.1 Scree plot for self-assessment of academic ability data

is determined that this is the point at which no more factors should be included in the solution. Figure 73.1 presents the scree plot of the self-assessment of academic ability data.

The scree plot presents eigenvalues as dots on the line. The horizontal axis shows the number of eigenvalues or components, beginning with 1 on the left and progressing to 20 on the right (because the test has 20 items). The vertical axis shows the size of the eigenvalue, starting with zero at the bottom. An eigenvalue of 1 is highlighted to remind users of Kaiser's rule. The first eigenvalue in the analysis can be seen at the dot where the line begins in the top left corner. The eigenvalue for this first factor is above 9, suggesting that much of the variance in scores can be accounted for by one underlying trait or factor. The second eigenvalue, which can be seen at the second dot on the line, is near 3, and the third, which is at the third dot on the line, is around 1.5. The twentieth eigenvalue is near zero at the far right hand of the scree plot. As can be seen, there is a sharp drop from the first to the second and the second to the third eigenvalues. Between the third and fourth and between the fourth and fifth, there is much less decrease in size. After the fifth, the line is almost horizontal.

Interpreting scree plots can be difficult because the researcher has to determine at what point the decrease in variance accounted for by a factor, that is, the difference in magnitudes of eigenvalues, is no longer large enough to justify including the factor in the solution. In the scree plot shown in Figure 73.1 for the self-assessment of academic ability data, it is clear that there are at least three factors present in the data because the drop is quite sharp from the first to the second and the second to the third points on the line. It is also quite clear that after the fifth point on the line, there is almost no decrease from point to point. However, determining whether there are three, four, or five factors requires some judgment on the part of the researcher. Given that the scree plot suggests three, four, or five factors and Kaiser's rule indicates four, it would be defensible to assume four factors in the analysis.

Selecting and Employing a Rotation Method

After factors have been extracted, a rotation method is used to improve the interpretability of the solution. Rotation maximizes or minimizes different statistics to amplify the results. Various rotation methods can be used, some of which simplify the factors, some the variables, and others both the factors and variables (Tabachnick & Fidell, 2006). The most important distinction for language testers is whether or not the rotation method employs an uncorrelated, also referred to as orthogonal, technique, or a correlated, also referred to as an oblique, technique. Orthogonal approaches assume that the factors are not correlated while oblique approaches assume that they are correlated. In the social sciences, factors are most often correlated (Bentler, 2008), and it is therefore usually more defensible for language assessment researchers to use oblique techniques. Orthogonal approaches include Varimax, Quartimax, and Equamax, and oblique approaches include Oblimin and Promax. The results from the computer program EQS 6.1 (Bentler, 1995–2008), based on the selection of four factors and using an Oblimin rotation for the self-assessment of academic ability data, are presented in Table 73.2.

Interpreting Factor Loadings

The relative magnitudes with which items load on factors should drive an analysis. Specific guidance for determining the magnitude of a factor loading to use as

Table 73.2 Four-factor solution for self-assessment of academic ability data

Item 20	0.675	0.116	0.134	0.117

a cutoff is somewhat unclear. Some researchers suggest that values above 0.30 indicate a legitimate factor loading while others recommend conducting statistical tests which take sample size into account (Stevens, 2002). If the latter approach is used, it generally requires very large sample sizes for loadings as low as 0.30 to be considered large enough. Thus, 0.30 should be used as a cutoff only when sample sizes are quite large. When loadings are much higher than 0.30, and sample sizes are fairly large as in the self-assessment of academic abilities data set, judgments based on relative magnitudes of factor loadings generally provide an appropriate interpretation.

In Table 73.2, items which correlate highly (greater than .55) with each factor have been bolded. For instance, items 3, 14, 16, and 20 correlate highly with, or more technically, load on, factor 1. Items that load highly on one factor only measure one construct, that is, they are unidimensional. Items that load on more than one factor, such as item 11, which loads on factors 3 (.48) and 4 (.55), is multidimensional, that is, it measures aspects of both of these factors. Such split loadings can also suggest that the solution should have a different number of factors. For the most part, however, this factor structure could be considered a pretty unambiguous solution. All of the items loaded above 0.50 on one factor. Only two items, 5, and 11, loaded above .35 on a second factor.

After identifying the items which load on each factor, a content analysis of the items should be conducted to determine what the items for each factor have in common. This makes it possible to identify the constructs which underlie the test items. For the self-assessment of academic ability data, items that loaded on factor 1 were about enjoying school, items that loaded on factor 2 were about enjoying and doing well in language, items that loaded on factor 3 were about feeling confident to do well in school, and items that loaded on factor 4 were about enjoying and doing well in math. The self-assessment instrument could therefore be shown to measure these four constructs, one of which was a manifestation of language ability and enjoyment. It should be noted that since Oblimin rotation, a correlated factor model, was used, these four constructs were correlated.

Origins and Applications in Language Testing

The logic underlying EFA might have originated with fifth-century BC Greek philosophers, who believed that what is observable can only be explained by what cannot be observed. However, Spearman, who worked on finding intelligence factors in the early 20th century, is usually given credit for founding factor analysis (Mulaik, 1987).

The most common use of EFA in language assessment has been to assess the factor structure of a test or dimensionality of a data set (e.g., Green & Weir, 2004; Pae & Park, 2006; Ockey, 2007). EFA to measure the dimensionality of a data set is often encountered in item response theory (IRT) studies to assess the assumption of unidimensionality. EFA has also been used to develop rating scale subconstructs for writing (Tanaka, Tsubone, & Hajikano, 1998) and to determine the number of factors in cognitive strategy use when taking an examination (Song & Cheng, 2006).

Structural Equation Modeling

SEM is a set of statistical techniques that can be used to show the relationships among a group of variables. More specifically, SEM combines multiple regression, factor analysis, and path analysis techniques to model the relationships among measured and latent variables, which can be either continuous or categorical. SEM is also referred to as analysis of covariance structures and causal modeling. Confirmatory factor analysis (CFA) and structural regression are commonly encountered types of SEM in the language assessment literature. Other types of SEM analyses which may be encountered by language assessment researchers include path, growth, multiple-groups, and multitrait-multimethod models. Various computer software programs and notational schemes are used by SEM researchers. This introductory chapter is based on the Bentler and Weeks (1980) model, and the example analyses are conducted using this model in the EQS (Bentler, 1995–2008) program.

Model diagrams are often used to help researchers picture relationships among the variables in an SEM analysis, and they often appear in published studies as visual representations of the models under investigation. These diagrams represent the hypothesized relationships in a covariance matrix. Arrows between variables indicate that the variables are expected to be meaningfully related. The absence of arrows between variables indicates that the magnitude of the relationships, that is, the covariances among these variables, are not expected to be large enough to be meaningful. A model diagram which shows a hypothesized relationship between compliance, shyness, and second language oral ability is presented in Figure 73.2.

The 11 rectangles represent observed variables, and the ovals, labeled shyness, compliance, and oral ability, indicate factors or latent variables. When one variable is hypothesized to predict another, a single-headed arrow pointing toward the predicted variable is used. For example, in Figure 73.2, the latent variable of shyness is hypothesized to predict three observed variables: avoid crowds, keep quiet, and loner. Double-headed arrows indicate that the variables are expected to correlate with each other, but the direction of the relationship is not assumed. An example in Figure 73.2 is the relationship between compliance and shyness. The model hypothesizes that compliance and shyness are correlated, but it doesn't suggest that one predicts the other. Error is labeled as either E for error, or D for disturbance. Errors are used when a latent variable predicts an observed variable, for instance, E (error) 11 in agreeable predicting compliance. Disturbance is used when a latent variable predicts another latent variable, for example, the D (disturbance) 1 for shyness and compliance predicting oral ability.

In SEM, a distinction is generally made between the part of the model that relates the measured variables to the latent variables, referred to as the measurement model, and the relationships among the latent variables, referred to as the structural model. In the model in Figure 73.2, there are three measurement models. One relates the latent variable of shyness to three observed variables: avoid crowds, keep quiet, and loner. Another measurement model relates the latent variable of compliance to three observed variables: agreeable, follower, and rarely

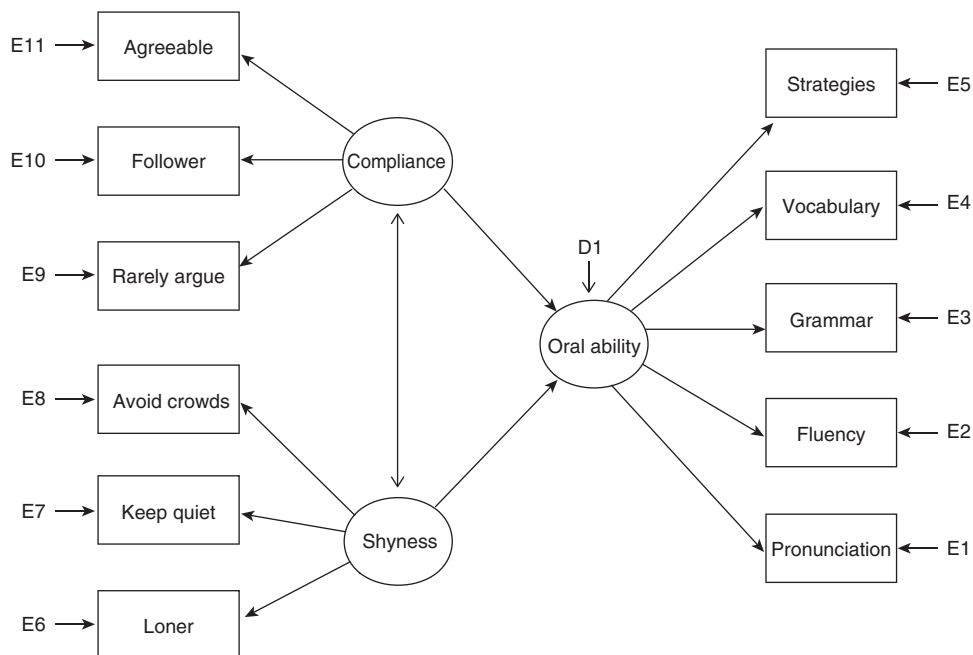

Figure 73.2 Example SEM model diagram

argue. The third measurement model is the relationship of the latent variable of oral ability to the observed variables of strategies, vocabulary, grammar, fluency, and pronunciation. There is one structural model in Figure 73.2, which relates the latent variables of shyness, compliance, and oral ability.

Researchers present the steps in an SEM analysis in slightly different ways. The seven-step approach that follows is recommended for language testers using a strictly confirmatory approach: (1) a model is proposed; (2) the proposed model is shown to be identified; (3) suitable data for the model are collected and screened; (4) the model parameters are estimated; (5) the fit of the model to the data is assessed; (6) parameters are interpreted; and (7) competing models are evaluated.

Despite the fact that SEM is a confirmatory technique, researchers may not always base their final analysis on their originally proposed model. This generally happens when the proposed model does not fit the observed data to an acceptable extent. Procedures for identifying parameters that are missing from a model are available when model fit is not acceptable. One of these procedures is the Lagrange multiplier (LM) test, which is analogous to forward selection in regression. It identifies parameters that have been excluded from the model which, if included, will have the largest effect on increasing model fit. The LM test's counterpart is the Wald test, which is used to identify parameters that have been hypothesized as meaningful in the proposed model but are not found to be substantial in the observed data. When the originally proposed model is respecified because it does not fit the data, it is crucial that the researcher provides relevant theory to support changes in the model as well as indicate that the analysis is no longer strictly

confirmatory. The results should be considered exploratory since an a priori model driven by theory and relevant research is no longer the object of investigation.

In language assessment research a CFA SEM is frequently used to confirm the underlying constructs of an assessment instrument. To determine the extent to which the four underlying constructs found in the self-assessment of academic abilities assessment instrument could be confirmed, data from 560 test takers who completed the same self-assessment were analyzed using SEM techniques. It should be noted that, like the analyses in this chapter, the same data should not be used to conduct an EFA and a CFA. The procedures follow the seven steps introduced above.

Proposal of Hypothesized Model

Because SEM is an a priori method, models should be hypothesized prior to the analysis. The proposed model for the self-assessment of academic abilities example is presented in Figure 73.3, which is based on previous research (the EFA conducted in the first section of this chapter).

Based on the results of the EFA described in the first half of this chapter, the items were hypothesized to load as follows: items 3, 14, 16, and 20 on factor 1, items 2, 4, 7, 9, 13, and 17 on factor 2, items 1, 6, 10, and 18 on factor 3, and items 5, 8, 11, 12, 15, and 19 on factor 4.

Identification of Proposed Model

To perform an SEM analysis, it must be possible to find a unique set of estimates for each of the parameters in the hypothesized model. All SEM models must satisfy two requirements to be identified. First, the number of unique elements in the variance–covariance matrix, or data points, must be equal to or greater than the number of parameters to be estimated. Data points are based on number of observed variables times the number of observed variables plus 1, all divided by 2. This is mathematically expressed as: $p(p + 1)/2$, where p = number of observed variables. Parameters to be estimated are based on the number of variances, covariances, and regression coefficients that are free to be estimated in the model. The number of parameters to be estimated is then subtracted from the number of data points in the data set to give model degrees of freedom. When this number is zero or greater, the first condition for identification is satisfied. Second, all latent variables must be set to a particular scale (Kline, 2005). This means that each factor variance or one of the regression paths from a factor variance to an observed variable must be fixed to a specified value, which is usually 1.0. It is best to fix the path to the most reliably measured variable. Although necessary, satisfying both requirements does not ensure that an SEM model is identified. For unidimensional CFA models with two or more factors, each factor must predict at least two observed variables. When the model has only one factor, three or more observed variables are required. Kline (2005) provides further discussion about model identification.

The self-assessment of academic abilities example satisfies both conditions for model identification. As can be seen in Figure 73.3, there are 20 observed variables

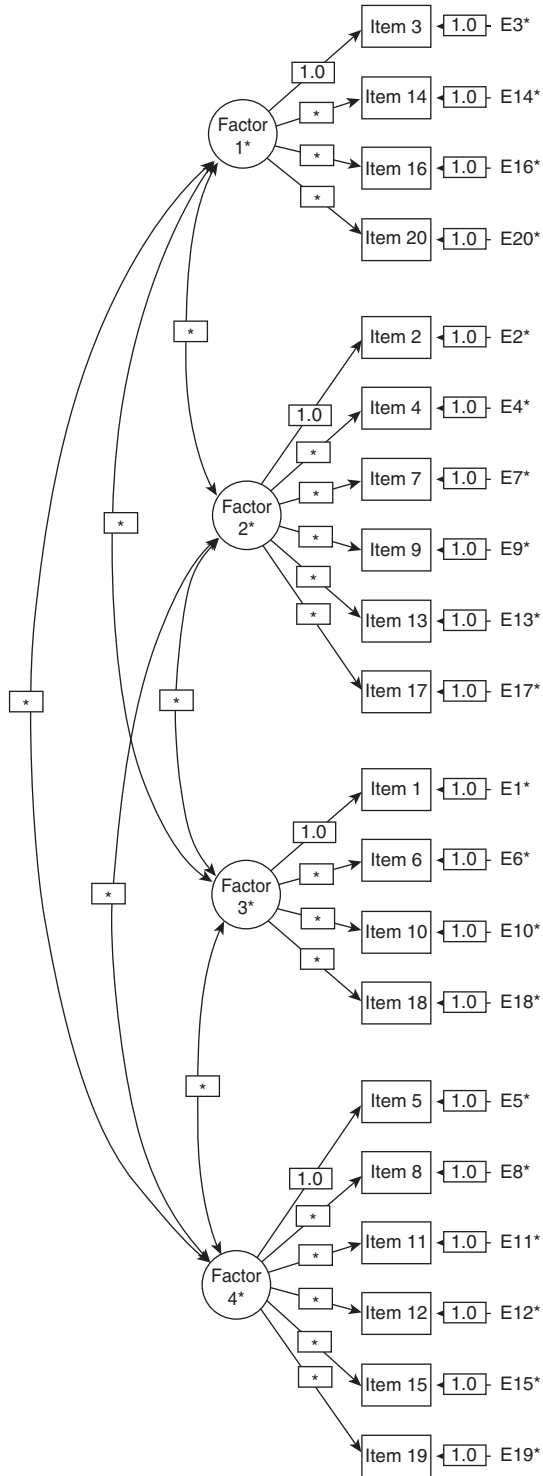

Figure 73.3 Proposed model for the self-assessment of academic abilities example

(based on the number of rectangles). Replacing p with 20 in the formula: number of data points = $p(p + 1)/2$, gives $20(21)/2 = 210$ unique elements for the observed variance–covariance matrix. The number of parameters to be estimated is equal to 46. These 46 parameters to be estimated are calculated by SEM software and are indicated by asterisks in Figure 73.3. There are 24 variances, based on the 20 error rectangles and 4 factor ovals. There are 16 regression coefficients, or factor loadings, based on 16 of the 20 one-headed arrows from factors to observed variables with asterisks; the four regression coefficients with 1.0 rather than an asterisk have to be fixed—one for each factor, to satisfy the second condition of identification. Finally, there are 6 covariances, based on the 6 two-headed arrows. Subtracting 46 from 210 results in 164 model degrees of freedom, which satisfies the condition of being zero or greater, indicating that the first identification requirement is met. To satisfy the second requirement of model identification, one regression path for each of the factors was fixed, as can be seen by the 1.0 on four of the paths in the model, and all of the paths from error variances to the observed variables were fixed to 1.0.

Collection and Screening of Data

After the data is collected, it must be screened to determine the extent to which it is appropriate for an SEM analysis. Like EFA, SEM techniques generally rely on independence of observations, linear relationships between variables (although nonlinear relationships between variables can be modeled), and absence of multicollinearity and singularity. Outliers can also negatively affect an SEM analysis. (See “Data Screening” in the EFA section above for a discussion on diagnosing and remedying violations of these assumptions.) Because of the use of test statistics, an additional assumption of an SEM analysis, for most estimation procedures, is that the data set is multivariate normal (Ullman, 2001). The first step for assessing multivariate normality is to assess the univariate normality of each variable in the analysis. Variables with skewness absolute values above 3.0 or kurtosis absolute values greater than 10.0 are considered problematic (Kline, 2005). Transformations are commonly used to normalize a variable (Keppel & Wickens, 2004). Univariate normality of all the variables in an analysis, however, does not insure multivariate normality of a data set, and therefore multivariate normality tests, such as Mardia’s coefficient of multivariate kurtosis, should also be investigated.

Because the assumption of multivariate normality in a data set is commonly violated, procedures for working with such data sets have been developed. One approach is to use a technique that does not assume multivariate normality, such as asymptotic distribution free or arbitrary distribution function (ADF) estimation procedures (Kline, 2005). Unfortunately, these techniques generally require rather large sample sizes, which are often not available to language assessment researchers. Another approach is to remove cases that have a large effect on multivariate normality. This approach is usually not favorably viewed, however, because of the difficulty of collecting data and the questions associated with the ways in which dropping the scores of individuals in a data set can affect the generalizability of the results. A third approach for working with data that is not multivariate normal is to use a corrected normal theory method. This approach is commonly

encountered in the language assessment literature and is therefore discussed in the “Assessment of Model Fit” section below.

Appropriate sample size in an SEM analysis depends on various factors, including complexity of the model and the degree of precision that the researcher expects. More complex models and higher degrees of precision require larger sample sizes. Analyses which include reliably measured variables require smaller samples than ones which include unreliable measures. Even with quite simple models, SEM analyses require rather large data sets. Kunnan (1998) states that sample sizes of less than 150 are unlikely to provide stable estimates. Techniques which require smaller samples, however, continue to be developed as researchers make efforts to make SEM techniques appropriate for more contexts (Bentler, 2008).

Estimation of Proposed Model Parameters

The purpose of an estimation procedure is to identify estimates for each of the parameters (e.g., factor variances, factor loadings, error variances, disturbance variances) in the hypothesized model which minimize the difference between the observed and hypothesized covariance matrices. The process is iterative. It begins with an initial set of parameter estimates and then evaluates other similar estimates in an attempt to get closer to the optimal solution. The model is said to converge on a solution when the best values are found (Brown, 2006). The most commonly encountered estimation procedure in language assessment research and in most other fields of study is ML. ML is based on probabilities and patterns in the data. It is referred to as a full information method because it estimates all parameters simultaneously (Bentler, 2008).

To estimate the self-assessment of academic abilities proposed four-factor model, ML estimation as implemented in the EQS 6.1 program (Bentler, 1995–2008) was used. The program converged on a solution with no noted problems.

Assessment of Model Fit

Model fit indicates the degree to which the observed data can plausibly be explained by the proposed model. The data must fit the model to an acceptable extent if the proposed model is to be accepted. For normal theory data, the chi-square statistic along with various fit indices are used. The chi-square statistic tests the hypothesis that the difference between the estimated population covariance matrix based on the model and the sample covariance matrix based on the data is not significantly different. The logic is that if there is not a significant difference between the proposed model data and the actual data, the model fits the data. It is important, however, to point out that this logic is not a guarantee that the model fits the data. Chi-square statistics are almost always used to assess model fit; however, because they depend on sample size, the null hypothesis can be rejected when the proposed model data and actual data are only slightly different in large data sets (Ullman & Bentler, 2003). Thus, fit indices which take into account sample size and other factors should accompany chi-square statistics.

There are a number of fit indices, and results should be based on more than one of them. Different fit indices focus on different aspects of model fit, and therefore one measure of fit should not be used by itself. Based on simulation studies, Bentler (2008) recommends that along with the chi-square statistic, an absolute fit index, a relative fit index, and the standardized root mean square residual (SRMR) be reported. The root mean square error of approximation (RMSEA), arguably the most popular absolute fit index, and the comparative fit index (CFI), one of the most popular relative fit indices, are commonly encountered in language assessment research. Based on their review of language assessment SEM studies and current SEM theory, In'nami and Koizumi (2011) have similar recommendations to those of Bentler. They recommend that along with chi-square, researchers report SRMR and either the CFI; or the Tucker-Lewis index (a relative fit index); and the RMSEA, accompanied by its confidence interval.

SRMR is based on a standardized average of the differences between the actual and hypothesized covariances. These differences, or residuals, would be zero if the actual data and the modeled data were identical. Values below .10 are considered good (Kline, 2005). CFI assesses fit compared to other models; fit is seen as a continuum ranging from 0 to 1, in which 0 indicates that the model is not accounting for the covariances among the variables, and 1 indicates that the model accounts for all of the covariances perfectly (Bentler, 2008). A fit of above .95 is an indication of a good fit (Hu & Bentler, 1999), while a value of .90 and above may indicate reasonably good fit (Kline, 2005). RMSEA compares the lack of fit in a model to a completely saturated model, that is, a model in which all variables are correlated. A value which approaches zero indicates perfect fit. Values equal to or less than .05 indicate close-fitting models, and values between .05 and .08 suggest reasonable fit (Kline, 2005).

Scaled fit indices developed to function when the assumption of multivariate normality is violated are often encountered in the language assessment literature. When data violate the assumption of multivariate normality, ML parameter estimates are fairly accurate, but standard errors are usually low. Thus, parameter estimates are generally accurate, but true factor structures can be rejected when standard fit indices are used on non-normal data. To remedy this problem, a corrected normal theory method (Bentler, 2008) can be used. In this procedure, ML procedures, along with Satorra and Bentler (S-B) (1988) robust standard errors, corrected test statistics, and scaled fit indices which are adjusted for the degree of observed kurtosis, can be used. These scaled fit indices can be interpreted using the same cutoff values as normal theory fit indices.

For the self-assessment of academic abilities data, the proposed model and the observed data fit approximately. The chi-square value was 610 on 164 degrees of freedom $p < .05$; CFI = .91; RMSEA = .07; and SRMR = .07. Based on the criteria discussed above, the chi-square value indicates poor fit, CFI and RMSEA reasonable fit, and SRMR good fit. Taken as a whole, the indicators suggest that the proposed model reasonably fits the data. Given that the proposed model is based on previous research (from the EFA analysis described earlier in the chapter), it may be reasonable to argue that the observed data from the 560 test takers provides support for the hypothesized model.

Interpretation of Parameter Estimates

SEM analyses generally lend themselves to a great deal of information of which only a small fraction is discussed here. Parameter estimates, standard errors of these estimates, and test statistics which assess the significance of these estimates are provided. Both unstandardized and standardized estimates are important in SEM output. While unstandardized estimates are generally difficult to interpret, they are crucial because standard errors and accompanying test statistics do not accompany standardized estimates. However, because standardized estimates are more easily interpreted, they are the basis of most interpretation. In addition to model fit, discussed in the previous section, most SEM research emphasizes interpretation of factor loadings, error estimates, factor correlations, relationships between observed variables, and relationships between latent variables. Interpretations of error estimates are also sometimes encountered in the language testing literature. SEM analyses can provide information for additional interpretations (Bentler, 2008; Byrne, 2006) that will not be discussed in this introductory chapter.

Factor loadings, indicated by arrows pointing from a factor to an observed variable, provide estimates of the change of the observed variable based on a one-unit change in the factor (holding other variables constant). That is, these factor loadings are interpreted in the same way as beta weights in a regression analysis. High factor loadings indicate that the observed variables are good indicators of the factors. Models in which each observed variable only loads on one factor provide evidence of convergent validity.

The magnitudes of the correlations between factors provide evidence of the extent to which factors are distinct constructs. Low correlations indicate that the factors are largely separate constructs. Factors which correlate above .85 are generally viewed as too similar to be distinct (Brown, 2006). However, lower (or possibly higher) cutoffs may be defensible depending on the research questions and the context of the study.

Direct effects between two variables (latent or observed) can also be interpreted in SEM. High path coefficients from one variable to another indicate that the factor to which the arrow is pointing is strongly predicted by the other factor. The coefficients are interpreted the same way as regression coefficients.

Measurement error is also modeled and accounted for in an SEM analysis. Two types of error are indicated by error terms associated with the measurement of the effect of a latent variable on an observed variable. The first is random error due to score unreliability, and the second is systematic error which is not due to the factors. Relationships between factors in a model are purified estimates. That is, measurement error, due to the imperfect reliability of an assessment instrument, is not included in the error term associated with the relationship between two latent variables.

The self-assessment of academic abilities data provides an example of parameter interpretation for a CFA model. The standardized estimates are presented in Figure 73.4.

Test statistics and standard errors are not presented, however. Test statistics should be used before interpretation to determine whether the relationships are significant. In this case, all relationships in the model were significant. The large

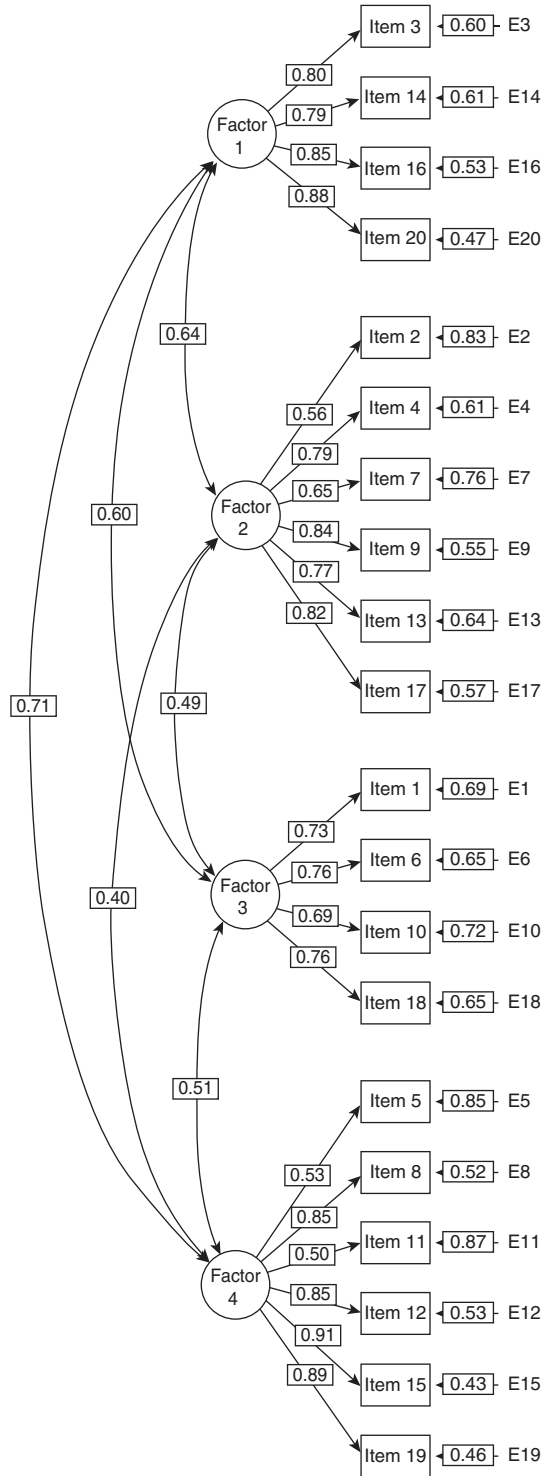

Figure 73.4 Standardized estimates for the self-assessment of academic abilities example

factor loadings from the latent variable, such as from factor 1, to the observed variables, such as item 3 (.80), suggest that the observed variables are good indicators of the latent traits. A couple of the loadings on factor 4 (for items 5 and 11) and one on factor 2 (for item 2) are medium-sized loadings (.53, .50, and .56, respectively), but overall, the loadings suggest that the observed variables provide good measures of the factors that they were hypothesized to assess, suggesting convergent validity of the assessment instrument.

The correlations between factors, indicated by the coefficients with the two-headed arrows, such as between factors 1 and 2 (correlation is .64), are all significant but well below the cutoff point of .85, suggesting that the four subconstructs of self-perceived academic ability are related but distinct enough to be viewed as separate constructs.

The paths from errors to observed variables suggest a fair amount of measurement error in the assessment instrument or procedures or both. This is a common finding in studies that employ self-assessment data obtained from Likert scale items and underscores the value of using SEM techniques when comparing constructs measured by such item types (Ockey, 2011).

Evaluation of Competing Models

A final step in an SEM analysis is to provide evidence that other plausible models have been investigated to determine whether they fit the data better than or as well as the proposed model. In fact, one approach to SEM analysis, referred to as model comparison, is to compare competing models to see which best fits the observed data. Turner's (1989) study, one of the first SEM studies to appear in the language-testing literature, provides a detailed example of how competing theoretical models can be compared to determine which is most plausible for a given data set. Given that the self-assessment of academic abilities data was used only as an example here, other possible competing models will not be investigated.

Origins and Applications in Language Testing

Sewall Wright is generally credited as the father of SEM because he was the first to propose path analysis techniques in the 1920s. It was in the 1970s when Jöreskog presented the LISREL model, which incorporates factor analysis, simultaneous equation models, and path analysis into a general covariance structure model that SEM exploded as a field.

Bachman and Palmer may have been the first language assessment researchers to use SEM in their construct validation study of the Foreign Service Institute oral interview (1981). The technique did not catch on quickly, however. Nearly two decades later, Kunnan (1998) stated, "A search for applications of SEM in the field of language assessment will certainly not turn up more than a handful of entries at the most" (p. 297). Since the early 2000s, however, use of the technique has grown rapidly. In'ami and Koizumi (2011) provide a review of SEM studies in language testing and learning which substantiates this rapid growth.

Recent uses of SEM in language assessment have been to confirm a test's structure or the abilities measured by a test (e.g., In'ami & Koizumi, 2012; Sawaki,

Stricker, & Oranje, 2009), assess the effect of test methods on test performance (e.g., Llosa, 2007; Sawaki, 2007), assess the equivalency of models for different populations (e.g., Llosa, 2005; Shin, 2005), and understand the effects of test-taker characteristics, test tasks, or types of language on a construct or test performance (e.g., Carr, 2006; Ockey, 2011; Romhild, Kenyon, & MacGregor, 2011).

Challenges and Future Directions

EFA and SEM research has been disparaged on different fronts. EFA has been criticized because it is a technique that can be used given almost any set of assessment data. As a result, it is commonly used when not much else can be done. SEM, on the other hand, has been criticized because researchers can inappropriately use the LM test to add parameters to a model that will make it fit a data set. Theory to justify the model modifications can be crafted *ex post facto* to justify the changes. When such an approach is used, results can be based on idiosyncrasies in the data that are unique to the data collection procedures or the test-taker population or both, leading to models that are not at all indications of real-world language assessment phenomena.

To limit the misuses and resulting criticisms of EFA and SEM, an important challenge for the language assessment community is to ensure that appropriate procedures are followed and reported. Accurate and detailed reporting is crucial because the degree to which the data satisfy necessary assumptions, decisions such as how many factors to retain and the rotation method used in an EFA, and the extent to which an SEM analysis is strictly confirmatory are crucial to the claims that can be made from findings. Ullman (2001) describes procedures that should be followed and provides an example report for an EFA. Ockey and Choi (in press) discuss some of the caveats when conducting SEM analysis and provide guidelines for what to report to limit misinterpretation of results. Based on their review of SEM articles in the language assessment literature, In'nami and Koizumi (2011) suggest that researchers provide appropriate procedures and sufficient information on parameter estimation methods, model fit indices, normality checks, missing data treatment, and sample size.

EFA and SEM are techniques which can be used to increase knowledge about language assessment. By following best practice guidelines laid out in this chapter, Ockey and Choi (in press), In'nami and Koizumi (2011), and Kunnan (1998) many of the criticisms of the uses of these techniques can be avoided. Future research employing these techniques will undoubtedly continue to become more stringent and sophisticated, and as a result, more enlightening.

Questionnaire Development and Analysis

Aek Phakiti

University of Sydney, Australia

Introduction

This chapter aims to provide an introduction to questionnaire development and questionnaire analyses for language assessment use and research purposes. The popularity of the questionnaire lies in its cost, time efficiency, and anonymity. The number of participants to which a questionnaire can reach out (i.e., its breadth) makes up for its potential lack of depth in investigating issues which are offered by other techniques, such as multiple interviews or observations. A large number of respondents can complete a questionnaire at the same time or any time convenient to them. Questionnaires can be administered in a large lecture theatre or hall or mailed out to a target population or sample. Online formats can also be made available (discussed further below). After being collected, responses to questions or items can be keyed or scanned for analysis. Answers to open-ended questions can be typed quickly since they are usually brief, or retrieved directly from online questionnaires. Furthermore, since most people are familiar with questionnaires, there is no need for us to spend much time explaining how to complete a questionnaire.

This chapter will first discuss contexts in which questionnaires can be used to elicit information from test takers, students, or other stakeholders. It will then present the limitations of questionnaires. The typical stages in questionnaire development and use will be outlined, followed by recommendations of how to construct a questionnaire, questionnaire analyses, and selected examples of questionnaires in published research. The word “researchers” will be used in this chapter to refer to anyone using a questionnaire for some purpose.

Questionnaire Use

For the purpose of this chapter, questionnaire use will be discussed in the contexts of teaching-related language assessment and research.

Questionnaires in Teaching-Related Language Assessment

Self-assessment questionnaires ask students to judge their own strengths and weaknesses in the target language. “Can-do” statements such as “I can identify main ideas in a text” and “I can write simple descriptions of places” are often used in a self-assessment questionnaire. Self-assessment questionnaires are useful when there is a need to group students into various levels or to help them reflect on the progress they have made in their own learning. Other questionnaires used in a language classroom include peer-evaluation questionnaires, which ask students to rate one another’s performance, and language program evaluation questionnaires, which ask students to judge the effectiveness of their courses and the classroom instruction. In language curriculum development, students’ needs in language learning (needs analysis) are often assessed with such questionnaires.

Questionnaires in Language Assessment Research

For many years language assessment research has used questionnaires as part of research instruments (see “Sample Published Questionnaires” below). There are various situations in which questionnaires are appropriate for language assessment research, such as when the goal of the research is to understand the cognitive processes involved during test taking without interfering with the real-time test situation. Furthermore, researchers may be interested in particular types of motivation or anxiety that may be related to language test performance. In this sort of research, questionnaires are suitable, because they are not obtrusive and allow standardized measures across test takers.

Limitations and Challenges of Questionnaires

The greatest challenges in questionnaire use are related to issues of the validity of respondents’ answers, because their answers are subject to certain types of bias resulting in measurement error. The first is called *prestige bias*, which refers to the fact that respondents will provide answers that make them look good or feel better. Usually this bias is more apparent when respondents’ identities are known to the researcher and there could be some personal implications or consequences for the respondents. Also, there can be prestige bias if respondents think they could be identified when the results are more widely known. Another type is *acquiescence bias*. This bias occurs when respondents tend to agree with the questions or items independent of the content. This is particularly a case in agree/disagree or true/false items. A third type is *self-deception bias*, which is related to the situation where respondents think they are able to do something when in fact

they cannot (see Wagner, 2010). It is important to note that a highly reliable questionnaire (e.g., $\alpha = 0.95$; see “Statistical Analysis for Questionnaire Data” below) does not imply that such a questionnaire is free from bias. A reliability estimate can only indicate a degree of consistency of the questionnaire items in eliciting information from the respondents, rather than in the validity of their answers. Although there is no best way to eliminate such bias completely, researchers need to be aware of the effect of potential bias in their data and the nature of inferences made on the basis of their data. It is also important to try to minimize any bias during the data collection (e.g., providing a clear purpose of questionnaire use and asking participants to be truthful in their answers). Researchers need to acknowledge any possible presence of bias and avoid overgeneralization of the findings. Certainly, various forms of such bias are key challenges to other kinds of data collection methods, including interviews and think-aloud protocols.

An additional challenge involved with questionnaire use is related to the format and appearance of the instrument. For instance, if a questionnaire is too long or requires a lot of time to complete, respondents will be less likely to participate or fully answer all the questions. Another possible problem researchers must be prepared to deal with is missing data. It is undesirable to have a lot of missing data as this renders questionnaires unusable. Some respondents may skip some questions and forget to return to answer them, while others may avoid answering particular questions. One other notable challenge in questionnaire use is a possible lack of or poor responses to open-ended questions. Often a questionnaire can ask respondents to explain why they gave a certain rating or to provide other general comments or feedback toward the end of the questionnaire. If researchers need this sort of information, they need to convince respondents to see the value of sharing it. Nevertheless, if they want to ask a lot of open-ended questions in a questionnaire, it may be more effective to conduct individual or group interviews, because respondents may find it easier to produce oral rather than written or typed responses. However, when anonymity is important (i.e., respondents should not be identifiable even by the researcher), questionnaires are more suitable than interviews. Finally, in most research contexts, relying on one type of research instrument is not sufficient to help researchers understand a complex issue under study. Questionnaires are useful to answer “what” questions, but they cannot answer “how and why” questions in great detail. Given this, questionnaires are often used in a mixed methods research design which utilizes various sources of data.

Stages in Questionnaire Development

There are various stages and important considerations when developing and using a questionnaire. This section outlines seven key stages of questionnaire development and use (see Figure 74.1): identifying, planning, developing, piloting, implementing, analyzing, and reporting. Although they may appear as a set of serial activities (one thing after another), in practice they are iterative in nature. This iterative nature of questionnaires is represented by the double-headed arrows in Figure 74.1.

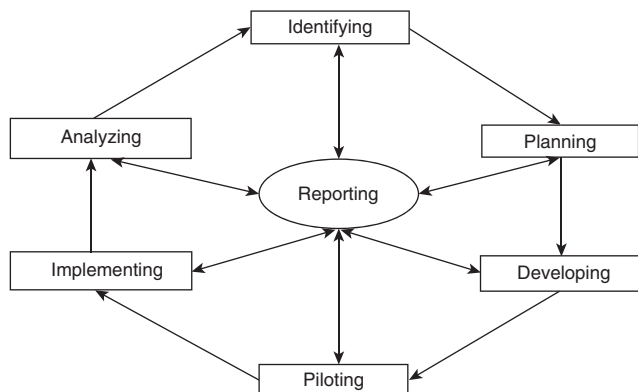

Figure 74.1 Seven key stages in questionnaire development and use

The identifying stage includes considering the purpose of the questionnaire and the kind of decisions teachers or researchers need to make after completing the data analysis (e.g., teaching-related, policy-informed, research inquiry). Another important issue to consider at this stage includes asking several questions: “Who are the target respondents?” “In what setting or context will the questionnaires be used?” “Do researchers need to do sampling and, if yes, what kind of defensible sampling do they adopt?” and “How will data be analyzed?” This stage often overlaps with the planning stage.

The planning stage includes considering the resources needed to complete the project successfully. In managing an available budget, researchers need to carefully plan what and how much to spend, and to keep to this plan. Key tasks in this stage are related to considering issues of practicality, comparing the resources available with the resources needed for their questionnaire. Another important consideration in planning is whether or not the approval of the governing ethics committee is required. In many academic institutions this is mandatory, as there may be legal implications of what researchers do with their respondents and questionnaires. Regardless of whether an ethics committee’s approval is needed, researchers should always follow an ethical standard in conducting their research (see Dörnyei, 2007, chap. 3).

In the developing stage, first and foremost, researchers need to identify and consider the content of the questionnaire. This is related to observable, representative behaviors or issues that can be used to make inferences about what researchers are looking for. The content of a questionnaire is typically provided in a questionnaire taxonomy which indicates a set of observable behaviors to be measured. This taxonomy is an essential part of a questionnaire blueprint (analogous to the so-called language test specifications). Table 74.1 provides an example of a taxonomy and behaviors to measure (see Phakiti, 2007, appendix D).

At this stage, researchers also need to consider the types of measurement to be used (see “Concepts of Measurement” below), formats or layout of questionnaires (see “Questionnaire Sections” below), items and types of questions (see “Types of Questions or Items” below) and whether translation is essential. When translating

Table 74.1 Example of a taxonomy of self-monitoring strategies in reading and observable processes

<i>Construct</i>	<i>Reading behaviors</i>
<i>Monitoring</i> is part of conscious processes that regulate reading processes. Monitoring is activated for checking ongoing comprehension.	I check if I understand what a text says. I double-check my comprehension when I come across new information in text. I tell myself to pay attention to my reading. I notice when I am confused in my reading.

a questionnaire from English to the language of the respondents, researchers need to check whether the translation is accurate. Another technique to double-check this is known as *back translation* (see Dörnyei, 2007). This method allows researchers to see whether the original meanings have changed (even though a translated sentence is rarely identical to the original sentence). A questionnaire must look professional and free of language errors, so professional typesetting, editing, and proofreading are essential.

In the piloting stage, researchers should aim to validate a questionnaire's quality and evaluate whether it is practical for actual use. The first thing they should do with the first draft questionnaire is to ask their colleagues to give some feedback on it. Researchers need to insure the instructions are comprehensible and it can be completed within the targeted time. They may ask their colleagues to check whether or not the questionnaire items are related to what they are intended for or whether adequate items are produced. Following this trial, researchers can revise their questionnaire, and they should then ask a group of people similar to the target respondents to answer it and, if possible, to provide some verbal feedback. This should allow researchers to understand whether the target respondents may have any particular difficulty completing the questionnaire or correctly understand the meaning of a particular item.

The implementing stage is often called the main study in research. There are several practical considerations at this stage. They are often related to issues considered during the planning stage. In paper-based questionnaire administration, researchers need to advertise their questionnaire and relevant details including its aim and when and where it is scheduled to be administered. In an online questionnaire, this can be done via e-mails, bulletin boards, listservs or other online forums. Researchers should attach a participant information statement which outlines the purpose and instructions, including information regarding privacy and confidentiality protection, and contact details if participants have any questions. Paper-based questionnaires can be collected in a classroom, a lecture theatre or hall, or other venues, but advance notices are important for success in the return rate. In some cases, where researchers have obtained permission to administer classroom questionnaires, they can ask teachers, lecturers, or professors to spare classroom time (especially at the beginning) to let their students complete the questionnaire. Ideally the researchers (or research assistants) should be there in person to explain the questionnaire and its procedures verbally and answer queries clearly and patiently. They should not expect other people who

are not involved in the questionnaire project to take responsibility for collecting the data. Being there at a questionnaire site is important, because researchers can check whether respondents complete the questionnaire, and, if not, they may ask respondents to complete it properly.

The analyzing stage involves activities ranging from sorting the questionnaires collected from participants and assigning data identity numbers (IDs) to coding, entering, and analyzing the data (see Dörnyei, 2007; Phakiti, 2010, for an overview of typical stages in preparing data for analysis; further discussed in “Statistical Analysis for Questionnaire Data” below). For qualitative data analysis, Holliday (2007) and Brown (2001) present a summary of accessible methods (see also Chapter 78, Content Analysis). At the data analysis stage, it is crucial to maintain a focus on the purpose of the questionnaire, the study, and the specific research questions.

At the reporting stage, researchers should consider the length of the report. The way it is presented or written depends on the target audience. For example, an executive company board may not need a detailed report: A one- or two-page executive summary containing key findings and conclusions in plain English, as well as any major recommendations they should consider, may be sufficient. Nonetheless, in a substantive research project, researchers are likely to write a dissertation or thesis (see Paltridge & Starfield, 2007) or research article (see Chapelle & Duff, 2003).

Questionnaire Analysis

The stages discussed above provide a model of what is involved in developing a questionnaire. This section will discuss particular issues related to questionnaire analysis.

Population, Sample, and Sampling

In the identifying and planning stages, it is important to understand the differences between the *population* and *sample* and issues involved in *sampling* (see Johnson & Christensen, 2008, for a comprehensive discussion). In brief, the population is the target respondents. If researchers can have the entirety of the target population answering their questionnaire, the data are likely to be generalizable to the population. There are several situations where a target population is large and impossible to collect from; for example, all undergraduate students at a particular university and TOEFL test takers between 2000 and 2011. In this sort of situations, a sample is used instead of the population. If questionnaires are collected from 300 people out of the 10,000 target population, how do researchers know that data from this sample are representative of the 10,000 people? This is a key *external validity* issue of research, that is, the extent to which findings can be generalized to the rest of the population. Researchers thus need to understand various probability sampling strategies, such as *systematic sampling*, *stratified sampling*, and *cluster sampling* (see Johnson & Christensen, 2008). Such sampling strategies when executed properly will allow us to claim that the findings represent the target population. Clearly,

sampling alone is not sufficient for generalization. Types of statistical inferences (discussed below) are needed to generalize research findings.

Concepts of Measurement

Measurement is an integral part of a questionnaire. Hence, there is a need to understand several concepts related to measurement, because researchers need to design a questionnaire so that it captures what they aim to measure and they can code the data appropriately for analysis. There are four measurement scales related to questionnaires (see Stone, 2003; Dörnyei, 2007; Phakiti, 2010): nominal, ordinal, interval, and ratio. First, a *nominal scale* involves assigning numbers to names, gender, nationality, native language, and so forth. This scale is often *categorical* in nature and is useful for reporting frequency counts or items treated as independent variables for comparative analysis. Coding such data is important for statistical analysis (e.g., coding 1 for male and 2 for female). Second, an *ordinal scale* is known as a rank-order scale, with uses such as ranking responses from the highest score to the lowest score. This type of scale does not indicate how much one point on the scale is greater than another (i.e., distances between ranks may not be equal). These scales can be *continuous* in nature. Third, an *interval scale* is somewhat similar to ordinal scales, but it has equal intervals between the numbers on the same scale (e.g., a temperature scale or a language test score). These scales do not have a true zero (i.e., the absence of something): 0 °C does not mean that there is no temperature, and a zero score on an English proficiency test does not imply a test taker has zero English competence. Fourth, a *ratio scale* is basically a scale that has all the properties of the above three scales plus a *true zero point* (e.g., weight, height, time, age, and income).

Statistical Analysis for Questionnaire Data

There is no single way to statistically analyze questionnaire data because this depends on research purposes and types of research questions. For example, if researchers aim to find out whether or not, and if so to what extent, two things are related (e.g., the amount of time devoted to study and test performance), they will need to perform a statistical test for correlation and regression. If researchers aim to examine whether particular groups of students differ in some aspects (e.g., strategy use, anxiety, motivation), they will need to consider a statistical test such as a *t* test or analysis of variance (ANOVA). In order to make use of the statistics for questionnaire data appropriately, one needs to have both conceptual and analytical understandings of statistical principles such as hypothesis testing, probability, and parametric versus nonparametric tests. It is, however, not the purpose of this chapter to cover this ground. For a comprehensive treatment of statistical analysis, see Bachman (2004), Brown (2001) and Larson-Hall (2010). This section only provides some basic information of statistics and statistical tests typically used for questionnaire analysis.

- *Descriptive statistics* are used for describing, summarizing and explaining the distribution of questionnaire data. Descriptive statistics include frequency

counts, percentages, and average scores. Four descriptive statistics that are usually considered before conducting statistical tests such as correlations, t tests, and ANOVAs are the mean (average score across participants), median (middle score from the lowest to the highest score), mode (the most frequent score), and standard deviation (the average point from the mean, which indicates on average how much the individual scores spread around the mean). These statistics are useful for checking whether the data meet a normal distribution assumption (bell-curve shaped) for some statistical tests.

- *Correlations* are used to examine systematic relationships between two variables. There are various correlational tests for use depending on the nature of the data (e.g., continuous or categorical data). Examples of correlational tests include Pearson product moment correlations, Spearman rho correlation, phi correlations, and point-biserial correlations. A correlation (r) is typically expressed on a scale from 0 (no relationship) to 1 (strongest relationship). A positive (+) correlation indicates that the two variables are associated and move in the same direction in a systematic way. A negative (–) correlation suggests that the two variables are associated but move systematically in opposite directions.
- *Reliability analysis* is usually performed for Likert scale items. This analysis makes use of correlations among questionnaire items. Hence, a reliability estimate of a questionnaire reflects on its consistency as a measure. Reliability estimates should be performed for the overall questionnaire as well as its subsections. Cronbach's alpha (α) is often used to analyze questionnaire data, particularly on Likert scale items. Generally speaking, a reliability estimate ranges from 0 (0% reliable) to 1 (100% reliable). A reliability coefficient of 0.70 onwards (70% or above of the items consistently collects information about the target construct) is acceptable for research (Dörnyei, 2007).
- *Factor analysis* helps researchers determine how the observed variables from questionnaires (answers to questions) are linked to underlying factors. In psychological research, an underlying factor, such as motivation or anxiety, may influence how individuals answer questionnaire items (namely observed variables). *Exploratory factor analysis* (EFA) is used to identify the clusterings of questionnaire items (i.e., groups of variables that are relatively homogeneous or highly correlated). A series of EFAs can result in clear factor structures underlying questionnaire items. Values of factor loadings (or correlation coefficients) range from 0 to 1. In an EFA, researchers need to decide the number of factors to be extracted and give names to the extracted factors. As this method is exploratory in nature, a number of questionnaire items can be lost during the analysis (see Phakiti, 2003). Another type of factor analysis is *confirmatory factor analysis* (CFA). CFA takes a theory-driven, hypothesis-testing approach to confirm that the observed variables in the questionnaire have a relationship with a particular latent (unobservable) variable. This can be achieved via examining the adequacy of goodness of fit (e.g., statistical fit indices) to the sample data. Interpretations of factor loadings are similar to EFAs. In a structural equation modeling approach, CFAs represent measurement models (see Phakiti, 2007).
- *Regression analysis*, an extension of a bivariate correlation, is used to examine a prediction of one dependent, continuous-scale variable (e.g., reading com-

prehension scores) based on values of another one or more independent variables (either categorical or continuous in nature; e.g., genders, age groups, motivation). *Simple regression* uses only one independent variable, whereas *multiple regression* uses two or more independent variables (which are correlated with each other) to predict a dependent variable. In a multiple regression, researchers can assess which independent variable is the best predictor of a dependent variable. A regression coefficient (ranging from 0 to 1) indicates a predicted change in a dependent variable given a one-unit change in an independent variable.

- A *chi-square test* can indicate whether a relationship between two categorical variables exists statistically. For example, males and females may differ in their choices of elective English subjects (e.g., conversation versus composition). A contingency table or a *cross-tabulation* (e.g., a row represents categories of the gender variable and a column represents categories of the subject variable) can be constructed by using frequency counts. A chi-square test will tell researchers whether male students are more likely than their female counterparts to choose a particular English subject.
- There are two types of *t tests* for questionnaire analysis: a repeated measures *t test* and an independent groups *t test*. A *repeated measures t test* is used to examine whether two mean scores from the same group of participants differ significantly. For example, researchers may want to see whether their participants' attitudes about peer assessment have changed after a one-month instruction period. Here researchers will have pre- and post-instruction questionnaires investigating their attitudes. An *independent groups t test* is used to determine whether the mean scores between two groups of participants are significantly different.
- ANOVA has a similar logic to the *t tests* above. A *within-group ANOVA* is similar to a repeated measures *t test*, and a *between-groups ANOVA* is similar to an independent groups *t test*. A difference is that ANOVAs can be used to compare two or more group mean scores, groups, or levels of an independent variable. A repeated measures ANOVA can be used to compare the mean scores among pre-, post-, and delay-post questionnaires. A between-groups ANOVA can be used to compare three or more groups of participants (e.g., high ability, intermediate ability, and low ability) in terms of their test anxiety. Typically when more than two means are used for ANOVAs, a post hoc test is used to determine exactly which groups significantly differ from each other. That is, there may be a statistically significant difference in an ANOVA, but the mean difference may be significant between the high ability and low ability groups only (but not between the high ability and intermediate ability groups, or the intermediate ability and the low ability groups).

There are other statistical analyses (e.g., nonparametric tests, Rasch item response theory, structural equation modeling) that are not discussed in this chapter. It should be noted that quantitative researchers do not have to calculate all the statistics above by hand. There are various reliable commercial statistical programs available for use, such as Microsoft Excel, Statistical Package for Social Sciences (SPSS), and Statistical Analysis System (SAS), which provide a

spreadsheet for data entry for statistical analysis. Despite the availability of such programs, it is important to stress that researchers need to know and understand the logic behind and standards for any statistical test adopted, so that inferences made beyond the raw questionnaire data are appropriate and well supported.

Skills and Strategies for Constructing a Questionnaire

Questionnaire Sections

There is no universal format for a questionnaire. Researchers tend to have their own preferred questionnaire structure (see, e.g., Brown, 2001; Dörnyei, 2010). Generally, a questionnaire should consist of a specific title; clear general instructions, including contact information; clear instructions for each section, with illustrated samples of responses; the questions or items; and a thank-you statement.

- A *title* should be related to a research topic (e.g., “Self-Regulated Learning Questionnaire”). It should not be too general or too long. A title “Questionnaire” does not tell the respondents what the questionnaire is about.
- A *general instruction* section informs respondents about the purpose of the questionnaire and what they are expected to do. Statements about confidentiality and anonymity should be noted here. Researchers should inform the respondents what will happen to the data or how the data will be used so that they are able to make an informed decision whether to participate or not.
- *Demographic questions* ask the respondents to provide some personal background information (e.g., age, gender, nationality, language, length of residence or study, test scores, grade point average).
- A *specific* section instruction should tell respondents what they need to do (e.g., rating items on a scale, ranking items in order of importance, checking a list). Examples of responses may be useful for respondents.
- Main *questions or items* (questions related to the questionnaire title) measure the target constructs of interest. Typically, this section begins with close-ended questions (checklists, ranking in order of importance, and rating items on scales) and ends with open-ended questions (specific opinions or other relevant comments). Alternatively some researchers may order questions from the least demanding to complete to the most demanding .
- Researchers should thank their respondents at the end of their questionnaire. Note that tick boxes allowing participants to agree to a follow-up and to see whether they will be interested in learning the results of the study can be included toward the end of the questionnaire.

Types of Questions or Items

Different types and forms of questionnaire items are used to collect information from respondents. Each of the question types below is adopted by researchers depending on the purpose of the study and the information sought.

- *Short answer* questions are used to capture factual information, such as demographic data. Where they can be specified ahead of time (e.g., male or female), it is practical to provide boxes for respondents to tick, rather than asking them to write down the answers themselves. This encourages respondents to complete the questionnaire. Most data from these types of items are from nominal or ratio scales. This type of information is useful to specify the characteristics of participants, and can be used to identify similarities or differences in a topic of inquiry (e.g., motivation, emotion, self-regulation).
- *Dichotomous items* include yes/no, true/false, aware/not aware, and agree/disagree items. They are specific types of short answer questions that involve choosing between two responses. Information from dichotomous items can be used to identify a tendency among a group of respondents or compare individual differences.
- *Checklist items* ask respondents to indicate whether they agree with a statement or a list of things to do: 1 (ticked) or 0 (not ticked) are used to code this sort of item. A high average of one item across all respondents suggests that most of the respondents agree with the statement or do this item.
- *Rank order* items ask respondents to rank items in order of importance, such as 1 to 5 (1 = least important; 5 = most important). The higher the average score is for an item the more important that item is across participants. Not only is rank ordering an easy way for participants to respond, but the data collected are also convenient for the researcher to analyze as the need for reverse coding is eliminated. If researchers ask respondents to identify the top five, they should not provide too many choices (e.g., fifteen options). It is difficult and time consuming for respondents to discriminate across so many items.
- *Substantive open-ended questions* are usually few and at the end of the questionnaire. These questions measure qualitative answers, such as opinions or reasons. Content analysis is usually adopted for the data from such questions (see Brown, 2001; Dörnyei, 2007).
- *Likert scales* ask respondents to place a level of agreement, trueness, or frequency on a continuum of points ranging from lowest to highest. Measurement issues related to Likert scale descriptions can be controversial, so it is wise to examine what other researchers have said about particular Likert scale expressions (see Dörnyei, 2010; Wagner, 2010). Usually four- to six-point Likert scales are suitable for a questionnaire. Some researchers try to increase the number of points on the scale by adding several unnecessary adverbs, such as 1 (very very sad), 2 (very sad) to 7 (very happy) and 8 (very very happy). Points 1 and 2 can actually represent the same degree of happiness, but the data we record indicate that the points are different. The words “partially agree” or “partially disagree” are problematic as well, because they share some value of agreement, yet receive a different rating value. They can be confusing for respondents. Table 74.2 provides examples of Likert scales.

There are four important issues to consider here. First, researchers should consider whether they need “reversed wordings” in their questionnaire items (see Dörnyei, 2010; Wagner, 2010). Some researchers prefer a mixture of reverse coding

Table 74.2 Examples of five-point Likert scales

1	2	3	4	5
Strongly disagree	Disagree	Neutral	Agree	Strongly agree
Very unsatisfactory	Unsatisfactory	Neutral	Satisfactory	Very satisfactory
Never	Rarely	Often	Usually	Always
Not at all true of me	Not true of me	Somewhat true of me	True of me	Very true of me
Not at all like me	Not like me	Somewhat like me	Like me	Totally like me
Very poor	Poor	Adequate	Good	Very good
Not at all important	Not important	Neither important nor unimportant	Important	Very important

items in their questionnaire as they enhance the validity of measures, but then researchers must remember to reverse the coding. For example, self-monitoring items (see Table 74.1) might ask respondents to rate 1 (strongly disagree) to 5 (strongly agree).

1. I check if I understand what a text says.
- *2. I forget to double-check my comprehension when I come across new information in text.
3. I notice when I am confused in my reading.
- *4. I do not pay attention to my reading.

Items 2 and 4, marked with an asterisk, need to be reversed (e.g., a response of 1 becomes 5, 2 becomes 4, and 5 becomes 1) before summing the responses for the four items.

Second, *numerical rating scales* such as

(very unhappy) 1 2 3 4 5 6 7 8 9 10 (very happy)

or *semantic differential scales* which ask respondents to place "X" in the spaces provided, such as

(successful) _ _ _ _ _ (unsuccessful)

should be avoided. This is because respondents are left to interpret what 2 to 9 or blank spaces could mean. It may well be that 1–3, 4–6, 7–8, and 9–10 belong to the same categories, respectively. In semantic differential scales, researchers are likely to have to assign numerical values to points on the scale for analysis. This is not practical when there is a large sample size and the same point on the scale may mean different things to different respondents. In reality, on a nine-point scale, respondents can hardly distinguish 1 from 2 or 8 from 9 and often assume 5 to be

the mid-point. A similar problem occurs when respondents are asked to indicate their confidence from 0% to 100%. To some degree, they can distinguish the extremes or mid-values; however, it is much more difficult for them to distinguish, for example, 11% from 13%, or 50% from 51%. Such answers can create problems in measurement precision and interpreting the findings.

Third, points on Likert scales that do not belong together in a scale continuum (e.g., 1 [never], 2 [not too much], 3 [often], 4 [quite a lot], 5 [every day]) should be avoided. In this example, some scales are frequencies, while others are quantities. Scores from such items do not have the interval-like consistency needed for Likert scales, as in Table 74.2.

Fourth, if the aim is to perform some inferential statistics (discussed above), researchers should avoid including “unsure” and “don’t know” in their Likert scale. These expressions do not have values in line with the rest of the scales. “Unsure” and “don’t know” are not the same as “neutral” or “neither agree nor disagree” in an agreement statement. Sometimes “N/A” (not applicable) can be used as a separate, last option (marked as 9) in Likert scales, because some questions may be applicable to some groups of respondents only. But “N/A” does not have an interval-like mathematic property and should not be included for inferential statistics.

Ten Golden Rules in Item Writing

1. *Do not waste respondents' time.* This includes avoiding asking questions (such as hypothetical questions) that will not be used for analyses.
2. *Do not ask embarrassing or confrontational questions,* especially personal or private ones, unless they are crucial for the study.
3. *Do not use jargon or complex academic terms.* Use natural and simple language if possible.
4. *Do not use compound, complex, or lengthy sentences, if possible.* These are double-barreled questions which make it difficult for respondents to know which part of an item they agree or disagree with. In a sentence with a reason such as “because,” respondents may agree with the main clause but not with the reason provided.
5. *Do not use double-negative items,* especially when using anchored Likert scales for agreement items (e.g., not, unlikely, never, no longer).
6. *Do not use leading questions or ones with loaded words.* Leading questions promptly suggest certain answers (see the discussion above of types of bias), while questions with loaded words cause positive or negative emotional reactions (e.g. communist, rapist, fat, loser).
7. *Do not use one item per construct.* This would be like asking test takers to answer one multiple choice question and using their answer to decide whether they had a high level of language proficiency. In some cases, five items per construct may be sufficient.
8. *Do not ask a lot of open-ended questions,* because this affects completion and return rates. If there are many open-ended questions for respondents to elaborate upon, it may be more rigorous to conduct individual interviews, unless anonymity is of concern.

9. Do not rely on one particular type of question or rating scale. Combine various types of questions (see “Types of Questions or Items” above).
10. Do not give a questionnaire in English if the respondents’ English proficiency is not high. Consider a translation so they can focus on the content rather than their English proficiency.

Online Questionnaires

Nowadays online questionnaires have become popular thanks to advances in technology, such as broadband Internet speed. With increased access to technology, more and more people are being asked to participate in an online questionnaire. Online questionnaires can generate automated output files that can be imported into Excel or SPSS. Hence, all responses are ready for analysis as soon as respondents submit their answers to the questionnaire. There are several online questionnaire services available that are worth considering, such as

- www.surveymonkey.com. For a free account, users are limited to use 10 questions with 100 responses.
- www.surveygizmo.com. For a free account, users can ask unlimited questions with 250 responses.
- www.questionpro.com. This service provider offers the same services as Surveymonkey.

A method for learning about online questionnaires is to create a free account and try out what a particular online survey company has to offer. Each online questionnaire service has its own interface for designing a questionnaire, as well as some technical terms used for types of questions (e.g., radio button [only one answer], check box [all that apply], Likert scale [rating], textbox, open-ended essay). Of course, there will be limited services for a free account, such as tools for analyzing and viewing results. It should be noted that an online questionnaire is just another medium of delivery, so the principles involved in online questionnaire development are the same as for other ways of delivering questionnaires and should be followed.

Sample Published Questionnaires

This section aims to provide examples of questionnaires published in the journal *Language Testing*. They are not exhaustive and there are several other academic journal articles related to language testing and assessment that provide questionnaires for readers.

- *Lewkowicz’s (2000) questionnaire* asks the participants to provide their opinions about the end-of-course English for academic purposes (EAP) test. The questionnaire does not have a specific title. There are six questions, of which four are predominantly open-ended; for example, on what each part of the test measures, the good and bad points about the test, and whether the test assesses what they have learned and why. There is one question using checklist

items and one using semantic differential scales. Perhaps interview methods were not adopted because of anonymity concerns and the number of respondents required for the survey.

- *Cumming, Grant, Mulcahy-Ernt, and Powers's (2004) profile questionnaire* collects participants' background information and their general impressions about the prototype task for the project under examination. Anonymity is stressed. The questionnaire utilizes various question formats including short answers, semantic differential scales, checklist items, and open-ended questions.
- *Cheng, Rogers, and Hu's (2004) questionnaire* asks the teacher participants to identify different purposes of student assessment and assessment methods employed. The questionnaire does not have a specific title. It has predominantly checklist items and short answer questions.
- *Brown and Bailey's (2008) language testing description course questionnaire* is an online questionnaire asking participants to report on the characteristics and description of language-testing courses they are involved in. It uses several types of questions, including dichotomous items, short answer questions, checklist items, Likert scales, and open-ended questions.
- *Phakiti's (2008) trait and state strategy use questionnaires* ask participants to indicate the degree to which they employ strategies when they read in English or take an English reading test (i.e., trait) as well as what they did in a specific reading test context (i.e., state). Six-point Likert scales are adopted (0 = never, 5 = always).
- *Sinharay et al.'s (2009) listening and reading comprehension can-do questionnaires* ask participants to rate perceived difficulty in listening and then reading comprehension, using can-do statements. The questionnaires do not provide a complete list of statements, perhaps due to the space limitation. A five-point Likert scale is utilized (1 = not at all to 5 = easily).
- *Lee-Ellis's (2009) self-assessment questionnaire* asks participants to indicate how well they can carry out the given tasks in Korean. Five-point Likert scale items are used (1 = cannot at all, 5 = no problem at all). However, this questionnaire appears to be somewhat confusing because semantic differential scales ("really easy" to "really difficult") are placed along the items asked.
- *Alderson's (2010) aviation English tests (AET) survey questionnaire* asks providers of AETs to report information about their test. The questionnaire uses numerous dichotomous yes/no items, along with *contingency questions* directing respondents to some follow-up questions (e.g., if YES, answer questions 2 to 9b; if NO, go to Section 2 on page 3). Other question formats include short answer questions, checklist items and some substantive open-ended questions.

Summary

The premise of this chapter is that if researchers are to use a questionnaire for a particular assessment or research purpose appropriately, they need to know what it can or cannot do. Using information from questionnaires for assessment is

usually appropriate for low stakes decision making, such as grouping learners in an appropriate class, informing classroom teaching, or informally evaluating the effectiveness of classroom instruction. To use questionnaires for high stakes decision making (e.g., for passing a course, giving an award) is not appropriate, because of several limitations including bias and complexity of language ability. It is appropriate for research purposes when researchers aim to measure a construct that can be quantified and when other methods (e.g., think-aloud protocols, observations, and interviews) are not feasible. As with language tests and assessments, there is a need to consider any unintended consequences of using a questionnaire. Finally, questionnaires should not be the only source of information to assist in making decisions in language teaching, assessment, and evaluation.

Item Response Theory in Language Testing

David P. Ellis

University of Maryland, USA

Steven J. Ross

University of Maryland, USA

Introduction

Modern norm-referenced language testing often involves assessments taken by examinees competing for access to jobs, training, or higher education. Because these assessments are high stakes, it is critical they are fair, reliable, and valid. In actual practice, the methods employed to demonstrate their fairness, reliability, and validity often vary according to the cultural framework in which test developers and score users operate. The criteria for ascertaining fairness in score computation have often been created out of convention and convenience. To address this inconsistency across testing contexts, the International Language Testing Association (ILTA) published the ILTA Guidelines for Practice in 2007. The present chapter is an examination of these guidelines with respect to the different scoring options language-testing specialists have at their disposal. These options range from an approach based on traditional assumptions about fairness, which remains the default method in many contexts (Davidson & Lynch, 2002), to empirically grounded methods ranging from the classical test model to modern psychometric models based on item response theory. As an example of how different item analysis methods can be applied to an authentic high stakes language test, the analysis described in this chapter illustrates how item response theory and alternatives can be applied to the same set of item responses yet yield very different orders when ranking candidates based on ability.

The focus of this comparative approach to item analysis is built around a set of possible interpretations of the published guidelines for language testers. The 2007 version of the International Language Testing Association Guidelines specifies in Part I Section B Article 4 that

The work of task and item writers needs to be edited before pretesting. If pretesting is not possible, the tasks and items should be analyzed after the test has been admin-

istered but before results are reported. Malfunctioning or misfitting tasks and items should not be included in the calculation of individual test takers' reported scores.

Because the Guidelines do not allude to the different, and possibly diverging, methods of defining "malfunctioning or misfitting tasks and items," the challenge presented to language assessment specialists is the selection of an item analysis model that is a justifiable instantiation of the guidelines. We apply in this chapter a number of competing models to an authentic high stakes English as a foreign language (EFL) admissions test with the goal of comparing the agreement between a baseline analysis and several different models derived from conventional test moderation and score interpretation practice.

Examination H

In many countries, universities or individual departments/programs devise their own admissions tests. Examination H, the exam of focus in this chapter, represents a typical high stakes EFL test used for selective university admission in Japan. It comprises four multiple choice sections—reading comprehension (15 items), rational deletion cloze (20 items), synonyms (15 items), and error correction (20 items)—and is the product of many hours of test construction and internal moderation by a team of sequestered foreign language specialists. No pretesting of items was performed and no post hoc item analysis was conducted. The justification for this *moderation model* of test development is based on the belief that expert opinion and careful editing of test content are sufficient to create items that can measure candidate abilities fairly. In this model, the observed raw score is interpreted as the true score, so no post hoc item analysis need be performed. The moderation model is what Spolsky (1978, 1981) described as the "pre-scientific" approach to language testing, which predates both modern psychometric methods and the formulation of the ILTA Guidelines for test analysis yet arguably remains the most commonly used model around the world.

No detailed test specifications exist for Examination H. Test designers merely refer to previous versions of the exam to extract general design specifications. Short of a major format change, which requires an announcement to high schools and cram schools at least three years in advance, each new form is created via many rounds of test drafting, moderation, and internal critique. The 2005 version of Examination H, examined in this chapter, was administered to 2,320 test candidates in a single administration. The candidates for examinations like H tend to be homogeneous in their academic aptitude and preparation. Most have reviewed published test prep handbooks containing previous years' versions of the exam and have taken simulations at test prep centers around the country.

Moderation Model of Scoring

Large-volume admissions examinations like H are typically multiple choice and machine scored, with a cursory check of the raw score histogram (see Figure 75.1) and scoring key to ensure there are no clerical errors in the scoring. Thereafter,

Figure 75.1 Distribution of raw scores on Examination H

the number of correct items is summed to produce the final score. The validity of this summation score is predicated on one very strong assumption: The moderation process identifies only one correct answer but preserves plausible options that can serve to discriminate among candidates with less overall knowledge.

Although the examination is norm-referenced, a cut score (λ) is derived to determine acceptance or rejection. Using the estimated retention rate (r') and admissions quota (Q) as its basis, the cut score is the raw score at which the quota will be reached:

$$\lambda = \frac{Q}{r'}$$

The quota is based on capacity limitations stipulated by a university accreditation board, and the projected retention is based primarily on historical retention patterns. For this university, the ideal quota of matriculates would be met at the 405th rank, as shown below:

$$\lambda = \frac{Q}{r'} = \frac{150}{.37} = 405$$

In reality, however, the raw score model yields a large number of candidates with the same raw score at the cut point. The immediate problem for the raw score approach then is that it would lead (in this case) to the admission of 462 candidates, which is likely to result in a freshman class well over the target. The admissions policy committee must therefore decide whether to move the cut score one raw

score category higher to avoid potential overflow or to set the cut score at the raw score attained by the smallest number of tied candidates. Previous cohort patterns of overflow influence the decision, as serial overflows are likely to invoke sanctions from the university accreditation board. As shown in Figure 75.1, the raw score distribution for Examination H is peaked, indicating considerable homogeneity among the candidates. The internal consistency (KR-20) for the raw score model is .78, suggesting there is a subset of the 70 items on Examination H that do not separate the candidates well, even after extensive moderation. Because pretesting of items is proscribed, examinations like H often do not reach thresholds of internal consistency considered sufficient for high stakes examinations. This fact highlights a major limitation of examinations that are constructed, administered, and interpreted under the moderation model; the design and administration of Examination H only partially fulfills the tenets of the ILTA Guidelines. Nevertheless, it is possible to determine whether the moderation process was successful by examining visual plots of keyed items and distracters in a post hoc manner.

A few items from Examination H exemplify the value of post hoc visual displays of item functioning. Item 51, shown in Figure 75.2, instantiates an ideal item. As candidate ability increases (horizontal axis), the probability of selecting the keyed option (B) increases while the probability of selecting one of the four distracters decreases. Under moderation model assumptions, all items are expected to function like Item 51.

In reality, even an extensively moderated test like Examination H typically contains some malfunctioning items, which is suggested by its mediocre internal consistency estimate of .78. Figure 75.3, for example, illustrates an item that did not discriminate between high and low proficiency candidates.

Figure 75.2 Optimally functioning item (51): The (a) *term* automobile is commonly (b) *applies* to a four-wheeled vehicle designed (c) *to carry* two to six passengers and a limited amount of cargo, as (d) *contrasted* with a truck. (e) *no error*; characteristic curve(s) by category

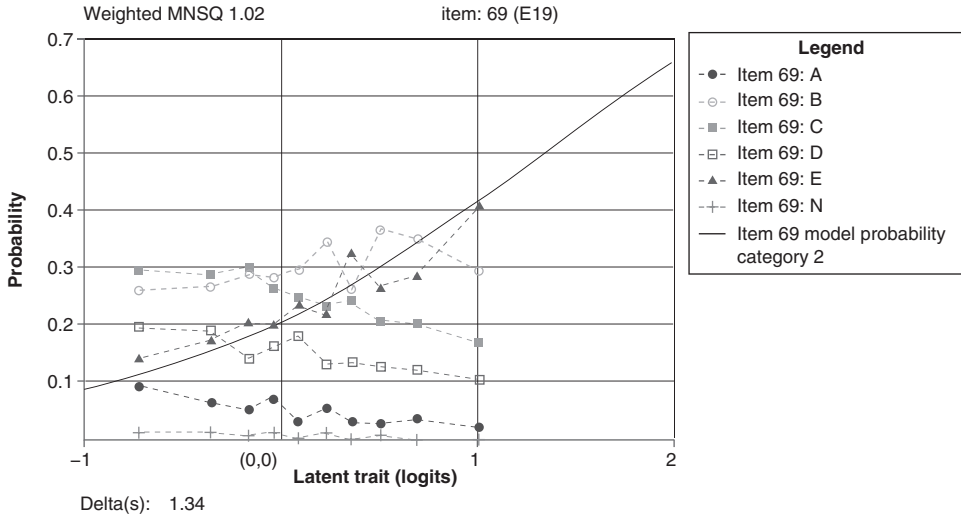

Figure 75.3 Malfunctioning item (69): The sun is the (a) *center* of the solar system (b) *with nine planets* (c) *revolving around* (d) *it*. (e) *no error*; characteristic curve(s) by category

For candidates of the lowest ability (bottom left portion of the figure) the probability of guessing the right answer ranges from .1 (Option A) to .3 (Option C). As overall ability increases, the endorsement of the keyed option (E) does not adequately differentiate ability levels.

Another reason for item malfunction is the possibility of a double key. In such cases, the test moderation panel might not detect ambiguity in the answer choices. Put another way, even expert moderation often does not consistently identify hair-splitting, ambiguous, or biased items (Ross & Okabe, 2006). Figure 75.4 illustrates one such item.

While three of the distracters function as designed, many test candidates experiencing overseas residence and naturalistic language acquisition may have noticed that native speakers permit *separate* as an adverb split from the verb. Candidates with more experience with pedagogical grammar and test prep training are likely to be coached about such items and are thus wary of hair-splitting usage items. As a result, one of the distracters (E) attracts a subset of candidates who are within the same ability range as candidates selecting the keyed (C) option, yet the former subset would get the item wrong.

Alternatives to the Moderation Model

Examples like the items described in Figures 75.3 and 75.4 offer some insight into the weakness of the moderation model of scoring high stakes exams. As a result, four scoring alternatives were investigated using the raw score summation method, the result of the moderation model, as the baseline. The objective is to determine the number of malfunctioning items identified by each of the item

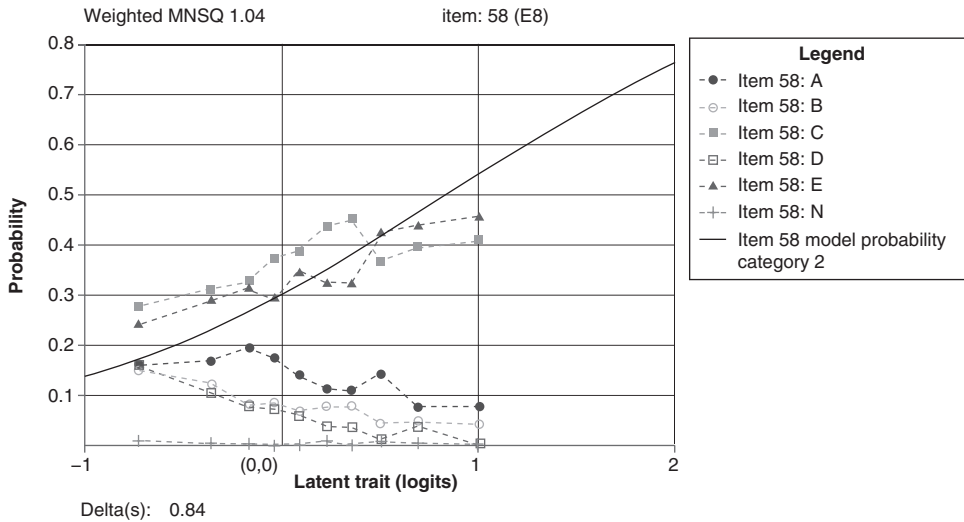

Figure 75.4 Double-keyed item (58): If you are (a) *doing* the laundry, you (b) *should* try to wash white things and bright colored things (c) *separate*, or the colors might (d) *ruin* the white clothes. (e) *no error*; characteristic curve(s) by category

analysis methods and the impact of omitting these items from scoring on the ordinal ranking of candidates. The goal is thus to compare different approaches to fulfilling the ILTA Guidelines as well as to identify the possible tradeoffs attendant with each approach.

Classical Test Theory (CTT)

The first alternative to be considered is based on classical test theory (CTT). With this approach, the purpose is to identify any items that do not contribute to the internal consistency of the test. Omission of such items yields greater score reliability and less measurement error. That is, items that correlate with the total score are considered to contribute to the true score and thus help define the score; items that do not discriminate between higher and lower ranges of candidates reduce reliability of the total score and increase the standard error of measurement.

Items may fail to discriminate for a number of reasons. Options on a multiple choice test for instance may distract higher ability and lower ability candidates at equal rates, as seen in Figure 75.3. Items that are too difficult for even the most able candidates often fail to discriminate among ability levels and can induce random guessing. Item analysis under CTT involves correlating dichotomous or polytomous item responses to the total score to yield a point biserial or polyserial correlation. With this method of item analysis, item responses are dichotomized into correct and incorrect responses on multiple choice tests. The mean of the subset of candidates getting the item correct is subtracted from the mean of the candidates getting the item incorrect. The product of the mean difference relative to the total score dispersion and the square root of the proportions of

Table 75.1 RawCut * PtBisCut crosstabulation

Count		PtBisCut		Total
		Fail	Pass	
RawCut	Fail	1,807	51	1,858
	Pass	71	391	462
Total		1,878	442	2,320

candidates with correct (n_c) and incorrect (n_w) responses define the point biserial correlation for each item:

$$r_{pb} = \frac{\bar{x}_c - \bar{x}_w}{s_{tot}} \sqrt{\frac{n_c}{n_t} * \frac{n_w}{n_t}}$$

While there is no firm basis for establishing an absolute standard for a point biserial correlation cutoff, widespread practice suggests an item with a point biserial correlation less than .20 does not adequately separate higher- and lower-scoring groups.

Using the $r_{pb} < .20$ criterion, 15 items on the 70-item Examination H were flagged as poorly functioning. Following the ILTA Guidelines, the total score would be recalculated without the 15 misfitting items to yield a truncated exam with 55 items. As described below, the omission of misfitting items does not appear to affect exam scoring adversely. For example, the internal consistency of the exam remains stable at .79 and the kappa coefficient of agreement, adjusting for chance agreement, is strong ($K = .832$).

A comparison of the two methods shows that 85% of the same candidates are identified as passing (Table 75.1, 391/462). Put another way, 15% of the candidates would be displaced from the passing categorization were the alternative scoring method used. Candidates benefiting from the recalculation are fewer; 11% of those failing via the raw score method would pass the truncated version of Exam H (51/462). This shorter exam would also reduce the number of candidates at the cut score from 462 to 442, a desirable result as it would reduce admissions overflow.

As illustrated, the classical test theory approach would provide an improvement over the moderation model of scoring. The removal of 15 items with low point biserial correlations would not diminish the internal consistency of the test and a closer approximation to the admissions quota would be reached. However, a considerable number of initially passed candidates would be displaced relative to the number of candidates changed from the fail to pass categorization, a potential concern.

Limitations of CTT

While the use of CTT is an improvement over the raw-scoring method, it is not without limitation. First, CTT item statistics are population dependent, meaning they are applicable only to the group of examinees who took the test at that

particular time. For Examination H, this limitation does not present a problem because it is a single-use examination. Another limitation is the assumption of item equivalence, meaning total scores are the sum of all individual item scores. That is, even though CTT analysis can help identify and eliminate non-discriminating items, it still assumes item equivalence in that all dichotomously scored items receive a value of 1 or 0.

A third limitation of CTT is its treatment of measurement error. In CTT, it is assumed the standard error of measurement (SEM) is constant across all ability levels. However, this assumption is often unreasonable. The ideal item difficulty value is $p = 0.50$. At this level of difficulty, item discrimination can be maximized, so the majority of test items on a well-designed test will have difficulty (p) values around 0.50. The consequence of this design is that there are relatively few items that are extremely difficult (e.g., $p = 0.10$) or extremely easy (e.g., $p = 0.90$), so examinees whose abilities are at the extremes confront very few items at their level of ability. This is problematic because reliability is positively correlated with the number of items, so fewer items generally equate to lower reliability, which in turn equates to greater measurement error in examinee scores for those in the tails of the distribution. In short, the standard error of measurement in most cases will not be constant across ability levels, so the assumption of a constant measurement error is problematic. Given the fact the cut score applied to Examination H is one standard deviation from the mean, the larger measurement error at the right of the score distribution presents a possible problem.

Item Response Theory (IRT)

While the CTT model is one strategy for better fulfilling the ILTA Guidelines than the moderation model, a more generalizable approach like item response theory (IRT) may be more appropriate. In development since the 1950s, with several seminal publications emerging in the 1960s (e.g., Rasch, 1960; Birnbaum, 1968; Lord & Novick, 1968), it was not until the 1980s that IRT realized its full potential, when computers became powerful enough to execute the complex calculations (e.g., BILOG: Mislevy & Bock, 1982). To this day, IRT models are the preferred choice for large-scale, high stakes test administrations because of their strong theoretical underpinnings and their practical benefits, including, for instance, sample-free item calibration, item-free person measurement, misfitting item and person identification, and test equating and linking (Henning, 1987).

The prominence of IRT is quite evident throughout psychometric research, including as the focus of book chapters (e.g., Yen & Fitzpatrick, 2006) and full monographs (e.g., Hambleton & Swaminathan, 1985; Embretson & Reise, 2000; Baker, 2001). It has been applied to numerous contexts as well, including subscale scores (e.g., Kolen, Zeng, & Hanson, 1996; Skorupski & Carvajal, 2010), differential item functioning (e.g., Zenisky, Hambleton, & Robin, 2004; Wyse & Mapuranga, 2009), and growth/change modeling (Reise & Haviland, 2005).

In contrast to CTT, which focuses primarily on test level concerns like reliability and conventional item analysis, IRT focuses primarily on the factors that influence the observed scores on each individual item. Common to IRT models is the

estimation of one, two, or three parameters, the possible influences on the functioning of each discrete test item. The models vary only in the assumptions they make about each of the parameters.

IRT Assumptions

There are two primary assumptions required for application of IRT to a data set—*unidimensionality* (a collection of items defines a single ability) and *local item independence* (item responses do not depend on each other). Because these assumptions are often difficult to satisfy on language tests, they have been the source of much debate in the second language-testing literature. Broadly speaking, three approaches have been advocated for dealing with assumption violations: *overcome them* (using more advanced measurement models like multidimensional IRT modeling and testlet response theory), *mitigate them* (through modification of existing IRT methods like Bejar's [1980]), or *disregard them* (by relaxing the requirements of assumption satisfaction through claims of "essential unidimensionality" or "psychometric unidimensionality").

Different approaches to dealing with the dimensionality issue have been developed over the years. Bejar (1980), for instance, created a method that tests unidimensionality via item parameter estimate comparison, where one set of estimates is obtained using all of the items on the test and another using only the items contained within a particular subsection. When violations of unidimensionality are apparent, a decision must be made whether to accept the subsection-based estimates or total-test-based estimates. If the total-test-based estimates are accepted, the implicit assumption is that the entire latent space is unidimensional and everything outside that space is "error" (i.e., sources of variation are of no concern). On the other hand, if the content-area-based estimates are accepted, then there is implicit acknowledgment of a multidimensional latent space. The question then is whether the multidimensionality found is important for practical purposes, and whether score users will be able to incorporate different dimensions in admissions decisions.

Zhang (2008) provides a recent summary of the issue of dimensionality, stating that, when a unidimensional model is applied to tests with two ability traits, the unidimensional ability estimate shows each examinee's original standing on two traits by one statistic and that this statistic will probably reflect the stronger trait more than the weaker one. The question is to decide whether the influence from the weaker trait can be ignored or, to the extent it cannot, whether items that measure multiple ability dimensions do so to the same degree, because, if this is the case, unidimensionality can be assumed to not be violated.

Two relevant applications of IRT support this argument for essential unidimensionality. In the first study, Childs and Oppler (1999) conducted an IRT analysis of the Medical College Admission Test (MCAT) based on the presumed multidimensionality of each of the three test sections—verbal reasoning, physical sciences, and biological sciences. Results showed that, while some items in each section were not completely homogeneous, violation of unidimensionality was not a particular concern; in other words, essential unidimensionality was achieved.

In the second, Schedl, Gordon, Carey, and Tang (1996) examined the dimensionality of the TOEFL reading subtest in an effort to determine whether reasoning skill—a construct putatively tested in four item types appearing in the ETS test specifications—was a separate dimension from general reading ability. Using Stout's (1987) procedure for assessing essential unidimensionality and McDonald's (1982) nonlinear factor analysis (NLFA) procedure, Schedl et al. found a two-factor solution but no evidence of a reasoning skill factor. Instead, it appeared the second factor was related to either passage content or passage position (the final two passages had the highest second-factor loadings). As a result, the authors claimed support for the finding of Lunzer, Waite, and Dolan (1979) that reading comprehension is a single construct (cf. Freedle & Kostin, 1993; Grabe & Stoller, 2002), or rather that the psychological construct is multidimensional but the psychometric construct is unidimensional (Reckase, Ackerman, & Carlson, 1988; Henning, 1992).

Despite considerable research on item-based methods of dealing with the dimensionality issue, factor analysis has persisted over the years as the preferred means of diagnosing violations of the unidimensionality assumption. A recent example of this is the use of confirmatory factor analysis to test the dimensionality of the TOEFL examination. Sawaki, Stricker, and Oranje (2009) compared competing unidimensional, higher order, and bidimensional factor models across four skill domains measured by TOEFL, finding the higher order factor with four first-order latent variables indicated by the skill subtests most compatible with the observed data.

With respect to local item independence, Yen (1993) provided a good summary of the causes of local item dependence (LID; i.e., a violation of LII), including test-external factors like assistance, interference, speededness, fatigue, practice, the explanation of a previous answer, scoring rubrics, and raters, as well as test-internal factors like item/response format, passage dependence, and item chaining. In her study, Yen described how performance assessments are susceptible to violations of LII because multiple items are often based on a single setting (e.g., on a test in language arts, a setting might be established with a short story and then the student is asked to contrast two characters in the story, provide and defend an alternative ending, and relate events in the story to a personal experience). Yen also stated that violations of LII typically lead to overestimates of test information and reliability while underestimating the standard error of measurement, suggesting the need to use *testlets* (Wainer & Kiely, 1986, 1987) to offset this effect. In her conclusion, Yen identified six procedures that can be employed to reduce LID or, when not feasible, to analyze the data in a way that ensures LID has a minimal impact on parameter estimation:

1. Create independent items.
2. Administer tests under favorable conditions (e.g., eliminate likelihood of fatigue).
3. Combine the grading of LID items.
4. Review tests to identify LID items a priori.
5. Create separate scales to grade items.
6. Use testlets.

Testing of IRT Assumptions

For Examination H, which was designed to assess candidates' developed proficiency in basic EFL literacy, test design specifications assume a unidimensional score is derivable from the four sections of the exam. However, two confirmatory factor models were tested using the subscores from each of the four parts of the test to test this assumption. A unitary factor model with one latent variable (reading proficiency) was initially tested for fit to the data. A second model hypothesized the existence of two latent factors, one indicating discourse-based reading as measured by sections I and II (reading and cloze), and the other indicating lexicogrammatical knowledge, as measured by sections III and IV (synonyms and error identification). Both models fit the data using conventional fit criteria—independence chi-square $>.05$, comparative fit indices $>.95$, and root mean squared errors of approximation $<.05$. No significant difference between the unidimensional and bidimensional models was detected, justifying the acceptance of the more parsimonious unidimensional interpretation. Given the fact that Exam H does not include speaking, listening comprehension, or productive writing, it is plausible that the four sections of the test measure a single dimension of language proficiency.

For examinations like H, which typically utilize many items per passage, a violation of the local item independence assumption is certainly a risk. For such test designs, test scoring may need to be preceded by a check of the inter-item independence assumption. This assumption is not explicit in the ILTA Guidelines.

IRT Models

One-Parameter (Rasch) IRT Model

The first of three IRT models, the one-parameter logistic (1PL) model, in practice is often applied from the perspective applied in Rasch (1960), which makes the key assumption that persons with more latent ability (θ) than the difficulty of any particular item (b) are expected more often than not to answer the item correctly (Bond & Fox, 2006). The larger the θ - b difference, the larger the probability of a correct answer. The only item parameter used is the difficulty of the item, which is compared to the person ability estimate derived from the sum of correct answers. All items are assumed to discriminate across ability levels, and random guessing is not assumed to influence the choice of the correct response in any systematic manner, resulting in the following formula:

$$p(y = 1 | \theta) = \frac{e^{(\theta-b)}}{1 + e^{(\theta-b)}}$$

Items that deviate from the Rasch model probabilistic expectations (i.e., involving a critical mass of unexpected right and wrong responses) are identified as misfitting items. Items might misfit the model for many reasons, including ambiguity in the item, extreme ranges of difficulty that provoke guessing, or systematic

Table 75.2 RawCut * RaschCut crosstabulation

Count		RaschCut		Total
		Fail	Pass	
RawCut	Fail	1,821	37	1,858
	Pass	82	380	462
Total		1,903	417	2,320

bias that leads subsets of test candidates with sufficient latent ability to select a distracter instead of the option deemed correct by the test designers.

Conventional guidelines for identifying misfitting items suggest a Rasch misfit statistic of 1.30 or larger be used (McNamara 1996; Bond & Fox, 2006). When *Winsteps* (Version 3.68.2) was applied to Examination H, however, this criterion would not identify *any* of the 70 items as malfunctioning. An alternative, which is used in the present analysis of Examination H, uses a statistical criterion based on the magnitude of the deviation from the Rasch model expectation of fit. Using this criterion, 20 of the 70 items show a standardized information-weighted misfit test statistic of $t > +2.0$. With a large sample size, a t-ratio statistic is likely to identify a large number of faulty items. The dilemma thus faced in using the Rasch model is the fact that the absolute misfit criterion does not identify any malfunctioning items while the relative fit criterion results in the deletion of 28% of the original items.

To carry out the score recalculation, the 20 misfitting items were removed and candidate ability estimates were recalculated. The resulting crosstabulation with the original raw score rank ordering of candidates indicates the Rasch approach would lead to 82% of the original candidates being passed with both methods (Table 75.2, 380/462). The kappa statistic of agreement is also slightly lower than that observed using the CTT approach ($K = .822$).

On the other hand, a closer approximation of the target quota is met (417 vs. 462) without much loss in internal consistency ($KR-20 = .77$). A possible ethical issue could arise, however, because 18% of the original passing candidates would be displaced from the roster of candidates admitted using the original raw scores. More problematic could be the use of the relative misfit criterion. Removal of the 20 faulty items under the statistical criterion yields a second estimate of person ability and item fit. Because standardized fit statistics are relative, more misfitting items would be found, thus leading to further rounds of item deletion. For Examination H, use of the Rasch model using absolute fit criteria would lead to a result perfectly consistent with the moderation model, while the relative fit criterion would result in a series of fit-based item deletions leading to large rank order discrepancies compared to the original rank orders.

The Two-Parameter IRT Model

While the Rasch model uses only item difficulty to estimate fit, the two-parameter logistic (2PL) model includes discrimination as well:

$$p(y = 1|\theta) = \frac{1}{1 + e^{-Da(\theta-b)}}$$

Discrimination is the capacity of the item to differentiate across levels of candidate ability. Item 51 in Figure 75.2 illustrates an item with consistent discrimination across ability groupings.

With the 2PL model, items are weighted by their difficulty and discriminating power such that correct responses on more difficult items optimally separating ability count more in defining candidates' relative ability than easier items with less discrimination power. That is, successes on strings of items with steep discrimination and greater relative difficulty will increase a candidate's estimate of ability relative to candidates with equal raw score counts derived from successes on easier items with flatter discrimination patterns.

As the discrimination parameter is readily deducible from item responses, the 2PL model is one of the more widely used IRT models for large-scale multiple choice tests—particularly those aiming to screen out faulty items *before* items become operational. In applying the 2PL model to Exam H (using the software Xcaliber 4.1), a decision is required as to the criteria for identifying faulty items. Items with a discrimination parameter (a) $<.30$, a residual larger than 2.0, or a difficulty (b) estimate larger than $+/- 2.95$ were flagged as malfunctioning items. Using these criteria, 20 items were deleted before candidate ability estimates were recalculated. It is noteworthy that the items flagged for omission using the two-parameter approach do not completely overlap with those identified using the Rasch approach. The estimate of latent candidate ability under the two-parameter model yields considerably more granularity of ability estimates (thetas). This is a clear advantage, as the target quota of candidates can be admitted with minimal risk of an over-the-quota enrollment.

Even with the omission of 20 items, the internal consistency of the test remains undiminished at .79, indicating the omitted items did little to reduce internal consistency. However, this removal of items led to considerable displacement of members on the initial roster of admitted candidates. About 80% of the candidates who passed based on their raw scores also passed after item deletion based on the 2PL analysis (Table 75.3, 371/462). The kappa coefficient for the agreement between the raw score method and shortened version of Exam H is $K = .823$. A total of 91 candidates who passed with the raw score criterion would be found to be below the cut point on the two-parameter model, while 34 candidates would be found to rank higher and thus be eligible for admission after the faulty items were omitted.

Table 75.3 Rawcut * 2PL short form crosstabulation

Count		2PLSHCUT		Total
		Fail	Pass	
RawCut	Fail	1,824	34	1,858
	Pass	91	371	462
Total		1,915	405	2,320

The Three-Parameter IRT Model

As item difficulty increases, the likelihood of guessing among the least able candidates often increases as well. The three-parameter logistic (3PL) model accounts for guessing by including a *pseudo-guessing* parameter (as distinguished from random guessing; see Yen & Fitzpatrick, 2006). The other two parameters, difficulty and discrimination, are the same as in the two-parameter model. More specifically, the 3PL estimates the probability (p) a person of a given ability (θ) will answer item i correctly, which is a (logistic) function of the item's discrimination power, a_i , with its scaling constant $-D$, its difficulty, b_i , and the likelihood the correct answer can be guessed by the lowest ability candidates, c_i :

$$p(y = 1|\theta) = c_i + \frac{1 - c_i}{1 + e^{-D a_i (\theta - b_i)}}$$

Applying this model to the 70 original items on Examination H and using the same misfit criteria as the 2PL ($a < .30$, residual larger than 2.0, $b > +/- 2.95$) with the added misfit criterion that the probability of guessing (c) surpasses .40, 14 items were flagged as malfunctioning. As shown, 81% of the original passing candidates would also pass under the 3PL model (Table 75.4, 375/462). The 3PL model also yields a strong agreement kappa with the original rank order ($K = .834$) and, like the two-parameter model, provides an exact match to the intended quota (405).

Accordingly, 87 candidates would be displaced from the original roster, slightly fewer than observed in the two-parameter model but nevertheless a significant number of candidates.

Summary of Findings

Table 75.5 illustrates the items identified for deletion across the four methods of analysis. Note that less than half were unanimously flagged as faulty by all of the methods.

Alternatives to Item Deletion

The ILTA Guidelines specify that malfunctioning items should be deleted before recalculation of scores used for rank ordering test candidates. However, the four

item analysis methods used to identify malfunctioning items on this administration of Examination H resulted in differing subsets of deleted items as well as differing admissions rosters. Because of this variance, one possibility is to select the IRT model that best fits the data without deletion, a possibility due to the fact that both methods weight individual items by their respective parameters. In other words, it is possible to construct the admission roster using the full version of Examination H due to the fact that the malfunctioning items will have less impact on the estimation of person abilities.

To test this alternative, person ability thetas based on the full 70-item examination were recalculated with the 2PL model. Table 75.6 shows the number of candidates displaced after the passing roster is ordered according to theta estimates derived from the two-parameter IRT model without deletion.

The corresponding kappa coefficient of agreement is .880, suggesting strong agreement with the original rank order. Still, 71 candidates would be displaced from the original pass roster even when all items are retained, a result important enough to call into question the validity of the moderation model of scoring.

A similar result is observed with the use of the 3PL IRT model. The addition of the guessing parameter apparently has little effect on the estimation of the person ability thetas for these data, including the reordering of the pass roster. Compared to the 2PL model, only two more test candidates would be displaced after the addition of the guessing parameter. Table 75.7 indicates that the results for the 3PL model are nearly identical to those of the 2PL model.

In sum, practitioners aiming to follow the ILTA Guidelines have a number of scoring options at their disposal. Alternatives to deletion, as summarized in the IRT approaches, can include confirmation of the accuracy of the scoring key and, in some cases, inclusion of keys permitting more than one correct answer. These strategies, in combination with 2PL and 3PL IRT approaches, afford testers with

Table 75.7 Rawcut * 3PL full form crosstabulation

Total		1,915	405	2,320

strategies that avoid outright item deletion yet still address the presence of malfunctioning items.

Practical Constraints and Ethical Issues

For this exam, it is clear the moderation model of test scoring is at least problematic in terms of admissions overflow. Accreditation criteria are in place to ensure admitted students do not encounter overcrowded classes and have adequate access to libraries, cafeterias, and on-campus facilities. Admissions overflow can also subtly reduce the quality of instruction, not just through larger classes, but through the possible need for instructors to accommodate less qualified undergraduates. In other words, the quality of instruction for the more qualified candidates seeking a challenging and stimulating higher educational experience could be compromised. Overflows also affect the relatively weaker students, who may face a larger probability of not graduating on time, demoralization, or possibly even dropping out due to admission to a university slightly beyond their academic grasp.

Nevertheless, the displacement that would occur if an alternative scoring model were employed is equally troubling for this context. Because the passages, questions, and correct answers for many high stakes admissions examinations are released to the media soon after the test, candidates often try to compare their responses to the key to calculate their total score. Depending on the method used for identifying malfunctioning items, implementation of the ILTA Guidelines would result in some candidates being moved off the admissions roster after the malfunctioning items were deleted from the test. Stakeholders, teachers, parents, and test candidates, if not informed well in advance of the start of such a policy, would be understandably incredulous and suspicious of the validity of such a policy.

In this case, while some candidates would benefit from a recalculation of scores, a larger proportion would be adversely affected. The beneficial fail-to-pass displacement percentage based on the $FP/(FP+PF)$ cases provides a metric by which an item analysis-driven rescoring policy, or the possible IRT alternatives, can be compared. Overflow percentage, the percentage of candidates moved from the fail to the pass category, and the total number of item deletions provide three criteria for evaluating the options available to language-testing specialists intending to fulfill the ILTA Guidelines.

Table 75.8 Relative item analysis utility

<i>Method</i>	<i>Overflow %</i>	<i>Fail to Pass %</i>	<i>Items</i>
Point biserial	9.1	41	55
Rasch short	2.9	32	50
IRT 2PL short	0	31	50
IRT 3PL short	0	29	56
IRT 2PL full	0	16	70
IRT 3PL full	0	17	70

As shown in Table 75.8, the various approaches examined here entail different strengths and weaknesses. The Rasch model applied to Examination H would be problematic in terms of fit criteria and overflow. The conventional fit criterion (infit mean square >1.3) would not have identified any malfunctioning items; the statistical criterion of misfit $t > 2.0$ potentially leads to relative criteria, which after omission of the offending 20 items would, after parameter re-estimation, identify another set of relatively malfunctioning items. This fact makes the use of any relative fit criterion alone problematic. Even though the Rasch approach would provide a logit estimate, since Examination H is a power test, skipped or non-reached items are scored as incorrect, making the ability logit correspond with the raw score correct.

The two IRT-based methods of identifying malfunctioning items produce very similar percentages of fail-to-pass reclassification and agreement and have the added advantage of generating no quota overflow. Should language-testing specialists strive to fulfill the ILTA Guidelines through item deletion, the three-parameter logistic model would most likely suit their aims. For Examination H, it leads to the deletion of the smallest number of items, gives a substantial fail-to-pass percentage, and produces no admissions overflow. The three-parameter IRT approach typically requires a large n -size, however, so, while it would be suitable for an examination like the one investigated here, it may not be suitable for all admissions testing situations.

It is likely that, in many testing contexts, test score user expectations will be in conflict with a policy allowing the omission of test items before score recalculation. In such circumstances, the two IRT methods applied to the full 70-item version of Examination H provide an intermediate strategy for fulfilling the ILTA Guidelines. While the IRT approaches do not omit faulty items, such items will be weighted less in the estimation of person ability, which in the end is the basis for rank ordering candidates. For either the two- or three-parameter model, there would be some movement from fail-to-pass categorization, and thus maybe a sufficiently fair instantiation of the ILTA Guidelines.

Conclusion

Language assessment specialists aiming to use a post hoc item analysis method to conform to ILTA Guidelines with respect to misfitting items may face a number

of practical challenges. One salient challenge involves the cultural context in which the testing takes place. Belief that the simple raw score count is a legitimate criterion for rank ordering even high stakes candidates may be entrenched over many generations of testing practice. The use of post hoc item analysis methods and item deletion may be viewed with suspicion among stakeholders, so careful introduction of the best practice rationale for using any of the methods described above would be a wise first step before effecting a policy change.

A second caution involves exploratory investigative analyses of existing data sets from authentic high stakes tests such as Examination H. As test designs and candidatures can be expected to differ, the unidimensionality assumption would have to be checked before any particular item analysis model could legitimately be deployed. Given differences in sample size and response format, the choice of a post hoc item analysis method to instantiate the ILTA Guidelines may well vary according to local conditions. Implementation of any of the approaches outlined above can be expected to yield benefits likely to outweigh the costs and are much more likely to be more viable than systems like the moderation model to provide an optimally trustworthy and fair language assessment system.

Test fairness (see Chapter 66, Fairness and Justice in Language Assessment) indicates that “examinees of equal standing with respect to the construct the test is intended to measure should on average earn the same test score, irrespective of group membership” (American Educational Research Association/American Psychological Association/National Council on Measurement in Education [AERA/APA/NCME], 1999, p. 74). Test fairness has been closely related to test validity and test validation in language testing (Kunnan, 2000, 2004; Xi, 2010). Multiple testing standards related to test development and test use stress the importance of test fairness. The Code of Fair Testing Practices in Education (Joint Committee on Testing Practices, 2005) states that tests should be fair to all test takers regardless of age, gender, disability, race, ethnicity, national origin, religion, sexual orientation, linguistic background, or other personal characteristics. The *International Guidelines for Test Use* developed by the International Test Commission (ITC) (2000) emphasize fair use of the test results for various demographic groups (e.g., gender, cultural background, or ethnicity groups), language groups within or across countries, and regular and disabled groups. According to the joint Standards (AERA/APA/NCME, 1999), any test should be without bias, provide a standardized testing process to assure equitable treatment of examinees, and have equality of testing outcomes for subgroups of examinees by race, gender, and disability.

Test fairness may be jeopardized by bias at the item, item group, or test level. Bias is a systematic inaccurate evaluation of a group’s ability. Two methods can be used to detect bias: qualitative and quantitative. The qualitative analysis of bias can be approached from different perspectives, related to gender, race, ethnicity, culture, economic and social class, and region, through a content review procedure adopted by major testing companies in the process of item development. Quantitative analysis for bias relies on the statistical methods developed for detecting

group differences given matched ability. These statistical methods include differential item functioning (DIF), differential testlet functioning (DTF), and differential test functioning analyses, which help to detect any potential statistical bias at item, item group, or test levels respectively.

For language assessments, differential functioning analysis at both item and item group levels will provide informative evidence for the investigation of potential bias. The main function of language is to facilitate communication among people; communication is often embedded in a situational context; thus an efficient and accurate assessment of language skills is often embedded in communication contexts. These contexts could be passages in reading comprehension tests, or a discourse in listening and speaking tests. These scenarios create dependence among items associated with a common stimulus—a testlet (Wainer & Kiely, 1987). DIF and DTF analyses are necessary in extracting more information related to the potential bias in items and testlets. Thus this chapter elaborates the methodologies for both DIF and DTF analyses.

Differential Item Functioning

DIF is broadly defined as a psychometric difference in how an item functions for two groups of test takers (Dorans & Holland, 1993). DIF exists if “two individuals with equal ability but from different groups do not have equal probability of success on the item” (Shepard, Camilli, & Averill, 1981, p. 319). The reason for this unequal probability of success can be explained by multidimensionality (Shealy & Stout, 1993a). A test is generally designed to measure one latent construct, its primary dimension. However, items flagged with DIF may measure at least one additional dimension. If one of the groups of interest has less ability on this additional dimension, the item may exhibit DIF against this group. DIF generally indicates conditional dependence between examinee group and item performance.

Differential functioning analysis involves two subgroups of the examinee population: focal and reference group. A focal group, a group of interest, is a subgroup that is suspected to be at risk of being disadvantaged by the test, while a reference group is a group that the test is expected to favor, and often serves as a basis for comparison. A focal group is usually female; or Black, Hispanic, Asian, and American Indian; or with limited English proficiency (LEP); while a reference group is usually male, or White, or non-LEP. The two groups are matched in terms of the variable that measures the intended construct, such as ability or language proficiency. The matching variable could be total raw scores or estimated latent ability based on a measurement model.

There are two types of DIF: uniform and nonuniform. Uniform DIF indicates that one group is consistently favored or disadvantaged relative to the other group, with a constant magnitude across all levels of the ability scale. Nonuniform DIF indicates that the conditional dependence differs in magnitude and in direction along the ability scale. When the difference is larger at some ability levels than others, this is noncrossing nonuniform DIF. When one group is favored at some ability levels but disadvantaged at others (Camilli & Shepard, 1994), this is

crossing nonuniform DIF. In general, nonuniform DIF indicates an interaction between group membership and the latent construct being measured (Narayanan & Swaminathan, 1994).

Various statistical methods have been developed for detecting DIF (Camilli, 2006; Penfield & Camilli, 2007). These include methods based on item response theory (IRT) (see Chapter 75, *Item Response Theory in Language Testing*), regression analysis, and nonparametric approaches based on observed item scores or the odds ratio.

IRT-Based DIF Detection Methods

IRT-based DIF detection methods compare either item parameter differences (Lord, 1980) or differences in item characteristic curves (ICC) between the reference and focal groups (e.g., Rudner, Getson, & Knight, 1980; Raju, 1988). A third approach (Thissen, Steinberg, & Gerrard, 1986; Thissen, Steinberg, & Wainer, 1988) is based on the likelihood ratio test. All the methods work for both dichotomous and polytomous items. However, multiple score categories in polytomous items complicate the conceptualization of DIF, and while multiple patterns of DIF in polytomous items can be evaluated (Zwick, Donoghue, & Grima, 1993), the existence of multiple polytomous IRT models adds to the complexity.

All IRT-based DIF detection methods require fitting an IRT model to the response data. The model–data fit should be checked in such applications. The estimation errors in model parameters affect the detection of DIF using these methods. Further, sample size is a factor worthy of attention.

Regression-Based DIF Detection Methods

Logistic regression-based DIF detection methods model the probability of a correct response in terms of observed test score, group membership, and the interaction of the two (Swaminathan & Rogers, 1990). The logistic regression model is expressed as follows:

$$P(Y = 1|X, G) = \frac{1}{1 + \exp(-(\beta_0 + \beta_1 X + \beta_2 G + \beta_3 (XG)))}$$

The coefficient β_2 indicates the group effect. The coefficient β_3 represents the interaction between group membership and ability. When there is no DIF, $\beta_2 = \beta_3 = 0$. When uniform DIF is present, $\beta_2 \neq 0$ but $\beta_3 = 0$. When DIF is nonuniform, $\beta_2 \neq 0$ and $\beta_3 \neq 0$. To test the null hypothesis of no DIF, three models with these constraints are compared using the likelihood ratio tests.

The logistic regression-based DIF detection method is widely applied in practice because of its flexibility in testing both uniform and nonuniform DIF. The use of the observed test score can tolerate smaller group size. However, the assumption for the valid application of this method is that the observed test score is an accurate representation of the latent ability, which typically only holds when the Rasch model (see Chapter 77, *Multifaceted Rasch Analysis for Test Evaluation*) is fitted to the data. The logistic regression DIF method can be extended to

polytomous item response data by recoding K response categories into $K - 1$ coded variables (French & Miller, 1996).

Nonparametric DIF Detection Methods

Nonparametric DIF procedures utilizing item score information include the standardized p -difference (SPD) index (Dorans & Kulick, 1986). The absolute value of SPD is often used as an effect size measure (Dorans & Holland, 1993). However, SPD may be misleading when DIF is nonuniform because the conditional proportion differences may cancel each other out when summed across all ability levels. An unsigned equivalent measure, the unsigned p -difference (UPD) index (Camilli & Shepard, 1994), was proposed to deal with this issue. One issue with SPD and UPD is that the observed total test score, which is used as the stratification variable, may not be a sufficient measure of latent ability when a non-Rasch model is fitted to the data. Also, the measurement error in the observed total test score may lead to a false rejection of the null hypothesis for no DIF. Possible solutions are using multivariate matching incorporating additional criteria; data reduction methods like factor analysis (see Chapter 73, Exploratory Factor Analysis and Structural Equation Modeling); and iterative removal of DIF items and recomputing of the matching variable. A nonparametric multidimensional DIF method employed in the simultaneous item bias test (SIBTEST) (Shealy & Stout, 1993a) also helps deal with these issues.

An equivalent of SPD for polytomous items is the standardized mean-difference (SMD) index (Dorans & Schmitt, 1991), which is also a signed index and only appropriate for uniform DIF. SMD may mis-flag an item as a DIF item because of a substantial mean difference between the two comparison groups. A procedure in the SIBTEST (Chang, Mazzeo, & Roussos, 1996) for polytomous items helps deal with this issue.

Another commonly used nonparametric approach is the Mantel–Haenszel (MH) common odds ratio ($\hat{\alpha}_{MH}$), expressed in terms of frequencies of correct and incorrect responses for the reference and focal groups and the sample size within each stratum (Penfield & Camilli, 2007). To get an effect size measure of $\hat{\alpha}_{MH}$, the natural logarithm is taken over $\hat{\alpha}_{MH}$ to get the estimate of the common log-odds ratio, $\hat{\lambda}_{MH} = \ln(\hat{\alpha}_{MH})$. However, $\hat{\lambda}_{MH}$ may not properly detect nonuniform DIF. Another index, the Mantel–Haenszel chi-square (χ^2) test (Mantel & Haenszel, 1959), provides the most powerful unbiased test for the null hypothesis of no DIF (Holland & Thayer, 1988). When sample size is large, all the above-mentioned nonparametric test statistics tend to reject the null hypothesis of no DIF. An effect size measure proposed by the Educational Testing Service (ETS) is often used as a measure of DIF effect size. The ETS effect size measure was proposed based on $D - DIF = -2.35\hat{\lambda}_{MH}$ (Zieky, 1993).

A cumulative common odds ratio (Liu & Agresti, 1996) can be computed to get a measure of DIF effect size for polytomous items. Another nonparametric DIF index for polytomous items is Mantel- χ^2 (Mantel, 1963). Mantel- χ^2 is reduced to the Mantel–Haenszel chi-square test when applied to dichotomous items.

Chen and Henning (1985) first studied DIF in language assessments. They compared two language groups on a placement test and concluded that the first

language led to DIF. Kunnan's (1990) analysis detected gender DIF and DIF related to the native language of the studied groups. Sasaki (1991) replicated Chen and Henning's (1985) analyses and came to different conclusions due to different methods and sample sizes. From 1990 to 2005, 27 papers did DIF analysis in language testing (Ferne & Rupp, 2007). Different DIF detection methods have been applied in evaluating item quality in language tests. Different DIF effects were reported, and the explanations for DIF results differed.

Differential Testlet Functioning

DIF detects the statistical bias at the item level. Statistical bias is also possible at the item group (subtest) level (Stout, 2002). Item groups or testlets (Wainer & Kiely, 1987) are frequently used in language assessment to measure comprehension skills in a communicative context. The testlet is a more informative unit on which to conduct differential functioning analysis. With its increased statistical power, this further enhances test fairness.

The necessity of DTF analysis was supported by the cancellation and amplification of DIF (Wainer, Sireci, & Thissen, 1991) in addition to the fact that testlets are often the building blocks for language tests such as passage-based reading comprehension tests. DIF amplification describes the scenario where differential functioning at the item level is not significant, but when accumulated to the item group (item bundle) level, the bundle/item group/testlet is functioning differentially. By contrast, DIF cancellation refers to the scenario where DIF is significant, but when aggregated to the item group level, the effects cancel each other out, which leads to nonsignificant differential functioning at the testlet level. Shealy and Stout (1993b) and Nandakumar (1993) conceptualized differential bundle functioning (DBF), which is essentially DTF, to address the issues of DIF amplification and cancellation (Drasgow, 1987; Roznowski, 1987).

Further, hypothesis testing for flagging item groups is often more powerful than testing for flagging individual items, because of the accumulative effects. Statistical tests for differential functioning at item group level are often preferred when small item performances are aggregated to a large performance difference (Nandakumar, 1993). Another important impetus for conducting differential functioning analysis at the item group level is to use the information at this level to explain the source of DIF (Gierl, Bisanz, Bisanz, Boughton, & Khaliq, 2001). It is believed that performance-characteristic patterns across multiple items in a group may be more informative than the information at the individual item level. Item groups are a better sample of substantive characteristics than an individual item. Some potentially important characteristics can be identified at the item group level and can help in the explanation of DIF (Douglas, Roussos, & Stout, 1996; Oshima, Raju, Flowers, & Slinde, 1998).

From the multidimensional DIF perspective (Douglas et al., 1996; Nandakumar, 1993), an individual item may not be able to provide an accurate measure of the second dimension causing DIF. Thus it is difficult to detect the secondary dimension in an individual item and to explain it. Bundling items assessing the same secondary dimension makes the detection of group differences more sensitive. As

item groups represent a broader sample of the secondary dimensions, it should be easier to interpret differential functioning substantively and get better explanations about its source.

The item group testlet used in Wainer et al.'s (1991) study matches the item bundle concepts in Shealy and Stout (1993b), with the following differences. The former refers to testlets as the explicit item clustering around a common stimulus, such as passages and discourses embedded in a situational context. The clustering of items is manifest and observed. On the other hand, the item bundle refers to the unobserved, latent clustering of items, often identified by substantive analysis, factor analysis, clustering analysis, and multidimensional scaling (Gierl et al., 2001). Despite these differences (Oshima et al., 1998), this chapter adopts a unified framework by treating item clusters, testlets, and item bundles as testlets.

DTF analysis can be done in either a confirmatory or an exploratory manner. It is recommended to use DTF as a confirmatory tool to explore the source for DIF. A hypothesis is put forward based on qualitative analysis of the items' content by content experts. This approach has considerable potential for integrating psychometric and psychological aspects to study differential group performances (Gierl et al., 2001).

IRT-Based DTF Detection Methods

Wainer et al. (1991) proposed the first DTF method by combining the items within one testlet into one polytomous item. A polytomous IRT model is fitted to the reconstructed polytomous items twice, once with the polytomous item parameter constrained to be the same across the reference and focal groups, the second time allowing the polytomous item parameters to be freely estimated for the studied testlet. Then the IRT-based likelihood ratio test described above can be used to test DTF. The advantage of this method is that it takes into account local item dependence, which may impact item parameter estimation accuracy in the IRT-based DIF detection method. The disadvantage is that the item-level information is lost when items associated with one testlet are combined into one super-item.

Another framework is the differential functioning of items and tests (DFIT) introduced by Raju, van der Linden, and Fler (1992). It is an IRT-based DIF and differential test functioning detection method. This framework can assess DIF and DTF for both dichotomous and polytomous items fitted to both unidimensional and multidimensional IRT models. Two indices are introduced in the DFIT framework: noncompensatory DIF (NCDIF) and compensatory DIF (CDIF). NCDIF can detect both uniform and nonuniform DIF, and assumes all items are DIF-free except the one studied. A further extension of NCDIF is differential test functioning. CDIF is additive in that its summation is equal to differential test functioning, defined above. DTF is defined as the sum of the CDIF (Oshima et al., 1998) for items in a testlet. Conceptually, DTF is the expected squared differences in the testlet score between two comparison groups over the ability distribution of the focal group.

The test statistics for the significance tests for NCDIF and differential test functioning are too sensitive to large sample size, and the cutoff value is impacted by

sample size and IRT models (e.g., Bolt, 2002). The item parameter replication (IPR) method (Oshima, Raju, & Nanda, 2006) provides an empirical method to get cutoff values for a particular data set. The significance of CDIF is not tested directly. Instead, items with large CDIF are removed one by one until DTF reaches non-significance. Those removed CDIF items are then considered significant.

Nonparametric DTF Detection Methods

Shealy and Stout (1993a) proposed the SIBTEST, a nonparametric multidimensional framework for DIF and DBF at the item and the testlet level. The multidimensional DIF framework hypothesizes that the presence of DIF is due to the presence of a second dimension of ability, with a substantive characteristic affecting item performance, in addition to the primary dimension that the test is constructed to measure (Shealy & Stout, 1993a; Roussos & Stout, 1996). If secondary dimensions are built in intentionally as part of the test construct, they are referred to as auxiliary. Otherwise, when secondary dimensions unintentionally become part of the test construct, they are nuisance dimensions. DIF related to auxiliary dimensions is benign, while DIF related to nuisance dimensions is adverse. Whether DIF is benign or adverse requires judgments built upon the purpose of the test, the nature of the secondary dimensions, and the groups compared.

Multidimensional DIF can be analyzed in the SIBTEST software (Shealy & Stout, 1993a). Differential functioning analysis using this multidimensional framework starts with a substantive analysis (Roussos & Stout, 1996) to generate DIF hypotheses. Items or bundles of items are assumed to measure a secondary dimension in addition to the primary dimension. Four methods can be used to group items into a set suspected of DIF and DTF and another set free of differential functioning, based on (1) previous DIF analyses, (2) analysis of substantive content by content experts, (3) analysis of archival test data to identify contexts which may lead to DIF, or (4) other organizing principles (Douglas, Roussos, & Stout, 1996; Roussos & Stout, 1996). Overall test statistics are output by the software indicating the amount of DIF for each item or item bundle. SIBTEST can be used to test the hypotheses of both uniform DIF and nonuniform DIF (Li & Stout, 1996), and the extended software Poly-SIBTEST to test polytomous items (Chang et al., 1996). The substantive analysis helps to bundle items to identify the source of DIF by testing the hypothesis developed. Statistical analysis helps to confirm or negate the DIF hypotheses. Confirmed DIF hypotheses can be utilized to guide test development and test practices.

Latent Differential Item and Testlet Functioning

All the methods reviewed above are based on manifest grouping variables such as gender, ethnicity, language, and culture. DIF and DTF results depend on the contrasting group (Oshima et al., 1998). Usually the types of groups compared in DIF and DTF analyses are not exhaustive of all possible groups. The current practice in DIF analysis is to run the analyses based on a grouping variable one at a time. For example, in K-12 large-scale statewide assessments, DIF analysis is done

most often for gender groups (male vs. female) and ethnicity groups (White vs. Black), and sometimes for language groups (LEP vs. non-LEP) or accommodated groups (regular vs. accommodation). In large-scale international assessment programs such as the Programme for International Student Assessment (PISA), DIF is run for gender and countries. Evidently, the current practice of DIF analysis is limited to several manifest grouping variables, which may overlook some potential DIF caused by other sociological, structural community, and contextual variables (Zumbo & Gelin, 2005).

Zumbo (2007) stated that DIF may also be caused by characteristics of items or testing situations not relevant to the underlying ability of interest, such as item format and item content, or by contextual variables such as class size, socioeconomic status, teaching practices, and parental styles. However, these factors are seldom used as grouping variables in DIF analyses in large-scale assessments. Furthermore, the current widely applied DIF detection methods may not be able to correctly identify either a potentially biased item caused by the interaction of more than one grouping variable, or DIF caused by some latent grouping of examinees that cannot be fully represented by any manifest grouping variables. For example, when students apply different problem-solving strategies (Mislevy & Verhelst, 1990), an item may function differentially. Thus, DIF and DTF methods based on one manifest grouping variable cannot deal with the challenges of DIF due to problem-solving strategies, test speededness, or the interaction among several manifest grouping variables like gender and ethnicity.

To solve the problems associated with current practice in DIF analyses, some researchers have explored a latent DIF detection approach (Kelderman & Macready, 1990; De Ayala, Kim, Stapleton, & Dayton, 2002). This approach relies on the use of mixture IRT models, that is, a combination of IRT and latent class models. The use of mixture IRT models to detect DIF is similar to DIF analyses based on a manifest grouping variable. However, the differences lie in the nature of the grouping variable. The former differentiates groups based on an unknown latent grouping variable while the latter uses a manifest grouping variable known as an a priori. The latent DIF analyses may flag possible DIF items that cannot be flagged based on the observed grouping variables. With extended mixture testlet models (Cohen, Cho, & Kim, 2007; Jiao & von Davier, 2010), latent DIF and DTF can be detected simultaneously.

An Empirical Example

To illustrate the methodology for DIF and DTF analyses based on both manifest and latent grouping variables, a data set from the standardized international large-scale PISA 2009 reading assessment was used (Organization for Economic Cooperation and Development [OECD], 2010). A sample of 5,919 examinees was selected, with 52% from the United States (USA) ($n = 3080$) and 48% from Hong Kong–China (HKG) ($n = 2839$). The extracted sample data set contains 2,861 females (48.3%) and 3,058 males (51.7%). The analyses included 33 reading items, with 29 dichotomous items (scored 0 or 1) and 4 polytomous items (scored 0, 1, 2). In total, there were eight testlets, each with several homogeneous items related

to a common passage. Missing responses were included for analyses, and valid cases per item were from around 2,100 examinees.

Methods

DIF analysis was conducted for two grouping variables: gender and country. Females served as the focal group with males as the reference group in the gender DIF analyses. In the country DIF assessment, the HKG examinee group served as the focal group with the USA as the reference group. Differential Item Functioning Analysis Software (DIFAS) (Penfield, 2005, 2007) was used for assessing differential functioning at item, testlet, and test levels. DIFAS was used because it provides multiple DIF indices and can deal with both dichotomous and polytomous items. In DIF analyses, dichotomous and polytomous items have to be analyzed separately, but in analyzing DTF, dichotomous and polytomous items are allowed to enter jointly in a mixed format (Penfield & Algina, 2006; Penfield, 2007). To conduct DIF and DTF for manifest groups, the stratification variable needs to be specified in advance. This study used *reading plausible value* as the matching variable because the data set contains missing responses and thus the summated total score is an invalid ability estimate. This study reported DIF results using the first *reading plausible value* as the matching variable for illustration.

For dichotomous items, this study reported Mantel–Haenszel χ^2 (Holland & Thayer, 1988) and ETS category (Zieky, 1993). For polytomous items, Mantel χ^2 (Mantel, 1963) and the standardized Liu–Agresti cumulative common log-odds ratio were reported. DTF is the aggregated effect of DIF across the items within a testlet (Penfield & Algina, 2006). DIFAS computes v^2 , which is the variance of DIF effect across a mixed format of dichotomous and polytomous items of a testlet (Penfield & Algina, 2006).

This study further conducted latent DIF analyses. Latent groups were identified using the software package mdlm (von Davier, 2005). The mixture Rasch model (Rost, 1990) and the mixture Rasch testlet model (Jiao & von Davier, 2010) were fitted to dichotomous items, while the mixture partial credit model (Rost, 1991) and the mixture partial credit testlet model (Jiao, von Davier, & Wang, 2010) were fitted to polytomous items. Ability within each latent class was constrained to be zero for model identification. The Akaike information criterion (AIC) (Akaike, 1974), Bayesian information criterion (BIC) (Schwarz, 1978), corrected AIC (AIC_c) (Burnham & Anderson, 2002), and consistent AIC (CAIC) (Bozdogan, 1987) were applied to check model–data fit among mixture and mixture testlet models with one to four latent-class solutions.

Results

DIF for Dichotomous Items DIF items related to two manifest grouping variables, gender and country, are summarized in Table 76.1. In terms of gender DIF, a total of 10 items showed significant Mantel–Haenszel χ^2 ($p < .05$), among which 3 were flagged with moderate DIF (i.e., R3, R7, R21) and 1 with large effect sizes (i.e., R20). These 4 flagged items all favored the male group. Regarding country DIF, 20 items showed significant Mantel–Haenszel χ^2 . Among them, 4s were flagged

Table 76.1 DIF results for dichotomous items

Notes. * $p < .05$; ** $p < .01$; F = Female; M = Male; A = negligible DIF; B = moderate DIF; C = large DIF.

with moderate effect size (i.e., R8, R13, R23, R29) and 9 with large effect size (i.e., R1, R2, R10, R12, R17, R22, R25, R27, R33). Among these 13 DIF items with at least moderate effect sizes, 7 favored the USA examinee group (i.e., R1, R2, R8, R10, R12, R13, R33) while the other 6 favored the HKG examinee group (i.e., R17, R22, R23, R25, R27, R29). No item concurrently displayed gender DIF and country DIF.

DIF for Polytomous Items Table 76.2 presents DIF results for polytomous items. Regarding gender DIF, two items (i.e., R16, R18) were flagged as DIF items based on significant Mantel χ^2 ($p > .05$) as well as standardized Liu–Agresti cumulative common log-odds ratio test. Item R16 favored the male examinee group (i.e., positive value) and R18 favored the female group (i.e., negative value). Regarding

Table 76.2 DIF results for polytomous items

Item	Gender DIF			Country DIF		
	Mantel χ^2	LOR Z	Favored	Mantel χ^2	LOR Z	Favored
R16	8.79**	3.05	M	108.32**	-9.92	HKG
R18	6.34*	-2.52	F	86.13**	9.20	USA
R19	3.33	-1.84	F	0.20	-0.46	HKG

Testlet 8 (29–33)	0.20	0.13	Large	0.13	0.09	Medium

Notes. ^P = testlet includes polytomous item(s). Item numbers associated with each testlet are in parentheses.

country DIF, three items were flagged (i.e., R16, R18, R26), among which R16 and R26 favored the HKG examinee group whereas R18 favored the USA examinee group. Items R16 and R18 simultaneously exhibited gender DIF and country DIF.

Differential Testlet Functioning This data set contained eight testlets, among which three include both dichotomous and polytomous items (i.e., Testlets 4, 5, and 7). Table 76.3 summarizes the DTF results based on unweighted v^2 and weighted v^2 , which are the variances of DIF effects across a mixed format of dichotomous and

polytomous items of a testlet (Penfield & Algina, 2006). The effect sizes of DTF based on the DIF effect variance for a mixed format testlet can be classified into three categories: small ($v^2 < .07$), medium ($.07 \leq v^2 \leq .14$), and large ($v^2 > .14$) (Penfield & Algina, 2006, p. 15). Only one testlet displayed gender DTF with medium effect size based on unweighted v^2 . All testlets showed country DTF with medium or large effect sizes based on either unweighted or weighted v^2 values. It is noted that weighted v^2 is a more accurate estimator and recommended in evaluating DTF (Penfield & Algina, 2006).

For gender DIF and DTF, items 20 and 21 displayed moderate DIF, the effects canceling out each other and leading to small DTF for Testlet 6 (items 20–4). For country DIF and DTF, small DIF in items in Testlet 2 accumulated to medium DTF. Testlet 3 contained items with small, medium, and large DIF, but displayed large DTF. The same was true for Testlet 6. Small DIF in items in Testlet 4 led to large DTF. Large DIF in Testlets 7 and 8 were averaged with small DIF and resulted in medium DTF.

Latent DIF As this is a mixed format test consisting of both dichotomous and polytomous items, two analyses were run with one to four latent-class solutions, one using the mixture Rasch model and the mixture partial credit model, and the other using the mixture Rasch testlet model and the mixture partial credit testlet model. The model with the smallest information criterion was selected as the best fitting. In this example, the mixture model with two latent classes was chosen as the best fitting model based on BIC and CAIC values (i.e., BIC=82757; CAIC=82836; see Table 76.4). AIC and AIC_c tended to select models with more parameters. The mixture Rasch model was selected as fitting better than the mixture testlet models, indicating that the item clustering effects were not significant for this data set. Therefore no further exploration was conducted for latent DTF.

Tables 76.5 and 76.6 summarize the differences of item difficulty and step parameter estimates between two latent classes, respectively. The results of hypothesis testing were also computed. Among dichotomous items, 25 items exhibited significant latent DIF ($p < .05$). In terms of polytomous items, both step 1 and step 2 parameters of R16, R18, and R19 showed significant latent DIF. The step 1 parameter for item R26 between classes was not significant but the difference of step 2 parameter between classes was significant. Overall more items were flagged with latent DIF. Items displaying manifest and latent DIF are subject to content reviews by content experts to better understand the presence of latent DIF.

Table 76.4 Model fit indices between two models with one to four latent classes

Information criterion	Mixture model				Mixture testlet model			
	1-class	2-class	3-class	4-class	1-class	2-class	3-class	4-class
AIC	83014	82229	81988	81753	82724	82437	82323	82366
AIC _c	83014	82231	81993	81762	82724	82440	82329	82378
BIC	83274	82757	82783	82816	83024	83045	83239	83590
CAIC	83313	82836	82902	82975	83069	83136	83376	83773

Note. Choice of best fitting model was based on values in **bold**.

Summary and Discussions

This chapter reviews and illustrates several major differential functioning analyses at the item and testlet levels based on manifest grouping variables, such as gender, ethnicity, race, language groups, and socioeconomic status, as well as on latent grouping variables, for instance the interaction effect of several observed grouping variables or unobserved latent grouping variables such as problem-solving strategies or test speededness. The chapter emphasizes multidimensionality as the source of differential functioning and advocates formulating substantive hypotheses before the statistical analyses relying on DIF and DTF technical procedures. An iterative process of substantive hypotheses and statistical hypotheses is recommended in differential functioning exploration. That is, start differential function-

ing exploration with some substantive hypotheses, and then use the statistical procedures to test the substantive hypotheses and form new substantive hypotheses if needed or possible.

In practice, item review and bias review are often conducted to screen items with potential bias against any examinee groups. Items with potential bias are revised or removed. The presence of DIF or DTF does not necessarily mean that the item or testlet is unfair, but it is a sign of potential statistical bias in an item or testlet. Statistical bias is affected by many factors such as detection method, sample size, and sample. The results of DIF and DTF analyses provide a convenient starting point for investigating item or testlet bias. The content of the item or testlet that exhibits statistical bias should be carefully examined for potential bias against particular examinee groups.

There are many different statistical procedures for DIF and DTF detection.

The differential functioning detection is method dependent. Cross-validation of the analysis results is highly recommended to check the stability of DIF and DTF (Oshima et al., 1998) detection employing more than one method (e.g., Camilli & Shepard, 1994).

Some factors need to be taken into consideration when choosing differential functioning analysis methods. The choice of procedures depends on the available sample size. An IRT model-based approach usually requires a larger sample size. In general, the more points at which the groups need to be compared, the larger the sample size required. Technical complexity is also a consideration. Nonparametric and regression-based methods might be easily understood by researchers who have received statistical training in regression. IRT-based procedures require knowledge of the IRT framework.

In DIF analyses, groups may differ in target ability. Thus, matching groups based on the total scores may introduce bias in differential functioning analyses, as group differences might be part of the difference observed between the matched groups. Not many procedures deal with this issue, but SIBTEST corrects this bias in matching ability. If it is suspected that two comparison groups are unequal in terms of the matching ability distribution, this method should be considered.

When items or testlets are flagged with differential functioning, the recommendation often made to practitioners is that if an item with a moderate or large effect size of significant DIF measures an adverse secondary dimension, the item may need revision or removal from the test. If the significant DIF effect size is small, content experts should study the secondary dimension and assess its adverse impact. If an item with a significant DIF measures a benign secondary dimension, the item writer could be alerted to the nature of the secondary dimension. Under any circumstances, close examination of the item content or testlet content is always necessary before a decision is made.

If differential functioning analyses are done after test administration, the solution is not simple. Some research suggests experimental deletion of these items (Elder, McNamara, & Congdon, 2003), but caution should be exercised. When there are not many contaminated items or testlets, a small-scale deletion may not significantly impact the test's reliability (see Chapter 70, Classical Theory Reliability). However, validity in terms of content representation and construct invariance

might be jeopardized to some degree, especially when differential functioning items or testlets are in content areas with an overall small proportion of representation in the content distribution. Construct under-representation should be examined. A large-scale deletion of contaminated items could be disastrous (e.g., Zhang, Matthews-Lopes, & Dorans, 2003; Abbott, 2004). Moreover, differential functioning analyses rely on the assumption that at least some items are not DIF items. If a large proportion of items display DIF, procedures for DIF detection may not be recommended.

When a testlet is identified as functioning differentially across subgroups, it is recommended not to remove the whole testlet, but rather to investigate item(s) in it with DIF and revise or remove the items to save the testlet, as the development of testlets is expensive and time-consuming. DTF helps in finding the source of DIF, which helps in making the decision.

The ultimate purpose of DIF and DTF is to enhance test equity and fairness. Statistical methods introduced in this chapter are convenient tools with which to identify potential sources of bias. Utilizing statistical methods to explain DIF and DTF should be an indispensable part of differential functioning investigation. Approaches to explaining DIF and DTF by including various test-taker background variables as covariates (Li & Kolen, 2005) should be further explored. Hierarchical logistic regression models incorporating covariates from items, testlets, examinees, and examinee groups can be a viable method of getting more comprehensive information on possible sources and their interactions in causing DIF and DTF.

Based on a review of studies attempting to find explanations in language assessments conducted by the authors, the sources for differential functioning can be summarized as follows:

1. cognitive classification (knowledge, skill, understanding);
2. content knowledge (passages related to specialist areas such as constitutional law or not, cultural familiarity, cultural background knowledge);
3. reading strategy (bottom-up vs. top-down);
4. item expression (cognate vocabulary items vs. items using idiomatic expressions, English vocabulary items with vs. without close cognate forms, problem-solving strategies required to process knowledge of a testlet such as cognate and syntactic clues);
5. item types (restatements, reading comprehension, sentence completions), linguistic elements, first language effect, cognitive demands, previous instruction experience with discrete-point grammar items, item expression, type of prompt (picture, paragraph, graphic response, written response, schedule, passage); and subskills (grammar, pronunciation, fluency, listening, reading, writing, vocabulary).

Multifaceted Rasch Analysis for Test Evaluation

Khaled Barkaoui

York University, Canada

Identifying and measuring the factors that contribute to variability in assessment results is central to evaluating language tests. This chapter focuses on the use of Rasch models, specifically the multifaceted Rasch model (MFRM), for evaluating language tests. (For discussion of how statistical analyses, classical test theory, item response theory [IRT] models, and generalizability theory [G-theory] can be used to examine test scores, see Chapter 56, Statistics and Software for Test Revisions; Chapter 69, Classical Test Theory; Chapter 72, The Use of Generalizability Theory in Language Assessment; and Chapter 75, Item Response Theory in Language Testing.)

Rasch models, sometimes described as one-parameter IRT models, are a family of probabilistic measurement models that use sophisticated mathematical procedures to calibrate parameters in the assessment setting (e.g., test-taker ability, item difficulty) independently of each other (McNamara, 1996; Bond & Fox, 2007). According to the basic Rasch model, as proposed by George Rasch (1960), the probability of a correct response to a dichotomously scored test item (e.g., true/false, multiple choice) is a function of the difference between test-taker ability and item difficulty. Estimates or measures of test-taker ability and item difficulty are calibrated independently of each other and expressed in units called *logits*, which are log-odd transformations of observed scores across all test takers and items. The estimates are then placed on a common frame of reference, called the logit scale. As McNamara (1996) explained, a logit scale is a true interval scale to express the relationship between item difficulty and test-taker ability. When the ability of a test taker matches exactly the difficulty of an item, the model predicts success for the test taker half of the time (50%). For test takers with ability higher than the difficulty of a given item, the model predicts that they will answer the item correctly more than 50% of the time.

Various models have been developed from the basic, dichotomous Rasch model, including the rating scale model (RSM) (Andrich, 1978), the partial credit model (PCM) (Masters, 1982), and the MFRM (Linacre, 1989). The RSM extends the dichotomous Rasch model to polytomously scored items (i.e., items scored on a rating scale). An item with k possible score categories needs $k - 1$ *step difficulty* parameters, or *thresholds*, to separate the score categories (Pollitt, 1997). For example, for a 3-point rating scale, the RSM model estimates two thresholds: one for attaining a score of 2 versus 1 and one for attaining a score of 3 versus 2. According to the RSM, the probability of achieving a score on a particular test item is a function of the test-taker ability, the item difficulty, and *step difficulty*, that is, the difficulty of achieving a score in each of the k scoring categories for any item (McNamara, 1996, p. 284). Because the RSM assumes that the step difficulty of all items is the same, it requires that all items in a test are scored using the same number of score categories (McNamara, 1996). The PCM can be seen as an extension of the RSM that addresses this issue by allowing the number of score categories and their threshold estimates to vary from item to item in the same test (Bond & Fox, 2007). The PCM also allows the examination of responses that could be given partial credit (e.g., incorrect, partially correct, almost correct, and correct).

The MFRM

The MFRM (e.g., Linacre, 1989, 2011) is an extension of the PCM to assessment settings in which factors, called *facets*, other than test-taker ability and item difficulty can systematically influence test scores and, thus, need to be identified and measured (Bond & Fox, 2007). Examples of facets that can influence test scores include task type, rater, rating criteria, and rating occasion. The MFRM allows test developers to estimate the impact of each facet on the measurement process by estimating its difficulty (e.g., severity of each rater) and then including that difficulty estimate in computing the probability of any test taker responding to any item for any score category threshold for any rater (Bond & Fox, 2007).

The MFRM thus enables researchers to model various facets in the assessment setting, estimate their effects on scores, and place them on the same logit scale for comparison. Each facet is calibrated from the raw, potentially ordinal, ratings, when a rating scale is used, and all facets (test taker, task, rater, etc.) are placed on a single common linear scale called a *variable* or *facets map*. For example, in a writing test that involves responding to multiple writing tasks and then rating test takers' essays in terms of multiple rating criteria by multiple raters, there are four facets: test taker, task, rater, and rating criterion. The MFRM sees each rating as a function of the interaction of test-taker ability, task difficulty, criterion difficulty, and rater severity (McNamara, 1996). The model estimates rater severity/leniency, test-taker ability, task difficulty, criterion difficulty, and scale step difficulty.

The computer program FACETS (Linacre, 2011) operationalizes the MFRM. FACETS uses the ratings that raters assign (observed scores) to provide parameter estimates for each facet (i.e., rater severity, task difficulty, test-taker ability, etc.) as well as information about the reliability of each of these estimates, in the form of standard error (SE), and the validity of the measure in the form of fit statistics for

each element in each modeled facet. Each facet is calibrated from the relevant observed ratings and, usually, all facets except the test-taker facet are set at zero (Lunz, Stahl, & Wright, 1996). When the rating scale includes several rating criteria (e.g., analytic scale), FACETS allows the estimation of rating criteria difficulty as well.

FACETS also permits rating scale diagnosis and bias analysis. Scale diagnosis aims to assess the quality of the rating scale by examining how *scale steps* (or score levels) are functioning to create an interpretable measure and whether *scale-step thresholds* indicate a hierarchical pattern to the rating scale (Davidson, 1991; North, 2000; Bond & Fox, 2007). Bias analysis is similar to *differential item functioning* (DIF) analysis in that it aims to identify any systematic subpatterns of behavior occurring from an interaction of a particular rater (or any other facet) with a particular aspect of the rating situation (e.g., rating criteria, task, test taker) and to estimate the effects of these interactions on test scores (Wigglesworth, 1993; Lumley & McNamara, 1995; Kondo-Brown, 2002). Bond and Fox (2007) refer to bias analysis as *differential facet functioning* (DFF). The different analyses of FACETS thus permit us to move beyond and beneath raw scores to understand the effects of the conditions of assessment on test scores (Davidson, 1991; McNamara, 1996; Pollitt, 1997; North, 2000; Bond & Fox, 2007).

The MFRM provides a powerful framework and tool for evaluating assessment tools and procedures. In particular, it can help test developers address several important questions concerning the assumptions underlying the interpretive argument of an assessment program, such as the following:

1. What are the effects of the assessment setting and conditions (e.g., rater, task, and rating occasion) on test scores? (e.g., Weigle, 1999; Eckes, 2005; Lumley & O'Sullivan, 2005; Kim, 2009; Barkaoui, 2011)
2. Are there any biased interactions between facets in the assessment setting? (e.g., Kondo-Brown, 2002; Schaefer, 2008)
3. How can the effects of facets in the assessment setting be taken into account and compensated for when interpreting and using assessment results? (e.g., Kozaki, 2004)

In the following section, the MFRM, as operationalized by FACETS, is applied to scores from a writing test to illustrate the kind of questions that the MFRM can address and the types of insights it can provide about the quality of language assessment systems. The main statistical indices provided by FACETS are also defined and discussed briefly. Readers who want to learn more about these indices and the technical aspects of the MFRM and how to implement it should consult the references listed at the end of the chapter.

MFRM Analysis: An Example

Data for this analysis consist of the scores of 161 test takers on the writing section of a second language (L2) test to place internationally trained pharmacists in courses to improve their English proficiency. The writing section includes

three writing tasks. Task 1 consists of reading a medical alert in English and then writing a message to a colleague that summarizes the key points of the alert (i.e., a reading-based task). Task 2 consists of listening to and summarizing a four-minute lecture on a pharmacy-related topic (i.e., a listening-based task). Tasks 1 and 2 are rated analytically in terms of content, vocabulary, grammar, appropriacy, and effectiveness. Task 3 consists of writing an essay on one of three independent topics (i.e., an independent task). For the purposes of this analysis these three topics are treated as three different tasks (Tasks 3, 4, and 5). Tasks 3–5 are rated analytically in terms of organization, coherence, vocabulary, grammar, and effectiveness. Each rating criterion is rated on a 5-point scale (0 to 4). One rater rated all the writing samples ($n = 470$ samples), while a second rater marked the writing samples ($n = 149$ samples) of a random sample of 50 test takers. The data set consisted of 3,094 scores.

The scores were analyzed using the RSM as operationalized by FACETS (Linacre, 2011) to estimate test-taker writing ability, task and criterion difficulty, rater severity and self-consistency, scale-step difficulty, and any biased interactions between facets. A four-facet Rasch model was employed for analyzing the scores: test taker ($n = 161$), task ($n = 5$), rater ($n = 2$), and rating criterion ($n = 7$). Formally, the Rasch model for score analysis is as follows (McNamara, 1996; Bond & Fox, 2007; Linacre, 2011):

$$\log(P_{nmijk}/P_{nmijk-1}) = B_n - D_m - E_i - C_j - F_k,$$

where

P_{nmijk} = Probability of test taker n achieving on task m , for criterion i , by rater j , a score k

$P_{nmijk-1}$ = Probability of test taker n achieving on task m , for criterion i , by rater j , a score immediately below k ($k - 1$)

$\log(P_{nmijk}/P_{nmijk-1})$ = Log odds of achieving a score k , given the task, criterion, and rater, versus the probability of being rated $k - 1$

B_n = Ability (B) of test taker n , the test-taker facet, $n = 1$ to 161

D_m = Difficulty (D) of task m , the task facet, $m = 1$ to 5

E_i = Difficulty (E) of criterion i , the criterion facet, $i = 1$ to 7

C_j = Severity (C) of rater j , the rater facet, $j = 1$ to 2

F_k = Score category threshold (F) defined as the point where the probability of achieving a score of k and $k - 1$ is equal.

FACETS provides various statistics for each facet, including parameter estimates and SE for each element of each facet, strata index, reliability of separation, fixed X^2 , various rater agreement statistics, and infit and outfit mean square (IMS and OMS) statistics¹ (see Engelhard, 1994; McNamara, 1996; Weigle, 1998, 1999; Bond & Fox, 2007; Linacre, 2011). For each element of each facet (e.g., test taker, rater, task), FACETS provides (1) a measure of that parameter on a logit scale (e.g., test-taker ability, task difficulty, rater severity) together with (2) an SE that indicates the uncertainty of (i.e., error associated with) the parameter estimate.

Strata indicates the number of levels within a given facet (e.g., number of levels of rater severity, number of levels of test-taker ability, number of levels of task difficulty), while the *reliability of separation* indicates the degree to which the analysis reliably distinguishes between different strata within a given facet (e.g., rater severity, test-taker ability, task difficulty). It also provides information concerning the replicability of the placement of elements within each facet relative to each other (see below). *Fixed (all same) X²* tests the null hypothesis that all the elements of the facet are equal. If fixed *X²* is significant at *p*, this indicates that the elements are not equal (e.g., raters are not equal in severity, tasks are not of equal difficulty). While FACETS provides strata and reliability indices and fixed *X²* for each facet, the interpretation of these indices differs depending on the facet under consideration, as will be discussed below. For rater agreement, FACETS reports the observed and expected percentages of exact rater agreement among other statistics.

FACETS reports *IMS* and *OMS* statistics for each element in each facet. *IMS* statistics show the degree of variability in individual elements of a facet (e.g., rater, task, test taker) relative to the amount of variability in the entire set (of raters, test takers, tasks, etc.). Ideally, if the observed data conform to the model, the infit statistic is expected to have a value of 1.0. The closer the fit statistics are to this ideal, the better the assessment. As will be discussed below, the setting of appropriate upper and lower control limits for *IMS* indices depends on a variety of factors (Bond & Fox, 2007). For illustrative purposes, the upper and lower control limits for *IMS* in this analysis are set at 0.5 and 1.5, respectively. Elements with $IMS \leq .5$ indicate overfit; elements with $IMS \geq 1.5$ indicate misfit; while elements with $.5 < IMS < 1.5$ indicate acceptable fit. *OMS* has the same form as *IMS*, but is more sensitive to outliers (Linacre, 2011). The acceptable range for identifying misfitting *OMS* is the same as for *IMS*. Elements (e.g., raters, tasks, test takers) with *IMS* and *OMS* statistics outside the acceptable range are reviewed for inconsistency (misfit) or overconsistency (overfit) in score patterns.²

Test-Taker Ability

The MFRM can help test developers address several questions about their tests in relation to the test-taker facet, such as whether the test discriminates among test takers in terms of the ability being measured, how replicable the placement of test takers relative to each other is across other tests that measure the same construct, and whether the abilities of test takers are measured “properly” by the test (as indicated by fit statistics).

A summary of FACETS results for the test-taker facet is reported in Table 77.1. It shows that test takers’ ability estimates ranged between -4.07 logit and 4.20 logits, with a mean of -0.15 (standard deviation [SD] = 1.64). The negative mean (*M*) suggests that the test was slightly difficult for this group of test takers. The mean SE is $.35$; SE indicates the uncertainty or precision of the estimates of test-taker ability and depends on the amount of information about the element in a facet (McNamara, 1996). The relatively low SE is due to the fact that the data set included more than one score for each test taker (3 tasks by 5 criteria). The *X²* test, which tests the hypothesis that all test takers are equal in terms of the ability being measured, is statistically significant at $p < .001$. The strata and reliability indices

Table 77.1 Summary of test-taker facet statistics

<i>Test-taker ability estimates (n = 161)</i>	
M (model SE)	-.15 (.35)
SD (model SE)*	1.64 (.08)
Min.	-4.07
Max.	4.20
Infit	
M	.98
SD	.66
Separation statistics	
Strata	6.23
Reliability of separation	.95
Fixed chi-square statistic (degrees of freedom [df])	2838.9 (160), $p < .001$

Notes. SD refers to spread of scores between test-takers. SE refers to spread of estimates for a test taker.

Table 77.2 Frequencies (%) of test-taker IMS statistics

<i>Range of IMS</i>	<i>Frequency (%)</i>
Overfit: fit < 0.50	28 (17%)
Acceptable: 0.50 < fit < 1.50	109 (68%)
Misfit: fit > 1.50	24 (15%)

for the difference in test-taker ability are high (6.23 and .95, respectively). This high strata index indicates that the variance among test takers is substantially larger than the error of estimates and that the test separates the 161 test takers into approximately six statistically distinct levels in terms of the ability being measured. The high reliability statistic indicates that the same ordering of test takers would be more likely to obtain if test takers were to take another test measuring the same ability. High test-taker strata and reliability indices mean that the assessment distinguishes between test takers in terms of the ability being measured and that one can place confidence in the replicability of test-taker placement across other tasks or tests that measure the same construct (Bond & Fox, 2007). This means greater confidence in the consistency of score-based inferences.

In addition to ability estimates, FACETS provides fit statistics for each test taker, providing useful information about the validity of the assessment (Bond & Fox, 2007). Table 77.1 shows that the mean fit (.98) is close to the expected value of 1.0. Table 77.2 classifies test takers according to the magnitude of their IMS statistics. Acceptable fit indicates a pattern of ratings that closely approximates the predicted Rasch-model rating pattern based on the test-taker ability estimate (McNamara, 1996). Overfit indicates that ratings for a test taker are closer to expected ratings than the model predicts they should be. Misfit indicates that the observed ratings are farther from what the model expects given the test-taker ability. This may be due to inter-rater disagreement on the quality of that test

taker's performance. Both misfit and overfit suggest that the test-taker ability is not being measured appropriately by the test, but misfit is usually considered to be a more serious problem than overfit (McNamara, 1996; Bond & Fox, 2007).

Table 77.2 shows that about two thirds of the test takers (68%) had fit statistics within the acceptable range. There is a larger proportion of test takers with overfit than with misfit. Overfit may occur if test takers are assigned the same scores regardless of differences in their proficiency levels (Bonk & Ockey, 2003). Overfit also indicates a halo effect; test takers were assigned similar scores on the different rating criteria. Misfit indicates noisiness or unusual rating patterns and can occur when the data set includes few observations per test taker (Bonk & Ockey, 2003). Concerning analytic scales, Bonk and Ockey (2003) noted that because Rasch models treat rating criteria as "items," these models tend to flag departures from expected patterns of behavior as misfitting, even when they are not. For example, if a test taker is assigned different scores on different rating criteria, as some test takers may perform differently on different aspects of writing, Rasch models may consider the pattern of ratings unexpected and flag the test taker as misfitting. For this reason, Bonk and Ockey noted that test-taker misfit may not be a major problem with rating data and does not disqualify such data from inclusion in Rasch models.

Rater Severity and Self-Consistency

A major contribution of the MFRM is that it allows test developers and users to detect and measure various types of rater effects, biases, and errors such as severity/leniency, halo, restriction of range, central tendency, and order effects (Myford & Wolfe, 2004a, 2004b). Detecting and measuring such effects and errors is an important step in evaluating and improving assessment systems. For example, if it is found that several raters exhibit a halo effect, whereby similar scores are assigned to the same student on different criteria regardless of actual differences in the student's mastery of the various criteria, test developers may choose to revise and clarify the rating criteria, provide raters with feedback and additional training, or both (Myford & Wolfe, 2004a, 2004b).

Some of the questions that the MFRM can help address in relation to the rater facet are whether raters differ in the severity/leniency with which they rate test takers' performances, whether raters can effectively distinguish among test takers in terms of their levels of performance, whether raters can effectively differentiate between rating criteria, how self-consistent raters are, and whether ratings show evidence of a restriction in range or halo effects (adapted from Myford & Wolfe, 2004a, 2004b).

Table 77.3 summarizes FACETS results for the rater facet. It shows that the difference in severity between the two raters is very small (.06 logits). The low reliability and strata indices and the nonsignificant X^2 statistic in Table 77.3 indicate that the raters were similar in severity. Note that reliability in this context refers not to the traditional index of inter-rater agreement, but to the ability of the analysis to reliably separate raters into different levels of severity. As a result, a reliability index of zero is desirable, as it indicates that raters are interchangeable (McNamara, 1996; Weigle, 1999). A low strata value and a nonsignificant fixed X^2

Table 77.3 Rater measurement report

	<i>Measure</i>	<i>Model SE</i>	<i>IMS</i>
Rater 1	-.03	.03	.95
Rater 2	.03	.05	1.15
M (<i>n</i> = 2)	.00	.04	1.05
SD	.04	.02	.15
Strata: .42 Reliability (not inter-rater): .00			
Fixed (all same) chi-square: 1.0 df: 1 Significance (probability): .32			
Inter-rater agreement opportunities: 745 Exact agreements: 438 = 58.8%			
Expected: 301.8 = 40.5%			

are desirable outcomes too as they indicate that the assumption of equivalence among raters is held (Lunz et al., 1996; Weigle, 1998).

Table 77.3 reports both the observed and expected percentages of exact rater agreement. If the observed agreement rate is too low in comparison with the expected agreement rate, a model for predicting agreement is problematic. By contrast, when the observed agreement rate is higher than the expected rate, there is a possibility that raters do not perform ratings independently (Linacre, 2011). Table 77.3 shows that the percentage of observed exact agreement between raters is 59% of the total possible opportunities for agreement ($n = 745$), which is higher than the expected level of agreement (41%).

Table 77.3 also reports rater fit statistics. Rater fit statistics indicate the degree to which a rater is internally self-consistent across test takers, criteria, and tasks and is able to implement the rating scale to make distinctions among test takers' performances (Weigle, 1998; Bond & Fox, 2007). Table 77.3 shows that both raters have fit statistics close to the expected value of 1.0. This suggests that both raters used the rating scale consistently and maintained their personal level of severity across test takers, tasks, and criteria (i.e., *intra*-rater agreement). Misfit indicates inconsistency in applying the rating scale across tasks and test takers, while overfit indicates that the rater is unusually consistent or overly cautious in using the upper and lower levels of the rating scale (i.e., a central tendency) (McNamara, 1996; Myford & Wolfe, 2004a, 2004b). Rater misfit is a more serious threat to general test validity than overfit or test-taker misfit because it indicates divergent behavior from the norm on the part of the raters, and its effect on all other facet measure estimates can be strong (Bonk & Ockey, 2003). This is also something for which Rasch models do not adjust scores as they can in the case of rater severity (Bonk & Ockey, 2003, p. 101; Myford & Wolfe, 2004a, 2004b).³

Task Difficulty

Some of the questions that the MFRM can help test developers address in relation to the task facet are how difficult each task is; whether tasks (e.g., tasks that are assumed to be equivalent) differ significantly in terms of their difficulty; whether there are tasks that are redundant and can be deleted; and whether all tasks

Table 77.4 Task measurement report

	<i>Measure</i>	<i>Model SE</i>	<i>IMS</i>
Task 5	-.44	.08	.72
Task 4	-.28	.07	1.77
Task 2	.10	.04	.99
Task 3	.12	.10	.78
Task 1	.50	.04	.80
M ($n = 5$)	.00	.07	1.01
SD	.37	.02	.44
Strata: 7.18 Reliability: .96			
Fixed (all same) chi-square: 156.0 df: 4 Significance (probability): .00			

contribute to the measurement of the same underlying construct, and so scores on those tasks can be combined into a composite score or not.

As Table 77.4 shows, the five tasks, ordered from least to most difficult, differed significantly in terms of their difficulty, as indicated by the high reliability and strata indices and the significant X^2 statistic. The analysis reliably separated the tasks into seven levels of difficulty. Task 5 was the easiest and Task 1 the most difficult. Note that Tasks 3–5, which are assumed to be equivalent and hence test takers can choose to respond to only one of them, are not equal in terms of difficulty; Task 5 was the easiest followed by Task 4 and then Task 3. Note also that tasks based on reading and listening (Tasks 1 and 2) were generally more difficult than the independent tasks. The task reliability index indicates the replicability of task placements in terms of difficulty if these same tasks were given to another sample with comparable ability levels. The high reliability indicates that the analysis is reliably separating tasks into different levels of difficulty (Bond & Fox, 2007). For example, Task 3 will be more difficult than Task 5 with another sample of test takers.

Table 77.4 reports fit statistics for each task. While the mean IMS is close to 1.0, the fit for individual tasks varies between .72 and 1.77. Task 4 exhibits misfit, which suggests that (1) the task is poorly written or (2) the task is perfectly good in itself but does not form part of a set of tasks that together define a single measurement trait (McNamara, 1996). In the first instance, misfitting tasks need to be revised or deleted from the test. In the second scenario, scores on the tasks should be reported separately. Overfit, by contrast, indicates that the task is redundant. Overfitting tasks do not give information that the other tasks do not give; the pattern of response to these tasks is too predictable from overall pattern of response to other tasks (McNamara, 1996). The task can therefore be revised or removed. None of the tasks in Table 4 shows overfit.

Criterion Difficulty

Concerning rating criteria, the MFRM can help test developers address questions such as how difficult the rating criteria are; whether rating criteria differ significantly in terms of their difficulty; whether raters are able to effectively distinguish

Table 77.5 Rating criteria measurement report

	<i>Measure</i>	<i>Model SE</i>	<i>IMS</i>
Organization	-.22	.10	1.49
Appropriateness	-.04	.07	.93
Coherence	-.03	.10	1.19
Vocabulary	-.03	.06	.97
Content	-.02	.07	1.00
Grammar	-.01	.06	.94
Effectiveness	.35	.06	.92
M ($n = 7$)	.00	.07	1.06
SD	.17	.02	.21
Strata: 2.96 Reliability: .80			
Fixed (all same) chi-square: 39.1 df: 6 Significance (probability): .00			

among the rating criteria; whether there are rating criteria that are redundant and can be deleted; and whether all criteria contribute to the measurement of the same underlying construct, and so scores on different criteria can be combined into a composite score or not.

Table 77.5 reports FACETS analysis results for the rating criteria, with criteria ordered from least to most difficult. It shows that it was hardest for test takers to obtain high ratings on Effectiveness, with a difficulty of .35 logits, and easiest to get high ratings on Organization, with a difficulty of $-.22$ logits. The strata and reliability indices indicate that the analysis reliably (.80) distinguishes between about three distinct levels of difficulty among the rating criteria. These results indicate that the test takers performed significantly differently in the various aspects of writing, or the raters perceived these rating criteria differently, or both.

The fit statistics of the seven rating criteria are within the acceptable range of .5 to 1.5. Organization exhibited a larger degree of misfit than did the other criteria. Misfit indicates that a criterion does not form part of the same dimension as defined by the other criteria in the rating scale, and is therefore measuring a different construct or trait (i.e., evidence of psychometric multidimensionality; see below). This suggests that “it would not be appropriate to sum or average scores across the different [criteria]” (McNamara, 1996, p. 275). If there is no misfit, then this indicates that the criteria work together, that ratings on one criterion correspond well to ratings on other criteria, and that a single summary measure (e.g., average or total score) can appropriately capture the essence of test-taker performance across the different criteria of the rating scale. Overfit, on the other hand, indicates that (1) a criterion is redundant, that is, is measuring the same ability as other criteria; or (2) it significantly affected the scores assigned to the essays on the other criteria (i.e., halo effect) (McNamara, 1996; Eckes, 2005); or both of these.

Rating Scale Functioning

Scale functioning analysis assesses the quality of the rating scale by addressing such questions as whether the rating scale functions well in estimating the

Table 77.6 Scale statistics

Scale level	Observed counts		Average measure	Expected measure	OMS	Step calibration	
	Freq.	%				Measure	SE
0	260	8	-2.45	-2.42	1.0		
1	772	25	-1.27	-1.23	.9	-2.90	.08
2	1047	34	-.06	-.15	1.0	-.99	.05
3	854	28	.90	.98	1.1	.61	.05
4	161	5	2.38	2.29	.9	3.29	.09

construct being measured; whether raters use all parts of the rating scale; whether raters use the rating scale consistently, so the scale is associated with a progression of test-taker ability; whether raters employ the scale in the same way or interpret and use it differently; and whether there is evidence of a restriction of range or a central tendency (Davidson, 1991; North, 2000; Bonk & Ockey, 2003, p. 102; Bond & Fox, 2007). Answers to these questions can help test developers identify problems in the rating scale and rating process and address them by, for example, further clarifying and sufficiently differentiating the rating criteria and score levels, increasing or reducing the number of criteria and score levels on the rating scale (Myford & Wolfe, 2004a, 2004b), or both of these.

The results of FACETS scale analysis for the current data set are presented in Table 77.6. Table 77.6 includes several types of information. The first column shows the scale levels from 0 to 4. The second and third columns report the frequency and percentage of times a given score is assigned across all raters and writing samples. Bond and Fox (2007) suggest that, as a rule of thumb, each scale level should be assigned to at least 10 essays to allow scale diagnostics. Column 4 reports the (observed) average test-taker ability measure associated with each score level. This is computed by averaging the test-taker ability measures (in logits) for all test takers in the sample who were assigned that particular score. These measures are expected to increase monotonically⁴ in size as the variable being measured increases, indicating that, on average, those with higher ability will be assigned the higher scores (Bond & Fox, 2007; Linacre, 2011). Scale levels that violate the monotonicity pattern are flagged. Table 77.6 shows that the rating scale functioned as expected in that a higher score is always associated with a higher average measure. Column 5 reports the expected measure for each scale level, that is, the test-taker ability measure that the measurement model would predict for that scale level if the data were to fit the model.

Column 6 reports the OMS index for each scale level. The expected value of this index is 1.0, indicating that the observed and expected test-taker ability measures are equal. The larger the difference between the observed and expected measures, the larger the OMS index will be. An OMS index greater than 2.0 suggests that a rating in that level for one or more test takers' essays may not be contributing to meaningful measurement of the variable (Linacre, 2011). Note that, because OMS indices are sensitive to outlying ratings, scores at the ends of the scale are more

Figure 77.1 Scale category probability curves

likely to exhibit high OMS indices than are scores in the middle. The OMS indices in Table 77.6 are around 1.0. The last two columns in Table 77.6 report step or threshold calibrations, which are the difficulties estimated for choosing one response category over another (e.g., how difficult it is to endorse 4 over 3) (Davidson, 1991; Bond & Fox, 2007; Linacre, 2011).

MFRM software also provides *scale category probability curves* when an RSM is used. Figure 77.1 displays the scale category probability curves for the current data set. The probability curves enable one to see at a glance the structure of the rating scale and, particularly, whether raters are using all the score categories on the scale (Davidson, 1991). The horizontal axis represents the test-taker ability scale (in logits); the vertical axis represents probability (from 0 to 1). There is a probability curve for each of the scale levels (0 to 4). As Davidson (1991) explained, when examining such a graph, the chief concern is whether there is a separate peak for each score category probability curve or not, and whether the curves appear as an evenly spaced series of hills. A score category curve without a separate peak that rises above the peaks for adjacent category curves is problematic as it indicates that the category is never the most probable rating on any point along overall test-taker ability (Davidson, 1991). Davidson suggested three ways to address this problem: (1) rewriting the level descriptors to clarify what the level is intended to measure, (2) removing that step from the scale if it is not needed, and (3) providing rater training to explain the meaning of the underused step. The probability curves for the rating scale in Figure 77.1 show that each level is the most probable across some section of the ability being measured, indicating that the scale functions well.

Facets Variable Map

MFRM software also provides a visual display of the relationships between facets in the form of a *facets variable map*. An example of such a map appears as Figure 77.2. The map displays visually, from left to right, the relative abilities of the test

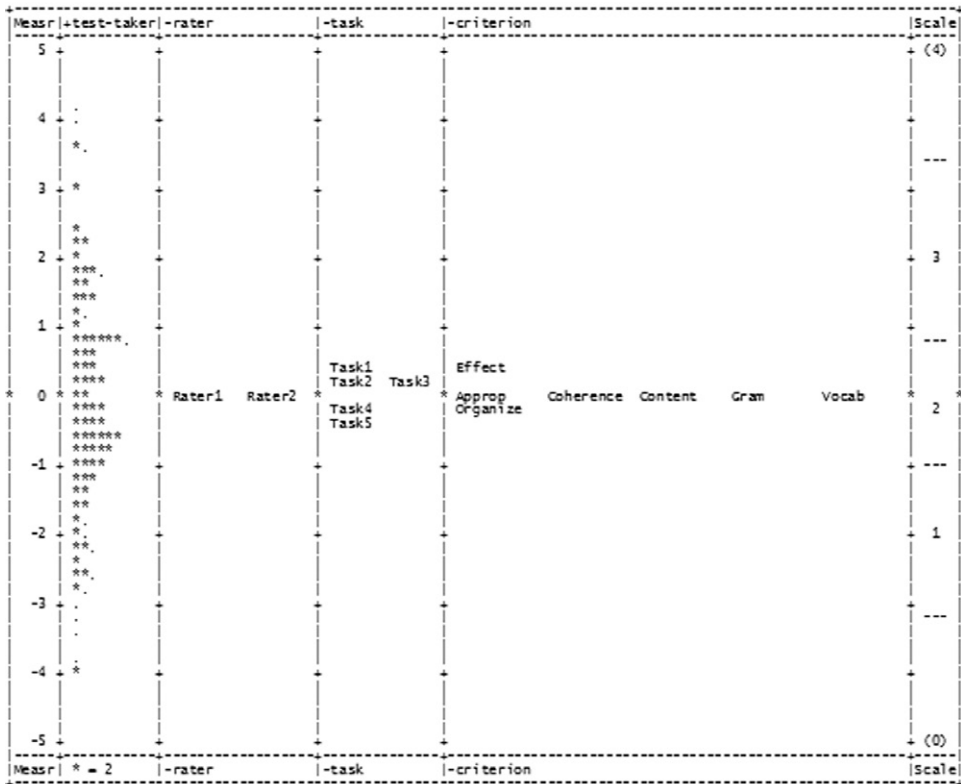

Figure 77.2 Facets variable map

takers, the relative severity of the raters, and the relative difficulties of the tasks, the rating criteria, and the scale steps. The information in columns 2 to 5 in Figure 77.2 is given in terms of the scale in column 1, which can be seen as a “scale of the chances of success of candidates and the degree of challenge presented by particular raters and particular [tasks, rating criteria and scale levels]” (McNamara, 1996, p. 134). Column 1, then, acts as a “ruler” against which each of the four facets (test taker, rater, task, and criterion), as well as scale step difficulty, is measured in ‘logit’ units (McNamara, 1996). A positive sign (above 0 on the “ruler” in column 1) indicates that a test taker is more able, a task or criterion is more difficult, and a rater is more severe. A negative sign (below 0) indicates the opposite. Test takers’ locations are plotted so that any test taker has a 50% probability of succeeding with a task located at the same point on the logit scale.

Bias Analysis

Bias analysis in the MFRM investigates whether a particular aspect of the assessment setting elicits a consistently biased pattern of scores. As McNamara (1996) explained, bias analysis consists in comparing expected and observed values in a set of data (i.e., *residuals*). After estimating overall rater severity (across all tasks),

task and criterion difficulty (across all raters), and test-taker ability (across all tasks, criteria, and raters), the MFRM estimates the most likely score for each test taker with a given rater on a specific task “if the rater were rating that [task and criterion] in the way he or she rated the other [tasks and criteria]” (McNamara, 1996, p. 142). These individual scores are totaled across all test takers to produce a total *expected* score from each rater on each task, which is then compared to the *observed* total score for all the test takers. If the observed score for a given task is higher than the expected score, then the task seems to have elicited more lenient behavior than usual on the part of the raters. “This difference is expressed as a measure on the logit scale; this tells us precisely how much less of a challenge was presented by this [task] with this rater than might have been expected, and the effect of this on the chances of success for candidates under those conditions” (1996, p. 142). Fit statistics summarize for each rater, task, and test taker the extent to which the differences between expected and observed values are within a normal range. McNamara (1996, pp. 141–2) explained:

The basic idea in bias analysis is to further analyze the residuals to see if any further sub-patterns emerge. For example, perhaps the differences are associated mainly with certain tasks or candidates for particular raters, or certain candidates on particular tasks, and so on. The study of bias is thus the study of *interaction* effects, e.g., systematic interaction between particular raters and particular candidates, or between particular raters and particular tasks/items, etc. There will still be some unexplained, random error left over at the end of this analysis; this represents unexplained random variation.

Subpatterns of bias are identified in relation to pairs of facets such as rater by test taker, rater by rating criterion, rater by task, test taker by task, and so forth (Lynch & McNamara, 1998).

Bias analyses can help address important questions about the quality of an assessment system, such as whether there is evidence of bias in the test; whether rater severity varies across test takers, rating criteria, tasks, time, or a combination of these; whether raters exercise differential severity depending on the race, ethnicity, age, or gender of the test taker; and whether some tasks, rating criteria, or both are more prone to rater bias than others.

For the current data set, the following possible interactions between facets were examined: rater by test taker, rater by task, rater by criterion, test taker by task, test taker by criterion, and task by criterion. Few significantly biased interactions were identified. To illustrate how bias analysis results are interpreted, the following paragraph focuses on the significantly biased rater-by-criterion interactions (see Table 77.7).

Table 77.7 shows that FACETS identified two significantly biased rater-by-criterion interactions (out of 14 possible interactions), both involving rater 2. Table 77.7 reports five types of information: (1) the elements of the facets under investigation and their measures in logits; (2) the observed and expected total raw scores for each combination of elements (e.g., rater 2 and grammar); (3) the average difference between observed and expected raw scores; (4) an estimate of the discrepancy between observed and expected values in logits and their SE; (5) *z* scores and IMS for each combination of elements of facets. *z* scores assess whether a

Table 77.7 Significantly biased rater-by-criterion interactions

<i>Criterion (measure)</i>	<i>Rater (measure)</i>	<i>Observed score</i>	<i>Expected score</i>	<i>Obs. – Exp. average</i>	<i>Bias (logit)</i>	<i>Model SE</i>	<i>z</i>	<i>IMS</i>
Appropriateness (-.04)	2 (.03)	221	204.6	16	-.34	.14	-2.33	1.0
Grammar (-.01)	2 (.03)	291	316.8	-17	.35	.12	3.02	1.1
M (<i>n</i> = 14)		433.7	433.7	.00	.00	.12	.00	1.1
SD		284.0	282.8	.07	.15	.05	1.27	.3
Fixed (all = 0) chi-square: 21.0		df: 14	Significance (probability): .10					

discrepancy is due to chance. Ideally all the *z* scores should be equal to zero. *z*-values larger than +2 or less than -2 indicate significantly biased interactions. For example, Table 77.7 shows that rater 2 was significantly more severe when rating grammar ($z > +2$) but significantly more lenient when rating appropriateness ($z < -2$) than is normal for this rater. Fit MS tells us how consistent this pattern of bias is across all the test takers involved on these criteria with this rater. McNamara (1996) and Kondo-Brown (2002) recommended that only biased interactions with *z*-values equal to or higher than the absolute value of 2 and with IMS values within the range of two SDs around the mean of infit are considered. Significant biased interactions point to the need for more rater training for the particular raters on the particular criteria they interact with.

Issues and Considerations in the MFRM

This section discusses four main issues and considerations in the MFRM: sample size, model fit, dimensionality, and the interpretation of fit statistics.

Sample Size

As with other statistical models, users often want to know what “minimum sample size” is required to conduct MFRM analyses. However, to my knowledge, sample size is not discussed in the MFRM literature, although it is obvious that for the analysis to run, each facet (e.g., rater, task, test taker) must include at least two elements. M. Linacre (personal communication, June 22, 2012) explained that sample size is usually controlled by operational and financial considerations. But he added that “a reasonable FACETS analysis would contain 30 test takers, 10 raters, and 3 tasks, although researchers have used much smaller datasets.”

One practical advantage of the MFRM is that it is robust in the presence of missing data. This means that “sufficiently accurate estimates” of facets can be computed with substantially incomplete designs (Bond & Fox, 2007). The only design requirement for the MFRM is that there is “enough linkage between all elements of all facets that all parameters can be estimated within one frame of reference without indeterminacy” (Linacre, 1994, p. 138; Myford & Wolfe, 2000; Bond & Fox, 2007; Linacre, 2011). This can be achieved by, for example, having all

raters rate the same small subset of performances in addition to those performances they have to rate as part of their normal workload in a scoring session. However, it is important to keep in mind that as the sample size decreases (e.g., because of missing data), parameter estimates become less precise and stable, SEs of the parameter estimates become larger, and statistical power of the fit statistics becomes weaker (M. Linacre, personal communication, June 22, 2012). Future studies could examine empirically the effects of different sample sizes and missing data on parameter estimates and other indices in the MFRM.

Model–Data Fit

Model fit relates to the number of item parameters to be estimated. The Rasch model is sometimes referred to as a one-parameter IRT model as it estimates only item difficulty. Other IRT models include other parameters such as item discrimination (two-parameter models) and guessing (three-parameter models) (see Henning, 1992; Chapter 75, *Item Response Theory in Language Testing*). Although this is an important issue in dichotomously scored items, as McNamara (1996) pointed out, model fit is not a resolvable concern in performance assessment because currently only the Rasch models can operationally deal with judge-mediated scores. However, an issue often raised in relation to model fit is whether the measurement model should fit the data or the data should fit the measurement model. Rasch proponents insist that the data should fit the measurement model if valid measurement is the goal. As Bond and Fox (2007, p. 41) have argued:

The Rasch model provides a mathematical framework against which test developers can compare their data. The model is based on the idea that useful measurement involves examination of only one human attribute at a time (unidimensionality) on a hierarchical “more than/less than” line of inquiry. This line of inquiry is a theoretical idealization against which we can compare patterns of responses that do not coincide with this ideal. Person and item performance deviations from that line (fit) can be assessed, alerting the investigator to reconsider item wording and score interpretations from these data.

In the Rasch model, the criterion for success is not that the model fits the data, but that the data fit the model. However, because the Rasch model is probabilistic or stochastic, the data do not have to fit the model perfectly for the analysis to be successful (Bond & Fox, 2007). Misfitting data can be tolerated and may be revised or removed if it is found that, for example, the ratings of a rater are inconsistent. To diagnose the quality of overall data–model fit, one examines (1) the overall fit of each facet and its elements through fit statistics and (2) the responses that are unexpected given the assumptions of the model.⁵

Fit statistics provide information about how well the data for each element in each facet in the analysis “fit” or match the expectations of the measurement model that was used (McNamara, 1996; Myford & Wolfe, 2000). These statistics also allow test developers to determine to what extent the observed measures are drifting away from the expected measures (Bond & Fox, 2007). Fit is evaluated as the difference between the observed and predicted or expected score patterns. As noted above, the model expects that as ability increases, the chances of success on

each item increase. If this relationship between ability (or difficulty) and performance breaks down, the fit statistic indicates the extent to which the relationship has been lost. Generally, the expected mean square value of the fit for each facet is 1.0 for the data to conform to the Rasch model. Mean square fit values very different from 1.0 indicate an unanticipated problem, mostly with the quality of the item or its interaction with a specific context. As Masters (1998) noted, item misfit can be an indication that performance on the test is multidimensional and cannot be summarized in a single score. As reported above, the overall fit of each of the facets in the data set (test taker, task, rater, and rating criterion) was around 1.

Overall data–model fit can also be investigated through examining the responses that are unexpected given the assumptions of the Rasch measurement model. These unexpected responses result in large (absolute standardized) residuals, that is, differences between expected and observed scores. According to Linacre (2011), satisfactory model fit is indicated when about 5% or less of (absolute) standardized residuals are equal to or greater than 2, and about 1% or less of (absolute) standardized residuals are equal to or greater than 3.⁶ A standardized residual with absolute value greater than 2 indicates a rating that is two SDs away from the expected value of zero (Myford & Wolfe, 2000). One could examine the residuals and unexpected response patterns for a given element in a given facet (e.g., a rater, a test taker) to find out why it showed misfit. For the current data set, model–data fit was found to be satisfactory. About 3% ($n = 100$) of the 3,094 valid responses were associated with (absolute) standardized residuals equal to or greater than 2, and 0.3% ($n = 10$) were associated with (absolute) standardized residuals equal to or greater than 3. If these expectations are not met, elements in facets that exhibit high misfit (e.g., rater, task, test taker) could be excluded from the analysis.

Psychometric Dimensionality

Rasch analysis rests on an assumption of unidimensionality, that is, the measurement of a latent trait along a single linear scale at a time (Henning, 1992; McNamara, 1996; Eckes, 2005; Bond & Fox, 2007). As Eckes (2005) explained, the main question in judge-mediated scores is “whether ratings on one criterion follow a pattern that is markedly different from ratings on the others, indicating that [test takers’] scores relate to different dimensions, or whether the ratings on one criterion correspond well to ratings on the other criteria, indicating unidimensionality of the data” (p. 211).

Many authors have voiced concern about the Rasch models’ assumption of unidimensionality and its appropriateness when dealing with performance scores. McNamara (1996) succinctly summarized the issue. The major concern is that while performance on language tasks (e.g., writing) is complex or multidimensional because it involves drawing on various abilities and skills (e.g., planning, editing, grammar, content, organization), measurement models assume that the test is measuring one trait (i.e., is unidimensional). As a result, Rasch models have been branded as being simplistic (or reductionistic) and lacking in validity, as they reduce multidimensional performance to a single score.

In response to this critique, McNamara (1996) emphasized the need to distinguish between *psychometric* (i.e., measurement) and *psychological* (i.e., language ability) unidimensionality. Performance on any language task is necessarily *psychologically* multidimensional, as models of language ability suggest (e.g., Bachman, 1990). The psychometric model, however, deals with the question of whether it makes sense *in measurement terms* to use a single score to summarize examinee performance on different items or on one task that involves a variety of skills (i.e., psychologically multidimensional). As Bejar (1983, p. 31) explained,

Unidimensionality does not imply that performance on items is due to a single psychological process. In fact, a variety of psychological processes are involved in responding to a set of test items. However, as long as they are involved in unison—that is, performance on each item is affected by the same process and in the same form—unidimensionality will hold.

Henning (1992), using simulated data, demonstrated that psychological unidimensionality may be present in the context of psychometric multidimensionality and that psychometric unidimensionality may be present in the context of psychological multidimensionality. Henning concluded that dimensionality is sample dependent and that IRT approaches can be useful even in measuring a multicomponential ability such as language proficiency.

Traditionally, unidimensionality is evaluated by submitting test scores to factor analysis; if all items load on a single factor, then unidimensionality can be assumed to be present (see Chapter 73, Exploratory Factor Analysis and Structural Equation Modeling). Factor analysis of observed scores, however, assumes that raw scores are measured on an interval scale; an assumption that most Rasch proponents disagree with. An alternative approach is to examine fit statistics. Specifically, all facets must have infit and outfit statistics within the acceptable range for the unidimensionality assumption to be met (Linacre, 1998; Eckes, 2005). As McNamara (1996) noted, the Rasch model does not assume or take for granted measurement unidimensionality. Rather, it “*hypothesizes a single measurement dimension of ability and difficulty. Its analysis of test data represents a test of this hypothesis in relation to the data [through fit statistics]*” (p. 275, emphasis added). Table 77.5 shows that the IMS values for the seven rating criteria were within the quality control limits of 0.50 and 1.50; this provides evidence of psychometric unidimensionality in the current data set (Eckes, 2005).

Interpreting Fit Statistics

Another issue concerns the interpretation of fit statistics in Rasch models. While fit statistics as discussed above are central to the MFRM, there are no hard-and-fast rules for determining the “acceptable ranges” for fit statistics or for how to interpret them (Weigle, 1998; Bond & Fox, 2007). Some researchers recommend using the lower and upper limits of .7 and 1.3, respectively (e.g., McNamara, 1999), while others recommend using a wider range of .5 to 1.5 (e.g., Linacre, 1994). Still others (e.g., Kondo-Brown, 2002) used a range of two SDs around the mean of the fit statistics for each facet as a criterion for misfit. If an element in a facet has a fit

statistic higher or lower than that range, then there is misfit (high unpredictability) or overfit (lack of independence), respectively. Bond and Fox (2007) and Myford and Wolfe (2004a), on the other hand, argued that different fit ranges are appropriate for different assessment contexts and purposes. Other factors such as the type of test or rating scale, type of observation, examination design, expectations for rater agreement, or a combination of these can also affect the range and interpretation of fit statistics. In addition, interpreting the meaning of fit mean square indices is context bound and thus not an easy, straightforward process. Myford and Wolfe (2004a), for example, argued that if the results from the analyses are to inform high stakes decision making, then more stringent upper and lower control fit limits might be set. By contrast, if the results are to be used for making low stakes decisions, more relaxed fit limits might be set. The interpretation of fit statistics is an area that is still in progress.

Concluding Remarks

The MFRM has proven a valuable tool for investigating the effects of different facets in the assessment context and interactions among them on assessment scores. However, one has to be aware of the concerns discussed above when using and interpreting findings from this approach to score analysis. While the MFRM can make significant contributions to test development and evaluation, combining it with other score-analysis approaches and research methods allows test developers to examine important questions and gain significant insights into the quality of an assessment, its processes, its context of use, and its consequences. For example, some studies (e.g., Lynch & McNamara, 1998; Kozaki, 2004) have combined G-theory and MFRM analysis to investigate performance assessment, thus drawing on the advantages of both approaches to enhance the validity and reliability of both research and test data. The MFRM provides information at the individual level, while G-theory is useful in test development and research when the focus is on group differences.

It should be noted, however, that G-theory and the MFRM are based on different theoretical assumptions (Brennan, 1983, 2001). G-theory is a sampling theory, which views "an item as a [random] sample condition of one facet in a (usually) larger universe of conditions of measurement," while IRT (including the MFRM) is a scaling theory that attends to "individual items as fixed entities without specific consideration of other conditions of measurement" (Brennan, 1983, p. 22; cf. Bejar, 1983). As such, G-theory is useful for investigating the multiple factors that influence tasks and test scores, while Rasch and IRT models are useful for determining the stochastic relationship between test-taker ability and scores (Bejar, 1983). Finally, the MFRM cannot address questions about the relationships between two or more continuous variables such as the correlation between scores on two different tests or different sections of the same test (e.g., reading and writing scores). Other statistical models, such as regression analysis and multilevel modeling, are needed to address such questions (Barkaoui, 2013).

For these reasons, score analysis using the MFRM should be combined with other types of data and analyses. For example, several studies have used

qualitative methods such as interviews, text and discourse analysis, and observation to understand and explain results from MFRM analyses and to examine other issues in evaluating assessment systems (e.g., Weir & Wu, 2006; Kim, 2009). The use of mixed methods research, where qualitative data are collected and analyzed before, after, or simultaneously with score analyses using the MFRM (or other measurement models, or both), can contribute significantly to the evaluation and improvement of assessment systems and their interpretive arguments.

Notes

- 1 Issues of data screening and assumptions are discussed below.
- 2 In this chapter, only IMS statistics are discussed to keep the discussion brief and because (1) OMS statistics are often interpreted in the same way as IMS (but see McNamara, 1996; Bond & Fox, 2007) and (2) the IMS and OMS statistics for the current data set were almost identical for all facets.
- 3 The results presented here are not typical and so readers should not expect similar results. For example, unlike in this example, most studies report high reliability of separation for the rater facet and significant fixed X^2 tests.
- 4 That is, as the value of one increases, the value of the other increases as well.
- 5 In traditional statistics (e.g., analysis of variance [ANOVA]), assumptions about data characteristics (e.g., distribution) are checked before conducting the statistical test. In the MFRM, data screening is done during data analysis using the various indicators discussed in this section.
- 6 Strictly speaking, according to the statistical theory of the normal distribution (to which standardized residuals are modeled to conform), about 5% of the standardized residuals should fall outside the absolute value of 1.96, and about 1% should fall outside the absolute value of 2.58 (M. Linacre, personal communication, September 22, 2007).

Content Analysis

Evelina D. Galaczi

University of Cambridge, ESOL Examinations, England

Introduction

Content analysis (CA) is an empirical method which is used for the systematic analysis of text. Its aim is to reduce texts into content categories based on explicit rules of coding. This research tool, which has its origins in quantitative newspaper analysis as a technique of opinion research (Woodward, 1934), has now evolved into a repertoire of quantitative and qualitative methods which go beyond the domain of textual analysis and may be applied to a range of content in verbal, pictorial, or communication data (Krippendorff, 2004). In this chapter, “text” will be used in this general sense of communicative language.

At its inception, CA was typically limited to frequency counts of words—for example, the occurrence of war-related words in journalistic articles—and gradually evolved to focus not just on explicit propositions and word-level investigations, but on concepts which involve inferences and on investigations above the word level. A further change in CA has been driven by the advent of computer text processing and the compilation of large corpora of written and spoken language, which have replaced the time-consuming manual process of CA and allowed the automated analysis of large bodies of data in a systematic fashion.

CA has been shown to be a useful tool in second language (L2) assessment investigations, for example in carrying out investigations into construct and content validation of tests and assessment scales (e.g., Bachman, Davidson, Ryan, & Choi, 1995; Ducasse & Brown, 2009; Green, Ünalı, & Weir, 2010). It has also been useful in comparative investigations of target language use domains and of items or tasks and assessment scales, especially in English for specific purposes contexts (e.g., Jacoby & McNamara, 1999). CA has also been used in investigations of test-taker written and oral performance (e.g., Allison, Berry, &

Lewkowicz, 1995; O'Sullivan, Weir, & Saville, 2002), in impact research (e.g., Wall, 2005; Hawkey, 2006) and differential item functioning (DIF) and bias analyses (e.g., Geranpayeh & Kunnan, 2007).

The purpose of this chapter is to present an overview of CA as a methodology and to explain the fundamental issues to be considered during a CA investigation. Examples from L2 assessment will be used throughout the chapter as illustrations of general CA issues, and two L2 assessment studies which have used CA will be discussed in more detail at the end of the chapter.

Conceptualization

Traditionally, CA has been conceptualized as a quantitative research method, with qualitative techniques seen as falling outside its scope (Neuendorf, 2002). More recently, a variety of qualitative approaches have emerged and played an important role in analyses of written and oral communication. These approaches have followed basic CA principles but have moved beyond word frequency counts to include, for example, rhetorical analysis (where the focus is not simply what a text says but how it is said and what the resulting effect is), discourse analysis (with its emphasis on the social use of language to influence meaning), or conversation analysis (and its focus on the turn level to provide insights into the construction of conversations) (Krippendorff, 2004). It is now typical, therefore, to see references to "quantitative CA" and "qualitative CA" in the academic literature.

Krippendorff (2004), among others, has questioned the usefulness of the quantitative/qualitative dichotomy in the context of CA, arguing that "ultimately, all reading of texts is qualitative, even when certain characteristics of text are later converted into numbers" (p. 16). In the broader context of qualitative research, Richards (2009) examines "the distinction between quantity and quality" as "one of many convenient but rather crude alternatives" (p. 148). Despite its conceptual limitations, however, the quantitative–qualitative continuum is seen as offering a useful distinction and will be referred to in this chapter. This overview of CA follows Krippendorff's view that we may avail ourselves of a wide range of techniques in carrying out a CA, some of them more quantitative in nature, others more qualitative. In other words, quantification is not seen as a defining criterion of CA. In fact, the most meaningful content analyses often draw on both qualitative and quantitative paradigms in exploring particular research questions, a notion echoed in Cronbach's (1982) reference to a "reconciliation between 'scientific' and 'humanistic' research" and his argument for the value of multiple method approaches (p. 18). As a methodology, therefore, CA has evolved to include a broad range of tools and approaches. As Carley (1990) notes, "any procedure for analysis of a text, regardless of the origin of the text . . . , that goes beyond syntactic analysis to semantics, is only minimally concerned with conversational protocols, and admits empirical analysis can claim to fall under the general heading of content analysis" (p. 725). Despite this methodological expansion, the different approaches within CA share a common set of techniques, steps, and notions, which are outlined below.

Conducting a Content Analysis: Techniques, Steps, and Notions

In order to support valid and reliable inferences, a CA study should involve a set of *transparent* and *systematic* procedures for conducting the analysis. Although some of the steps are more suitable either to a quantitative or a qualitative CA study, below they are presented together, since the aim of this chapter is to focus on general CA methodological issues and not on the distinction between qualitative and quantitative CA studies.

Depending on the goals of the particular study, the CA methodology may be flexible or more standardized. Generally, though, any CA study needs to address the following (based on Weber, 1990; Neuendorf, 2002; Krippendorff, 2004; Zhang & Wildemuth, 2009):

- research questions;
- data collection;
- sampling techniques and units of analysis;
- development and application of the coding scheme, including coder qualifications, training, and level of agreement, as well as coding units and emergent versus a priori coding categories; and
- analysis of the coded data and the reporting of results.

Determining the Research Questions or Issues Underlying the Investigation

Developing research questions or general questions guiding the study is one of the first steps a researcher needs to take. In a CA inquiry, the research questions presuppose several possible and initially uncertain answers which must be confirmed through inferences drawn from texts. Accurate and clearly defined research questions provide focus to a study, and also enhance a study's efficiency since they allow a researcher to move more expeditiously from sampling relevant texts to answering given questions (Krippendorff, 2004). A relevant example can be found in Green et al. (2010), who aimed to establish the appropriacy of texts in tests of academic reading. As such, a guiding research question which provided focus to the study at the initial conceptual stage was "how closely IELTS [International English Language Testing System] Academic Reading texts resemble the texts that first-year undergraduates most need to read and understand . . . in their first year courses" (p. 192).

Collecting and Preparing the Data

CA inquiries can use various types of text, but generally the data need to be in written form before the analysis can begin. In L2 assessment CA studies, the data can be drawn from test content, related materials such as textbooks, or both. An illustration can be seen in Green et al.'s (2010) investigation of reading texts in academic English tests. In this study the authors carried out a CA of passages

extracted from undergraduate textbooks and reading texts from the IELTS test (a test of academic English).

Data collection can also draw on test-taker writing or speaking performances, as seen, for example, in Allison et al.'s (1995) study, which conducted a CA of summaries written by L2 students under three different task conditions. Data can also come from surveys, interviews, or verbal protocols, as seen in Ducasse and Brown's (2009) investigation of rater orientations to interactional competence.

When oral data are used, transcription becomes a significant part of the data-collection step and decisions have to be made whether to transcribe the entire set of verbal data or just part of it; whether to transcribe literally or in summary; what level of detail to include in the transcript (e.g., should pauses, overlaps and interruptions be captured?), and whether to capture nonverbal communication in the transcript. The decisions on these issues have to be made in the context of the research question. For example, studies which attempt to investigate the interactional behaviors observed in speaking tests may need a very detailed transcript which captures the entire test and includes micro-level interactional features, such as pauses and overlaps, as seen in Galaczi's (2008) investigation of interactional competence and turntaking in L2 learners at different ability levels. Other studies may choose only to capture the data orthographically, as seen in Ducasse and Brown's (2009) investigation of rater verbal protocols.

Sampling the Texts

Sampling is the process of selecting a representative part of a population in order to estimate characteristics of the whole population. When researchers analyze a sample of texts in place of the larger population of texts, they need careful sampling to ensure that the textual units sampled are representative of the larger population and do not bias the answers to the research questions(s); that is, sampling error is reduced. There are two general kinds of sampling: random and nonrandom sampling, both of which can be used in CA. When all sampling units are equally informative concerning a research question, then random sampling would be suitable; when sampling units are unequally informative, the sampling of texts is closely related to what is known about the distribution of content within all available texts, and information-rich texts or cases are selected; that is, nonrandom, purposeful sampling is used. Purposeful sampling is often called for in qualitative studies, since the focus there is on specific, relevant cases. Indeed, Watanabe (2004), writing in the context of impact research, where CA is often a useful approach, uses the term "selection" rather than "sampling," noting that in some types of research, "the selection is not to be made at random, but purposefully" (p. 29). Regardless of whether a study is qualitatively or quantitatively oriented, the sampling procedure(s) chosen would need to be as rigorous as possible. In other words, sampling would need to be done in a systematic and transparent manner, with a clear rationale for the type of sampling chosen and the samples selected. (See Krippendorff, 2004, for a useful overview of a variety of sampling techniques.)

Deciding on the sample size is another important sampling consideration. There are no universally accepted criteria for determining the "correct" sample size, and

the decisions depend on the methodological approach of the study, the research questions of interest, the size of the population, and the research context. For a quantitative CA study, see Neuendorf (2002, p. 89), who provides a useful method for determining the desired sample size using standard error and confidence intervals. Usually a substantial sample size is needed to ensure a high confidence interval in quantitative CA studies, although such large samples may present a challenge for coders. It is large-scale studies such as these that would benefit the most from computer text analysis software, which can deal more effectively with a large sample (provided it can measure the feature(s) of interest). An example of a detailed account of the sample employed can be found in Green et al. (2010), whose investigation on the appropriacy of texts in tests of academic English extracted 42 self-contained passages from the opening, middle, and concluding chapters from 14 core undergraduate textbooks at a UK university. They compared these with 42 reading passages taken from 14 representative tests.

Defining the Unit of Analysis

Krippendorff (2004) defines CA units as “wholes that analysts distinguish and treat as independent elements” (p. 97). Defining the coding unit is a fundamental decision since, as Zhang and Wildemuth (2009) note, differences in the unit definition can affect coding decisions and the transferability of the findings. The same text can produce different levels of units of analysis depending on the research questions of interest (Krippendorff, 2004). To take an example from L2 writing assessment, an L2 test taker may respond to the task as a whole experience, that is, as one unit; L2 assessment researchers may divide the test into different tasks or items for their purposes, so that each task or item becomes a unit of analysis; linguists would divide the script into sentences, utterances, words, or phrases; discourse analysts may be more interested in pragmatic meaning as the unit of analysis rather than linguistic units, and themes might be analyzed through various linguistic forms (single words, phrases, sentences, paragraphs, or an entire document); computational linguists would be interested in strings of words. The units of analysis, therefore, emerge as appropriate for the purpose of each CA. A useful example can be found in Green et al. (2010): part of the analysis (which focused on genre, rhetorical task, subject area, and cultural specificity) used entire reading passages as units of analysis, while another part of the analysis (which focused on, for example, grammatical characteristics) used the sentence and word as the unit of analysis.

Developing a Coding Scheme

Coding is one of the fundamental stages of CA. It involves the reduction of data by humans or computers into categories which have been specified by the researcher. Categories and a coding scheme can be derived from three sources: the data, previous related studies, and theories (Zhang & Wildemuth, 2009). Typically, investigations where the coding categories emerge from the data and are developed inductively intend to develop a theory, rather than verify an existing one. In such cases no preconceived descriptive categories are brought *to* the data,

but notions emerge *from* the data. In cases where a model or theory exists, an initial set of coding categories can be generated a priori from the model or theory, which may be modified within the course of the analysis. Coding schemes based on previous studies may provide a useful accumulation of research insights. Ducasse and Brown's (2009) investigation of raters' orientation toward salient interactional competence features in learner oral performances is an example of an inductive development of a coding scheme where categories emerged from the data. In contrast, Green et al.'s (2010) coding categories in the investigation of reading passages were developed based on theory and previous research, and covered issues previously shown to have an impact on reading comprehension, such as grammatical characteristics of the text, cohesion and rhetorical organization, genre and rhetorical task, and text abstractness.

The *reiterative, cyclical* nature of this stage of a CA is an essential step. In the words of Ducasse and Brown (2009): "defining [coding] categories involves repeated data reduction, rearranging and recoding as the researcher cycles through the data" (p. 432).

To ensure the consistency of coding, especially when multiple coders are involved, a coding manual needs to be developed which explicates the coding categories and rules and attempts to minimize subjective judgments in the coding process. As Krippendorff (2004) notes, "even very strict instructions need to be read, understood, and followed by humans, and coders are humans even when they are asked to act like computers" (pp. 126–7). Coder subjectivity is a part of the analysis process which needs to be acknowledged and controlled. Even when coding seems to be just a mechanical process of applying explicit rules to textual units, the coders must understand those rules and apply them systematically and consistently. Coders' cognitive abilities, appropriate background, and training, therefore, become an integral aspect of the study. As a result, it is important for the researcher(s) to provide explicit information about the background of the coders and justify why they were deemed suitable as coders. For example, Green et al. (2010) inform us that "two judges with PhDs in applied linguistics and experience of teaching and test development experience in the area of academic reading, discussed the criteria with the researchers and were given training on a set of five texts" (p. 197). Such transparency when reporting the study is important as it lends credibility and dependability to the investigation.

Weber (1990) suggests that a coding manual should include category names, definitions, rules for assigning codes, and examples. The goal in creating coding manuals is to make the rules so complete and unambiguous as almost to eliminate individual differences among coders: "different people should code the same text in the same way" (Weber, 1990, p. 12). For a useful example of a detailed code book used in an L2 assessment study, see Bachman et al. (1995).

Coding in CA invariably brings up the issue of the reductionist nature of coding instruments. The validity of a study could be compromised if the coding instrument is such that important features of the data are missed. It is important, therefore, when coding data to try to achieve a balance between coding with many narrow categories and coding so that the "spirit" of the data and the concepts and notions embedded in it are captured.

Applying the Coding Scheme

It is important to validate a coding scheme early in the study, to ensure that it can be used consistently by coders or raters. Coding a sample of the data during a pilot study is the best way to check the validity and reliability of the coding. Estimating coding consistency (in the form of intercoder agreement) is important at this stage. If the level of consistency is low, the coding rules must be revised. As Weber (1990) notes, “reliability problems usually grow out of the ambiguity of word meanings, category definitions, or other coding rules” (p. 15). Agreement between coders is often calculated and reported as Cohen’s kappa, a statistic which provides a measure of the agreement between coders after accounting for chance (Cohen, 1960). It ranges from 1 (perfect agreement) to 0 (no agreement other than what would be expected by chance), with values higher than 0.6 usually indicating substantial coder agreement.

Despite the use of explicit coding instructions, it is important for content analysts to provide coders with additional training in using the coding instructions, at the pilot stage and at the later stage of the full study. As part of the piloting process, the researcher may need to revise the code book repeatedly until all coders involved are comfortable with the coding scheme. During the pilot coding stage consensus building is important, since the objective is agreement in understanding and applying the coding categories, which may have to be developed and finalized through discussion. At the final coding stage, however, coding *individually* and *independently* without collaboration or discussion is necessary. In addition, Neuendorf (2002) recommends blind coding as desirable, where coders do not know the purpose of the study, since it reduces potential coder bias. Naturally, coders need to fully understand the variables and their measures, but if they are doing blind coding, they should not be aware of the research questions guiding the study.

Weber (1990) notes that the coding of sample texts, checking for intercoder agreement, and revising the coding rules is a *cyclical, iterative process*, which should continue until disagreements between coders are discussed and resolved and sufficient coding consistency is achieved. Indeed, the studies referred to in this chapter clearly illustrate the importance of a cyclical development and trialing (piloting) of coding schemes where improvements are made iteratively until coders can consistently apply coding categories.

When sufficient consistency of coding has been achieved, the coding rules can be applied to the entire corpus of text. Human coders are subject to fatigue and to making mistakes during coding, or their understanding of the categories and coding rules may have changed over the time, leading to inconsistency. It is essential, therefore, that the coding consistency is rechecked after the whole data set has been coded (Weber, 1990; Zhang & Wildemuth, 2009).

Drawing Conclusions from the Coded Data and Reporting Methods and Findings

This final stage of a CA study involves interpreting the results and reporting the study as *comprehensively* and *transparently* as possible in order to support its

trustworthiness. A quantitative CA study would typically produce counts and measures of statistical significance. For example, Bachman et al.'s quantitative (1995) study on the content comparability of test forms reported frequencies, means, and standard deviations of the coded text features. A qualitative CA study would, in contrast, present patterns or themes through description, interpretation, and illustration. An example is found in Ducasse and Brown (2009), who discussed general themes and used extended feedback from the study participants to support their findings.

Computer-Based Content Analysis

Contemporary CA is very different from the methods used at its inception. The most significant difference has been brought about by the use of computers, which have allowed automated coding in the case of quantitative CA studies, and have supported the organizing, managing, and coding of qualitative CA data.

Qualitative CA can be supported by software packages such as NVivo (http://www.qsrinternational.com/products_nvivo.aspx), ATLAS.ti (www.atlasti.com), or MAXqda (www.maxqda.com). These packages are not methods of analysis, but rather tools which can be used to facilitate the CA and assist researchers in tasks such as planning and managing the investigation, writing analytic memos, marking and commenting on the data, searching (for strings, words, phrases), developing a coding scheme, coding, retrieving coding segments, recoding, organizing data, hyperlinking, searching the database and the coding scheme, visual mapping, and generating output (Lewins & Silver, 2007). Some of these qualitative data analysis computer software packages can also provide statistics for word or phrase frequencies and their occurrence relative to other words or phrases, which would inform quantitative CA.

Automated CA (i.e., machine coding) is a useful tool for analyzing large data sets. It can provide stability and consistency to the coding, since the computer will reliably assign the same code to a given category. Automated coding is fast and can be relatively inexpensive after initial setup costs; it is also transparent, since the coding rules are explicitly stated. The inevitable tradeoff is that machine coding can use only information explicit in the text. When the aim of CA is to determine which concepts are present in a text or set of texts (so-called "conceptual CA"), both explicit and implicit concepts need to be identified. Explicit concept analysis, that is, the search for words or phrases which actually occur in the text, or the frequency with which they occur, is easy to automate. Consequently, a range of programs have been developed which can provide automated text analysis (for useful examples, see Green et al., 2010). Much of the meaning within a text, however, is conveyed through implicit concepts which may be lost if only automated coding methods are applied. Implicit concept extraction requires coders to make subjective judgments and to use implicit knowledge of a situation (for example, when they encounter a homonym), a skill which a computer can only replicate weakly. Automated coding, therefore, is of limited use when decisions have to be made about implicit meaning in a text, or when syntactically or lexically complex texts are to be analyzed. Note, however, the promise of

computer-based systems such as Coh-Metrix, which analyze texts on multiple levels of language and discourse using latent semantic analysis and have the potential to tap into implicit meaning (Graesser, McNamara, & Kulikowich, 2011).

The limitations of automated coding can be illustrated with an example from Schmitt (2009), cited in Galaczi and French (2011), who conducted an analysis of the lexical resources in test-taker speech at different proficiency levels. Counter-intuitively, the analysis found that the learners at the lowest proficiency levels had the highest percentage of words found in the Academic Word List (Coxhead, 2000). It was only through a complementary qualitative CA of the flagged up words that their different uses in the test-taker speech became apparent: for example, the test takers were using the word “credit” from the phrase “credit card”—a high frequency collocation, whereas in the Academic Word List the word “credit” is used as a verb, as in “to credit an idea to someone.”

Computer-based CA, therefore, can be a valuable tool, as long as its limitations are acknowledged and addressed.

Methodological Criteria for Evaluating a Content Analysis Investigation

A CA investigation must meet a range of methodological and conceptual requirements which provide evidence of its quality. These criteria are directly related to the basic methodological steps and requirements involved in conducting a CA investigation, which were overviewed above. A range of criteria have been adopted in the research literature when evaluating a CA study, mainly dictated by the empirical paradigm guiding the study, whether positivist or interpretive. Following a positivist paradigm, Neuendorf (2002) suggests that CA investigations need to be governed by the scientific requirements of objectivity, systematicity, validity, and reliability. Lincoln and Guba (1985), working in an interpretive research paradigm, propose the criteria of credibility, transferability, dependability, and confirmability. Adding to the latter, Richards (2009) suggests transparency. Despite the different terms used for the methodological criteria and irrespective of its methodological orientation, every CA study should be based on *methodological rigor*. Rigor in CA is achieved through valid, reliable, and dependable findings which are accurate and replicable; that is, researchers working at different points in time, using the same technique on the same data set, should get the same results.

Reliability in CA is achieved through coders, coding schemes, and the application of the coding scheme to data (as mentioned in the earlier part of the chapter). CA research must also produce *valid* results which represent only the intended concept or construct. The key question here is “Are we measuring what we want to measure?” This is dependent on focused questions guiding the study, on data collection strategies which can adequately elicit or collect raw data, on the design of the coding scheme, on transparent and dependable processes for coding, and on the adequacy of the conclusions drawn from the data.

The validity of a CA investigation is also achieved by drawing on a range of measures in order to arrive at a valid definition of a concept or category. For

example, a CA study might measure the occurrence of the concept of “argumentation” in advanced and intermediate learners’ writing tests. Using multiple codes, the concept category “argumentation” could be explicated by including in the analysis lexical items (e.g., believe, argue, suggest), grammatical exponents (e.g., complex structures), functional features (e.g., micro-level functions used to accomplish argumentation), or rhetorical features (e.g., hyperbole). Another example can be found in Green et al. (2010), where the authors used a range of text features in their study and relied both on automated computer coding and on human coders. Such broadening of the tools allows triangulation of methods (i.e., bringing in different methodological perspectives and drawing on the strengths of methodological approaches) and addresses the fundamental issue of whether the conclusions reached in the CA study are justifiable.

Applications of Content Analysis to Language Assessment

The remainder of this chapter will present two case studies, which have been selected for discussion here in order to illustrate some of the basic premises of a CA study and its application to L2 research. The first study (Bachman et al., 1995) focuses on the comparability of two tests of English as a foreign language. The second study (Ducasse & Brown, 2009) is an investigation of rater perceptions of interaction in a paired test. The studies have been chosen to highlight different aspects of CA in L2 assessment research.

Example 1: An Investigation Into Test Comparability

Bachman et al. (1995) carried out a project which investigated the comparability of two tests of English as a foreign language (the so-called TOEFL–Cambridge comparability study) and focused on the comparability of the content of the two tests under investigation. The research aim was to provide a description of the similarities and differences in content between the two tests, and, in the process, to develop operational instruments and general procedures for conducting CA of language tests which would be useful for the L2 assessment field at large.

The primary source of data for the CA in this project included three pairs of test materials with a test each from the Cambridge First Certificate in English exam and the TOEFL exam assessing reading comprehension, structure, and listening. The team of researchers developed two coding instruments, informed by Bachman’s (1990) theoretical framework, which includes communicative language ability (CLA) and test method facets (TMF). Both instruments were developed in several stages. The first stage of CA focused on counts of items in various categories, such as number of words per clause, number of content and function words, and numbers of different illocutionary acts. After detailed discussion with the advisory committee overseeing the project, a less complex approach to implementing the CA was adopted, which focused on developing a set of coding schemes which could quantify judgments of expert judges about test and task content and the abilities they measure. The next stage consisted of a refinement of the two initial coding schemes, and involved the project staff and other applied

linguists in applying the preliminary coding scheme to a small sample from the data. The primary goal was to use expert judgment to identify the most useful set of measures for the CA. The coders' experience, coupled with some additional statistical procedures, resulted in the finalized set of coding instruments (Bachman et al., 1995, pp. 191–209). The process of development of the coding instruments in this study is an example of the inevitable *iterative* nature of developing coding instruments.

The finalized CLA coding instrument consisted of scales which attempted to capture two aspects from the CA of the tests: the degree of involvement of a specified ability, such as lexis, morphology, syntax, phonology, or graphology ("not involved," "involved," "critical"), and the level of ability required to complete the task successfully ("basic," "intermediate," "advanced"). The TMF instrument included coding categories for relevant task method facets; for example, "facets of the test input" is a category here, which in turn includes "identification of the problem in the test input" and the options "vague," "sufficiently explicit" and "explicit."

Three coders (who were all trained applied linguists and therefore familiar with basic linguistic concepts underlying the study) were asked to rate (i.e., code) different pairs of tests from the two test batteries, using the CLA and TMF coding schemes. The three coders were given extensive training, had experience in EFL teaching, and were familiar with either or both of the two test batteries. The research team used generalizability theory to estimate the level of agreement and consistency across the three coders, and found a high degree of intercoder agreement, thus giving credibility to the study.

The validity and credibility of this study are supported by the detailed description and reporting of the research process, the careful measures taken in developing and cyclically refining the coding instruments, and the grounding of the instruments in a theoretical framework. The reliability of the findings rests on the highly consistent ratings across the coders involved in the study, largely the result of the rating instrument itself, which "forced raters to focus almost microscopically on very specific aspects of content, rather than on general categories, and provided a fixed range of judgements, as indicated in the rating scales for the various facets" (Bachman et al., 1995, p. 122). The high level of agreement across coders or raters was also influenced by the training of the raters and their involvement with the CA procedures from the project's inception and throughout its span. The analysis procedures and coding schemes were developed through a "cyclical process of trial, intense discussion of ratings among raters, revision of the procedures and the instrument and retrialling" (Bachman et al., 1995, p. 122). These procedures, which helped achieve the high reliability of the findings, are also, interestingly, a possible threat to the validity of the results—a point acknowledged by the authors. A very detailed, fixed, and micro-level coding scheme may pose problems with the validity of a study, since the very narrow focus may lead to important higher-level information not being captured. This tension in research between validity and reliability, seen here in the context of a coding instrument, but also widely acknowledged in the academic literature, is clearly an important question and one that a CA study is likely to encounter and has to address. The tension between validity and reliability is yet another indication of the importance

of a mixed method approach in CA studies, where the limitations of one methodological approach can be counterbalanced by a different, complementary approach.

A further threat to the validity of the findings, also discussed by Bachman and his colleagues, is the involvement of the coders or raters with the development of the coding instruments and with the project in general. Discussing this methodological dilemma, Krippendorff (2004) argues that when coders participate in the conceptual development of coding instruments, their high level of agreement could potentially be due to "a new, group-specific unwritten consensus concerning what is expected of them" (p. 130). Bachman et al. acknowledge this, but contend that such a procedure "is exactly . . . [the] sort of development and training that should go into the analysis of test content during the test development process itself, so that individuals responsible for the design, writing and moderation of the test are concurrently analysing its content" (p. 122). Clearly, this is a complex methodological issue which is nuanced and whose relevance will vary across different contexts.

Example 2: An Investigation of Rater Perceptions When Assessing Interactional Competence

The second example, taken from Ducasse and Brown (2009), is a much smaller-scale study than the previous one and provides an illustration of the application of CA not to test materials or test performances, but to rater perceptions of test performance. In this case the general aim of the study was to provide insights for the conceptualization of the construct of interactional competence, based on rater understanding of the construct.

The context of the study was a university-based Spanish beginner-level course, which ended with a paired oral test. The data consisted of 17 videorecorded paired tests; the test consisted of one task which lasted 10 minutes. Twelve trained raters with current or past teaching experience were asked to observe and record individually their comments on three assigned pairs of candidates. Each candidate pair was observed by at least two different raters. The raters were asked to watch the entire test performance and provide a summary of their impression of the paired interaction. They were, additionally, asked to watch the videorecorded performance a second time and to pause the recording at intervals to record comments. All verbal reports were recorded and transcribed orthographically. The transcripts served as the primary source of data for the CA. The CA of the transcripts was used to develop a coding scheme.

Given the large size of the data set, the authors sampled one report per rater for their analysis (i.e., they used one third of the data). Each transcript was segmented into relevant units, which were delimited by natural boundaries, such as the summary first impression of the raters, and the stopping and starting of the recording at intervals for comment. The unit of analysis emerged from the segmented transcripts and was called an "idea unit." The unit of analysis was in line with the purpose of the study, which focused on rater perceptions or ideas of a construct.

The breaking down of the transcripts into units was followed by the coding of the idea units. In contrast to the previous study, the analysis process here was

inductive in that the authors did not derive variables or coding categories from existing theories or previous related studies. The coding categories were not pre-determined, but were derived from the data. First, the main researcher focused on general features such as aspects of successful or unsuccessful interaction, which led to a set of coding categories emerging from the data. This "discovery stage" was followed by an iterative cycle of "repeated data reduction, rearranging and recoding" (Ducasse & Brown, 2009, p. 432) as the researchers sought to find a balance between too many/too few or too broad/too narrow coding categories. The cyclical iterative processing of the data gave rise to five categories which comprised the coding scheme ("body language," "listening," "turn taking," "topic cohesion," and "anything other than interaction"). Next, the stability of the coding scheme was investigated through applying it to the full data set by two coders (the main researcher and another coder), and calculating coder agreement. The authors reported intercoder agreement of 84%, which, even though lower than typically acceptable, was deemed to be within the range typically encountered in discourse studies (Tinsley & Weiss, 2000). The disagreements in the double-coded data were discussed and resolved, taking into account other findings in relevant studies. The process of discussing disagreements, that is, differential interpretation of coding categories, is an important stage of a CA study, and addressing this stage adds dependability and validity to the investigation. This process resulted in conflating two coding categories under a more general name, and keeping the subsumed categories as subcategories. The final coding scheme that emerged, therefore, had three broad categories ("non-verbal interpersonal communication," "interactive listening," and "interactional management").

The validity of this study is supported by the carefully designed data collection and data analysis procedures, the iterative and cyclical process of developing the coding instrument, and the numerous quotations from raters provided to support the author's findings and CA analysis. The data collection involved raters with suitable backgrounds and the elicitation of rater comments involved several distinct stages, which approximated real-life rater behavior (within the limits of verbal protocol analysis): a holistic summary of their impression of the interaction and a more detailed drilling into their reaction to the test-taker performances. The reliability and dependability of the research findings were established by the detail provided about the coding process, the estimation of intercoder agreement, and the cyclical revision of the coding scheme.

Conclusion

This chapter has provided an overview of CA as a methodological tool, given a practical account of issues and stages to be followed in a CA research study, and illustrated the use of this methodology in L2 assessment. The discussion and illustrations have also provided an account of the challenges associated with conducting a rigorous, reliable, and valid CA. As the chapter has demonstrated, the quality of a CA study is closely related to a rigorous research design, thorough data collection, iterative development of coding instruments, reliable coding, and careful interpretation.

The author would like to thank Roger Hawkey for his thorough, insightful, and encouraging comments on an earlier draft of this chapter. Special thanks are also due to the two *Companion to Language Assessment* reviewers, who provided valuable suggestions for improvement.
